# ABOUT THE EDITOR

Gavriel Salvendy is professor emeritus of Industrial Engineering at Purdue University and Chair Professor and Head of the Department of Industrial Engineering at Tsinghua University, Beijing, China. He is the author or co-author of over 550 research publications, including over 300 journal papers and is the author or editor of 42 books. His publications have appeared in seven languages. He is the major professor to 67 former and current Ph.D. students. His main research deals with the human aspects of design, operation, and management of advanced engineering systems. Gavriel Salvendy is the founding editor of two journals: the *International Journal on Human–Computer Interaction and Human Factors* and *Ergonomics in Manufacturing and Service Industries*. He was the founding chair of the International Commission on Human Aspects in Computing, headquartered in Geneva, Switzerland. In 1990 he became the first member of either the Human Factors and Ergonomics Society or the International Ergonomics Association to be elected to the National Academy of Engineering. He was elected "for fundamental contributions to and professional leadership in human, physical, and cognitive aspects of engineering systems." In 1995 he received an Honorary Doctorate from the Chinese Academy of Sciences, "for great contributions to the development of science and technology and for the great influence upon the development of science and technology in China." He is the fourth person in all fields of science and engineering in the 45 years of the Academy ever to receive this award. In 2006, he received the Friendship Award presented by the People's Republic of China. The award is the highest honor the Chinese government confers on foreign experts. In 2007, he received the John Fritz Medal which is the engineering profession's highest award for his "fundamental international and seminal leadership and technical contributions to human engineering and industrial engineering education, theory, and practice." He is an honorary fellow and life member of the Ergonomics Society and fellow of Human Factors and Ergonomics Society, Institute of Industrial Engineers, and the American Psychological Association. He has advised organizations in 31 countries on the human side of effective design, implementation and management of advanced technologies in the workplace. He earned his Ph.D. in engineering production at the University of Birmingham, United Kingdom.

# CONTRIBUTORS

Bashar Alyousef
Research Assistant
Industrial & Systems Engineering
University of Wisconsin—Madison
Madison, Wisconsin

Johan Hviid Andersen
Professor
Department of Occupational Medicine
Danish Ramazzini Centre
Herning Hospital
Herning, Denmark

Margherita Antona
Coordinator of the Centre for Universal Access
    and Assistive Technologies
Institute of Computer Science
Foundation for Research and
    Technology—Hellas (FORTH)
Heraklion, Crete, Greece

Susan Archer
Senior Vice President
Alion Science and Technology
Boulder, Colorado

Grazyna Bartkowiak
Researcher, Department of Personal Protective
    Equipment
Lab Manager, Protective Clothing Laboratory
Central Institute for Labour Protection—National
    Research Institute
Warsaw, Poland

Krzysztof Baszczynski
Researcher, Department of Personal Protective
    Equipment
Lab Manager, Laboratory of Safety Helmets and
    Equipment Protecting against Falls from a
    Height
Central Institute for Labour Protection—National
    Research Institute
Warsaw, Poland

Kevin B. Bennett
Professor and Human Factors Area Leader
Department of Psychology
Wright State University
Dayton, Ohio

Kenneth R. Boff
Principal Scientist
Tennenbaum Institute
Georgia Institute of Technology
Atlanta, Georgia

Anna Bogdan
Researcher, Department of Ergonomics
Lab Manager, Thermal Load Laboratory
Central Institute for Labour Protection—National
    Research Institute
Warsaw, Poland

Walter R. Boot
Assistant Professor
Department of Psychology
Florida State University
Tallahassee, Florida

Walter C. Borman
Professor
Department of Psychology
University of South Florida
and Personnel Decisions Research Institute
Tampa, Florida

Peter R. Boyce
Consultant
Canterbury, United Kingdom

Martin Braun
Senior Scientist
Fraunhofer Institute for Industrial Engineering
Stuttgart, Germany

Agnieszka Brochocka
Researcher, Department of Personal Protective
    Equipment
Laboratory for Respiratory Protective Equipment
Central Institute for Labour Protection—National
    Research Institute
Warsaw, Poland

Patrick F. Bruning
Graduate Research Assistant
Organizational Behavior and Human Resources

# PREFACE

This handbook is concerned with the role of humans in complex systems, the design of equipment and facilities for human use, and the development of environments for comfort and safety. The first, second, and third editions of the handbook were a major success and profoundly influenced the human factors profession. It was translated and published in Japanese and Russian and won the Institute of Industrial Engineers Joint Publishers Book of the Year Award. It has received strong endorsement from top management; the late Eliot Ester, retired president of General Motors Corporation, who wrote the forward to the first edition of the handbook, indicated that "regardless of what phase of the economy a person is involved in, this handbook is a very useful tool. Every area of human factors from environmental conditions and motivation to the use of new communication systems ... is well covered in the handbook by experts in every field."

In a literal sense, human factors and ergonomics is as old as the machine and environmental design, for it was aimed at designing them for human use. However, it was not until World War II that human factors emerged as a separate discipline. The field of human factors and ergonomics has developed and broadened considerably since its inception 70 years ago and has generated a body of knowledge in the following areas of specializations:

- Human factors profession
- Human factors fundamentals
- Design of tasks and jobs
- Equipment, workplace, and environmental design
- Design for health, safety, and comfort
- Performance modeling
- Evaluation
- Human–computer interaction
- Design for individual differences
- Selected applications

The foregoing list shows how broad the field has become. As such, this handbook should be of value to all human factors and ergonomics specialists, engineers, industrial hygienists, safety engineers, and human–computer interaction specialists. The 61 chapters constituting the fourth edition of the handbook were written by 131 experts. In creating this handbook, the authors gathered information from over 7500 references and presented over 500 figures and 200 tables to provide theoretically based and practically oriented material for use by both practitioners and researchers. In the fourth edition of the *Handbook of Human Factors and Ergonomics*, the chapters have been completely, newly written. This fourth edition

of the handbook covers totally new areas that were not included in the third edition. These include the following subjects:

- Managing low-back disorder risk in the workplace
- Neuroergonomics
- Social networking
- User requirements
- Human factors in ambient intelligent environments
- Online interactivity
- Office ergonomics
- Human factors and ergonomics in motor vehicle transportation
- Human factors and ergonomics in aviation

The main purpose of this handbook is to serve the needs of the human factors and ergonomics researchers, practitioners, and graduate students. Each chapter has a strong theory and science base and is heavily tilted toward application orientation. As such, a significant number of case studies, examples, figures, and tables are utilized to facilitate usability of the presented material.

The many contributing authors came through magnificently. I thank them all most sincerely for agreeing so willingly to create this handbook with me. I had the privilege of working with Robert L. Argentieri, our Wiley executive editor, who significantly facilitated my editorial work with his assistant Dan Magers. I was truly fortunate to have during the preparation of this handbook the most able contribution of Myrna Kasdorf, editorial coordinator of the handbook, who has done a truly outstanding job.

GAVRIEL SALVENDY
*January 2011*

# PART 1
# HUMAN FACTORS FUNCTION

# CHAPTER 1

# THE DISCIPLINE OF HUMAN FACTORS AND ERGONOMICS

**Waldemar Karwowski**
**University of Central Florida**
**Orlando, Florida**

*The purpose of science is mastery over nature.*

F. Bacon (*Novum Organum,* 1620)

## 1 INTRODUCTION

Over the last 60 years human factors, a term that is used here synonymously with ergonomics [and denoted as human factors ergonomics (HFE)], has been evolving as a unique and independent discipline that focuses on the nature of human–artifact interactions, viewed from the unified perspective of the science, engineering, design, technology, and management of human-compatible systems, including a variety of natural and artificial products, processes, and living environments (Karwowski, 2005). The various dimensions of such defined ergonomics discipline are shown in Figure 1. The International Ergonomics Association (IEA, 2003) defines ergonomics (or human factors) as the scientific discipline concerned with the understanding of the interactions among humans and other elements of a system and the profession that applies theory, principles, data, and methods to design in order to optimize human well-being and overall system performance. Human factors professionals contribute to the design

and evaluation of tasks, jobs, products, environments, and systems in order to make them compatible with the needs, abilities, and limitations of people. Ergonomics discipline promotes a holistic, human-centered approach to work systems design that considers the physical, cognitive, social, organizational, environmental, and other relevant factors (Grandjean, 1986; Wilson and Corlett, 1995; Sanders and McCormick, 1993; Chapanis, 1995, 1999; Salvendy, 1997; Karwowski, 2001; Vicente, 2004; Stanton et al., 2004).

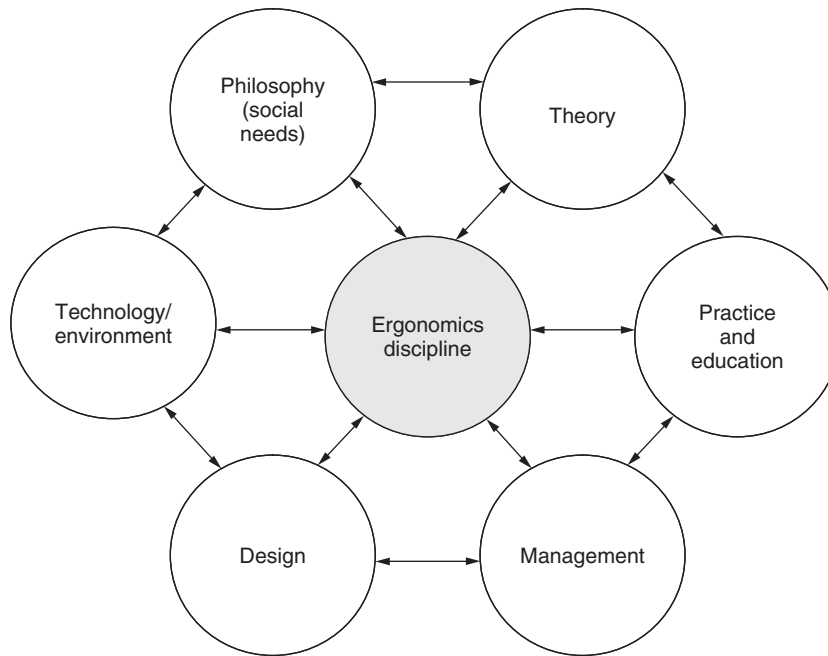
Historically, *ergonomics* (*ergon + nomos*), or "the study of work," was originally and proposed and defined by the Polish scientist B. W. Jastrzebowski (1857a-d) as the scientific discipline with a very broad scope and wide subject of interests and applications, encompassing all aspects of human activity, including labor, entertainment, reasoning, and dedication (Karwowski (1991, 2001). In his paper published in the journal *Nature and Industry* (1857), Jastrzebowski divided work into two main categories: the *useful work*, which brings improvement for the common good, and the *harmful work* that


**Figure 1**   General dimensions of ergonomics discipline (after Karwowski, 2005).

brings deterioration (discreditable work). Useful work, which aims to improve things and people, is classified into physical, aesthetic, rational, and moral work. According to Jastrzebowski, such work requires utilization of the motor forces, sensory forces, forces of reason (thinking and reasoning), and the spiritual force. The four main benefits of the useful work are exemplified through the property, ability, perfection, and felicity.

The contemporary ergonomics discipline, independently introduced by Murrell in 1949 (Edholm and Murrell, 1973), was viewed at that time as an applied science, the technology, and sometimes both. The British scientists had founded the Ergonomics Research Society in 1949. The development of ergonomics internationally can be linked to a project initiated by the *European Productivity Agency* (EPA), a branch of the *Organization for European Economic Cooperation*, which first established a Human Factors Section in 1955 (Kuorinka, 2000). Under the EPA project, in 1956 specialists from European countries visited the United States to observe human factors research. In 1957 the EPA organized a technical seminar on "Fitting the Job to the Worker" at the University of Leiden, The Netherlands, during which a set of proposals was presented to form an international association of work scientists. A steering committee consisting of H.S. Belding, G.C.E. Burger, S. Forssman, E. Grandjean, G. Lehman, B. Metz, K.U. Smith, and R.G. Stansfield, was charged to develop specific proposal for such association. The committee decided to adopt the name International Ergonomics Association. At the meeting in Paris in 1958 it was decided to proceed with forming the new association. The steering committee designated itself

as the Committee for the International Association of Ergonomic Scientists and elected G.C.E. Burger as its first president, K.U. Smith as treasurer, and E. Grandjean as secretary. The Committee for the International Association of Ergonomic Scientists met in Zurich in 1959 during a conference organized by the EPA and decided to retain the name International Ergonomics Association. On April 6, 1959, at the meeting in Oxford, England, E. Grandjean declared the founding of the IEA. The committee met again in Oxford, England, later in 1959 and agreed upon the set of bylaws or statutes of the IEA. These were formally approved by the IEA General Assembly at the first International Congress of Ergonomics held in Stockholm in 1961.

Traditionally, the most often cited domains of specialization within HFE are the physical, cognitive, and organizational ergonomics. Physical ergonomics is mainly concerned with human anatomical, anthropometric, physiological, and biomechanical characteristics as they relate to physical activity [Chaffin et al., 2006, Pheasant, 1986; Kroemer et al., 1994; Karwowski and Marras, 1999; National Research Council (NRC), 2001; Marras, 2008]. Cognitive ergonomics focuses on mental processes such as perception, memory, information processing, reasoning, and motor response as they affect interactions among humans and other elements of a system (Vicente, 1999; Hollnagel, 2003; Diaper and Stanton, 2004). Organizational ergonomics (also known as macroergonomics) is concerned with the optimization of sociotechnical systems, including their organizational structures, policies, and processes (Reason, 1997; Hendrick and Kleiner, 2002a,b; Hollman et al., 2003; Nemeth, 2004). Examples of the relevant topics include

**Table 1  Exemplary Domains of Disciplines of Medicine, Psychology, and Human Factors**

| Medicine | Psychology | Human factors |
| --- | --- | --- |
| Cardiology | Applied psychology | Physical ergonomics |
| Dermatology | Child psychology | Cognitive ergonomics |
| Gastroenterology | Clinical psychology | Macroergonomics |
| Neurology | Cognitive psychology | Knowledge ergonomics |
| Radiology | Community psychology | Rehabilitation ergonomics |
| Endocrinology | Counseling psychology | Participatory ergonomics |
| Pulmonology | Developmental psychology | Human–computer interaction |
| Gerontology | Experimental psychology | Neuroergonomics |
| Neuroscience | Educational psychology | Affective ergonomics |
| Nephrology | Environmental psychology | Ecological ergonomics |
| Oncology | Forensic psychology | Forensic ergonomics |
| Ophthalmology | Health psychology | Consumer ergonomics |
| Urology | Positive psychology | Human–systems integration |
| Psychiatry | Organizational psychology | Ergonomics of aging |
| Internal medicine | Social psychology | Information ergonomics |
| Community medicine | Quantitative psychology | Community ergonomics |
| Physical medicine | Social psychology | Nanoergonomics |
| | | Service ergonomics |

communication, crew resource management, design of working times, teamwork, participatory work design, community ergonomics, computer-supported cooperative work, new work paradigms, virtual organizations, telework, and quality management. The above traditional domains as well as new domains are listed in Table 1. According to the above discussion, the paramount objective of HFE is to understand the interactions between people and everything that surrounds us and based on such knowledge to optimize the human well-being and overall system performance. Table 2 provides a summary of the specific HFE objectives as discussed by Chapanis (1995). As recently pointed out by the National Academy of Engineering (NAE, 2004), in the future, ongoing developments in engineering will *expand toward tighter connections between technology and the human experience, including new products customized to the physical dimensions and capabilities of the user, and ergonomic design of engineered products*.

## 2  HUMAN–SYSTEM INTERACTIONS

While in the past ergonomics has been driven by technology (reactive design approach), in the future ergonomics should drive technology (proactive design approach). While technology is a product and a process involving both science and engineering, science aims to understand the "why" and "how" of nature through a process of scientific inquiry that generates knowledge about the natural world (Mitchem, 1994; NRC 2001). Engineering is the "design under constraints" of cost, reliability, safety, environmental impact, ease of use, available human and material resources, manufacturability, government regulations, laws, and politics (Wulf, 1998). Engineering, as a body of knowledge of design and creation of human-made products and a process for

**Table 2  Objectives of HFE Discipline**

Basic Operational Objectives
  Reduce errors
  Increase safety
  Improve system performance
Objectives Bearing on Reliability, Maintainability, and
  Availability (RMA) and Integrated Logistic Support (ILS)
  Increase reliability
  Improve maintainability
  Reduce personnel requirements
  Reduce training requirements
Objectives Affecting Users and Operators
  Improve the working environment
  Reduce fatigue and physical stress
  Increase ease of use
  Increase user acceptance
  Increase aesthetic appearance
Other Objectives
  Reduce losses of time and equipment
  Increase economy of production

*Source*: Chapanis (1995).

solving problems, seeks to shape the natural world to meet human needs and wants.

Contemporary HFE discovers and applies information about human behavior, abilities, limitations, and other characteristics to the design of tools, machines, systems, tasks, jobs, and environments for productive, safe, comfortable, and effective human use (Sanders and Mccormick, 1993; Helander, 1997). In this context, HFE deals with a broad scope of problems relevant to the design and evaluation of work systems, consumer

products, and working environments, in which human−machine interactions affect human performance and product usability (Carayon, 2006; Dekker, (2007; Karwowski, 2006; Bedny and Karwowski, 2007; Weick and Sutcliffe, 2007; Sears and Jacko, 2009; Wogalter, 2006; Reason, 2008; Bisantz and Burns, 2009; Karwowski et al., 2010). The wide scope of issues addressed by the contemporary HFE discipline is presented in Table 3. Figure 2 illustrates the evolution of the scope of HFE with respect to the nature of human−system interactions and applications of human− system integration in a large variety of domains (Vicente, 2004; Karwowski, 2007; Lehto and Buck, 2007; Marras and Karwowski 2006a,b; Rouse, 2007; Guerin et al., 2007; Dekker, 2007; Schmorrow and Stanney, 2008; Pew and Mavor, 2008.; Cook and Durso, 2008; Zacharias et al., 2008; Salas et al., 2008; Marras, 2008, Chebbykin et al., 2008; Salvendy and Karwowski, 2010; Kaber and Boy, 2010; Marek et al., 2010).

Originally, HFE focused on the local human− machine interactions, while today the main focus is on the broadly defined human−technology interactions. In

**Figure 2** Expanded view of the human–technology relationships (modified after Meister, 1999).

this view, the HFE can also be called the discipline of *technological ecology*. Tables 4 and 5 present taxonomy of the human-related and technology-related components, respectively, which are of great importance to HFE discipline. According to Meister (1987), the traditional concept of the human–machine system is an organization of people and the machines they operate and maintain in order to perform assigned jobs that implement the purpose for which the system was developed (Meister, 1987). In this context, a system

is a *construct* whose characteristics are manifested in physical and behavioral phenomena Meister (1991). The system is critical to HFE theorizing because it describes the substance of the human–technology relationship. General system variables of interest to HFE discipline are shown in Table 6.

The human functioning in human–machine systems can be described in terms of perception, information processing, decision making, memory, attention, feedback, and human response processes. Furthermore, the human work taxonomy can be used to describe five distinct levels of human functioning, ranging from primarily physical tasks to cognitive tasks (Karwowski, 1992a). These basic but universal human activities are (1) tasks that produce force (primarily muscular work),

**Table 6  General System Variables**

1. Requirement constraints imposed on the system
2. Resources required by the system
3. Nature of its internal components and processes
4. Functions and missions performed by the system
5. Nature, number, and specificity of goals
6. Structural and organizational characteristics of the system (e.g., its size, number of subsystems and units, communication channels, hierarchical levels, and amount of feedback)
7. Degree of automation
8. Nature of the environment in which the system functions
9. System attributes (e.g., complexity, sensitivity, flexibility, vulnerability, reliability, and determinacy)
10. Number and type of interdependencies (human–machine interactions) within the system and type of interaction (degree of dependency)
11. Nature of the system's terminal output(s) or mission effects

*Source*: Meister (1999).

(2) tasks of continuously coordinating sensorimonitor functions (e.g., assembling or tracking tasks), (3) tasks of converting information into motor actions (e.g., inspection tasks), (4) tasks of converting information into output information (e.g., required control tasks), and (5) tasks of producing information (primarily creative work) (Grandjean, 1986; Luczak et al., 1999). Any task in a human–machine system requires processing of information that is gathered based on perceived and interpreted relationships between system elements. The processed information may need to be stored by either a human or a machine for later use.

The scope of HFE factors that need to be considered in the design, testing, and evaluation of any human–system interactions is shown in Table 7 in the form of the exemplary ergonomics checklist. It should be noted that such checklists also reflect practical application of the discipline. According to the Board of Certification in Professional Ergonomics (BCPE), a practitioner of ergonomics is a person who (1) has a mastery of a body of ergonomics knowledge, (2) has a command of the methodologies used by ergonomists in applying that knowledge to the design of a product, system, job, or environment, and (3) has applied his or her knowledge to the analysis, design testing, and evaluation of products, systems, and environments. The areas of current practice in the field can be best described by examining the focus of Technical Groups of the Human Factors and Ergonomics Society, as illustrated in Table 8.

**Table 7  Examples of Factors to Be Used in Ergonomics Checklists**

*I. Anthropometric, Biomechanical, and Physiological Factors*

1. Are the differences in human body size accounted for by the design?
2. Have the right anthropometric tables been used for specific populations?
3. Are the body joints close to neutral positions?
4. Is the manual work performed close to the body?
5. Are there any forward-bending or twisted trunk postures involved?
6. Are sudden movements and force exertion present?
7. Is there a variation in worker postures and movements?
8. Is the duration of any continuous muscular effort limited?
9. Are the breaks of sufficient length and spread over the duration of the task?
10. Is the energy consumption for each manual task limited?

*II. Factors Related to Posture (Sitting and Standing)*

1. Is sitting/standing alternated with standing/sitting and walking?
2. Is the work height dependent on the task?
3. Is the height of the work table adjustable?
4. Are the height of the seat and backrest of the chair adjustable?
5. Is the number of chair adjustment possibilities limited?
6. Have good seating instructions been provided?
7. Is a footrest used where the work height is fixed?
8. Has the work above the shoulder or with hands behind the body been avoided?
9. Are excessive reaches avoided?
10. Is there enough room for the legs and feet?
11. Is there a sloping work surface for reading tasks?
12. Have the combined sit–stand workplaces been introduced?
13. Are handles of tools bent to allow for working with the straight wrists?

**Table 7 (*continued*)**

### III. Factors Related to Manual Materials Handling (Lifting, Carrying, Pushing, and Pulling Loads)

1. Have tasks involving manual displacement of loads been limited?
2. Have optimum lifting conditions been achieved?
3. Is anybody required to lift more than 23 kg?
4. Have lifting tasks been assessed using the NIOSH (1991) method?
5. Are handgrips fitted to the loads to be lifted?
6. Is more than one person involved in lifting or carrying tasks?
7. Are there mechanical aids for lifting or carrying available and used?
8. Is the weight of the load carried limited according to the recognized guidelines?
9. Is the load held as close to the body as possible?
10. Are pulling and pushing forces limited?
11. Are trolleys fitted with appropriate handles and handgrips?

### IV. Factors Related to Design of Tasks and Jobs

1. Does the job consist of more than one task?
2. Has a decision been made about allocating tasks between people and machines?
3. Do workers performing the tasks contribute to problem solving?
4. Are the difficult and easy tasks performed interchangeably?
5. Can workers decide independently on how the tasks are carried out?
6. Are there sufficient possibilities for communication between workers?
7. Is there sufficient information provided to control the assigned tasks?
8. Can the group take part in management decisions?
9. Are the shift workers given enough opportunities to recover?

### V. Factors Related to Information and Control Tasks

*Information*

1. Has an appropriate method of displaying information been selected?
2. Is the information presentation as simple as possible?
3. Has the potential confusion between characters been avoided?
4. Has the correct character/letter size been chosen?
5. Have texts with capital letters only been avoided?
6. Have familiar typefaces been chosen?
7. Is the text/background contrast good?
8. Are the diagrams easy to understand?
9. Have the pictograms been properly used?
10. Are sound signals reserved for warning purposes?

*Control*

1. Is the sense of touch used for feedback from controls?
2. Are differences between controls distinguishable by touch?
3. Is the location of controls consistent and is sufficient spacing provided?
4. Have the requirements for the control-display compatibility been considered?
5. Is the type of cursor control suitable for the intended task?
6. Is the direction of control movements consistent with human expectations?
7. Are the control objectives clear from the position of the controls?
8. Are controls within easy reach of female workers?
9. Are labels or symbols identifying controls properly used?
10. Is the use of color in controls design limited?

**Table 7  (*continued*)**

*Human–Computer Interaction*

1. Is the human–computer dialogue suitable for the intended task?
2. Is the dialogue self-descriptive and easy to control by the user?
3. Does the dialogue conform to the expectations on the part of the user?
4. Is the dialogue error tolerant and suitable for user learning?
5. Has command language been restricted to experienced users?
6. Have detailed menus been used for users with little knowledge and experience?
7. Is the type of help menu fitted to the level of the user's ability?
8. Has the QWERTY layout been selected for the keyboard?
9. Has a logical layout been chosen for the numerical keypad?
10. Is the number of function keys limited?
11. Have the limitations of speech in human–computer dialogue been considered?
12. Are touch screens used to facilitate operation by inexperienced users?

### *VI. Environmental Factors*

*Noise and Vibration*

1. Is the noise level at work below 80 dBA?
2. Is there an adequate separation between workers and source of noise?
3. Is the ceiling used for noise absorption?
4. Are the acoustic screens used?
5. Are hearing conservation measures fitted to the user?
6. Is personal monitoring to noise/vibration used?
7. Are the sources of uncomfortable and damaging body vibration recognized?
8. Is the vibration problem being solved at the source?
9. Are machines regularly maintained?
10. Is the transmission of vibration prevented?

*Illumination*

1. Is the light intensity for normal activities in the range of 200–800 lux?
2. Are large brightness differences in the visual field avoided?
3. Are the brightness differences between task area, close surroundings, and wider surroundings limited?
4. Is the information easily legible?
5. Is ambient lighting combined with localized lighting?
6. Are light sources properly screened?
7. Can the light reflections, shadows, or flicker from the fluorescent tubes be prevented?

*Climate*

1. Are workers able to control the climate themselves?
2. Is the air temperature suited to the physical demands of the task?
3. Is the air prevented from becoming either too dry to too humid?
4. Are draughts prevented?
5. Are the materials/surfaces that have to be touched neither too cold nor too hot?
6. Are the physical demands of the task adjusted to the external climate?
7. Are undesirable hot and cold radiation prevented?
8. Is the time spent in hot or cold environments limited?

**Table 8  Subject Interests of Technical Groups of Human Factors and Ergonomics Society**

| Technical Group | Description/Areas of Concerns |
| --- | --- |
| Aerospace systems | Application of human factors to the development, design, certification, operation, and maintenance of human–machine systems in aviation and space environments. The group addresses issues for civilian and military systems in the realms of performance and safety. |
| Aging | Human factors applications appropriate to meeting the emerging needs of older people and special populations in a wide variety of life settings. |
| Augmented cognition | Fostering the development and application of real-time physiological and neurophysiological sensing technologies that can ascertain a human's cognitive state while interacting with computing-based systems; data classification and integration architectures that enable closed-loop system applications; mitigation (adaptive) strategies that enable efficient and effective system adaptation based on a user's dynamically changing cognitive state; individually tailored training systems. |
| Cognitive engineering and decision making | Research on human cognition and decision making and the application of this knowledge to the design of systems and training programs. Emphasis is on considerations of descriptive models, processes, and characteristics of human decision making, alone or in conjunction with other individuals or intelligent systems; factors that affect decision making and cognition in naturalistic task settings; technologies for assisting, modifying, or supplementing human decision making; and training strategies for assisting or influencing decision making. |
| Communications | All aspects of human-to-human communication, with an emphasis on communication mediated by telecommunications technology, including multimedia and collaborative communications, information services, and interactive broadband applications. Design and evaluation of both enabling technologies and infrastructure technologies in education, medicine, business productivity, and personal quality of life. |
| Computer systems | Human factors in the design of computer systems. This includes the user-centered design of hardware, software, applications, documentation, work activities, and the work environment. Practitioners and researchers in the CSTG community take a holistic, systems approach to the design and evaluation of all aspects of user–computer interactions. Some goals are to ensure that computer systems are useful, usable, safe, and, where possible, fun and to enhance the quality of work life and recreational/educational computer use by ensuring that computer interface, function, and job design are interesting and provide opportunities for personal and professional growth. |
| Consumer products | Development of consumer products that are useful, usable, safe, and desirable. Application of the principles and methods of human factors, consumer research, and industrial design to ensure market success. |
| Education | Education and training of human factors and ergonomics specialists. This includes undergraduate, graduate, and continuing education needs, issues, techniques, curricula, and resources. In addition, a forum is provided to discuss and resolve issues involving professional registration and accreditation |
| Environmental design | Relationship between human behavior and the designed environment. Common areas of research and interest include ergonomic and macroergonomic aspects of design within home, office, and industrial settings. An overall objective of this group is to foster and encourage the integration of ergonomics principles into the design of environments |
| Forensics professional | Application of human factors knowledge and technique to ''standards of care'' and accountability established within legislative, regulatory, and judicial systems. The emphasis on providing a scientific basis to issues being interpreted by legal theory. |
| Health care | Maximizing the contributions of human factors and ergonomics to medical systems effectiveness and the quality of life of people who are functionally impaired |
| Individual differences | A wide range of personality and individual difference variables that are believed to mediate performance. |
| Industrial ergonomics | Application of ergonomics data and principles for improving safety, productivity, and quality of work in industry. Concentration on service and manufacturing processes, operations, and environments. |

**Table 8  (*continued*)**

| Technical Group | Description/Areas of Concerns |
|---|---|
| Internet | Human factor aspects of user interface design of Web content, Web-based applications, Web browsers, Webtops, Web-based user assistance, and Internet devices; behavioral and sociological phenomena associated with distributed network communication; human reliability in administration and maintenance of data networks; and accessibility of Web-based products. |
| Macroergonomics | Organizational design and management issues in human factors and ergonomics as well as work system design and human–organization interface technology. The Technical Group is committed to improving work system performance (e.g., productivity, quality, health and safety, quality of work life) by promoting work system analysis and design practice and the supporting empirical science concerned with the technological subsystem, personnel subsystem, external environment, organizational design, and their interactions. |
| Perception and performance | Perception and its relation to human performance. Areas of concern include the nature, content, and quantification of sensory information and the context in which it is displayed; the physics and psychophysics of information display; perceptual and cognitive representation and interpretation of displayed information; assessment of workload using tasks having a significant perceptual component; and actions and behaviors that are consequences of information presented to the various sensory systems. |
| Product design | Developing consumer products that are useful, usable, safe, and desirable. By applying the principles and methods of human factors, consumer research, and industrial design, the group works to ensure the success of products sold in the marketplace |
| Safety | Development and application of human factors technology as it relates to safety in all settings and attendant populations. These include, but are not limited to, aviation, transportation, industry, military, office, public building, recreation, and home environment |
| System development | Fostering research and exchanging information on the integration of human factors and ergonomics into the development of systems. Members are concerned with defining human factors/ergonomics activities and integrating them into the system development process in order to enable systems that meet user requirements. Specific topics of interest include the system development process itself; developing tools and methods for predicting and assessing human capabilities and limitations, notably modeling and simulation; creating principles that identify the role of humans in the use, operation, maintenance, and control of systems; applying human factors and ergonomics data and principles to the design of human–system interfaces; and the full integration of human requirements into system and product design through the application of HSI methods to ensure technical and programmatic integration of human considerations into systems acquisition and product development processes; the impact of increasing computerization and stress and workload effects on performance. |
| Surface transportation | Human factors related to the international surface transportation field. *Surface transportation* encompasses numerous mechanisms for conveying humans and resources: passenger, commercial, and military vehicles, on- and off-road; mass transit; maritime transportation; rail transit, including vessel traffic services (VTSs); pedestrian and bicycle traffic; and highway and infrastructure systems, including intelligent transportation systems (ITSs). |
| Test and evaluation | All aspects of human factors and ergonomics as applied to the evaluation of systems. Evaluation is a core skill for all human factors professionals and includes measuring performance, workload, situational awareness, safety, and acceptance of personnel engaged in operating and maintaining systems. Evaluation is conducted during system development when prototype equipment and systems are being introduced to operational usage and at intervals thereafter during the operational life of these systems. |
| Training | Fosters information and interchange among people interested in the fields of training and training research. |
| Virtual environment | Human factors issues associated with human–virtual environment interaction. These issues include maximizing human performance efficiency in virtual environments, ensuring health and safety, and circumventing potential social problems through proactive assessment. For VE/VR systems to be effective and well received by their users, researchers need to focus significant efforts on addressing human factors issues. |

## 3  HFE AND ECOLOGICAL COMPATIBILITY

The HFE discipline advocates systematic use of the knowledge concerning relevant human characteristics in order to achieve compatibility in the design of interactive systems of people, machines, environments, and devices of all kinds to ensure specific goals [Human Factors and Ergonomics Society (HFES), 2003)]. Typically such goals include improved (system) effectiveness, productivity, safety, ease of performance, and the contribution to overall human well-being and quality of life. Although the term *compatibility* is a key word in the above definition, it has been mainly used in a narrow sense only, often in the context of the design of displays and controls, including the studies of spatial (location) compatibility or the intention–response–stimulus compatibility related to movement of controls (Wickens and Carswell, 1997). Karwowski and his co-workers (Karwowski et al., 1988; Karwowski, 1985, 1991) advocated the use of compatibility in a greater context of the ergonomics system. For example, Karwowski (1997) introduced the term *human-compatible systems* in order to focus on the need for comprehensive treatment of compatibility in the human factors discipline.

The *American Heritage Dictionary of English Language* (Morris, 1978) defines "compatible" as (1) capable of living or performing in harmonious, agreeable, or congenial combination with another or others and (2) capable of orderly, efficient integration and operation with other elements in a system. From the beginning of contemporary ergonomics, the measurements of compatibility between the system and the human and evaluation of the results of ergonomics interventions were

based on the measures that best suited specific purposes (Karwowski, 2001). Such measures included the specific psychophysiological responses of the human body (example.g., heart rate, EMG, perceived human exertion, satisfaction, comfort or discomfort) as well as a number of indirect measures, such as the incidence of injury, economic losses or gains, system acceptance, or operational effectiveness, quality, or productivity. The lack of a universal matrix to quantify and measure human–system compatibility is an important obstacle in demonstrating the value of ergonomics science and profession (Karwowski, 1997). However, even though 20 years ago ergonomics was perceived by some (e.g., see Howell, 1986) as a highly unpredictable area of human scientific endeavor, today HFE has positioned itself as a unique, *design-oriented* discipline, independent of engineering and medicine (Moray, 1984; Sanders and McCormick, 1993; Helander, 1997; Karwowski, 1991, 2003).

Figure 3 illustrates the human–system compatibility approach to ergonomics in the context of quality of working life and system (an enterprise or business entity) performance. This approach reflects the nature of complex compatibility relationships between the human operator (human capacities and limitations), technology (in terms of products, machines, devices, processes, and computer-based systems), and the broadly defined environment (business processes, organizational structure, nature of work systems, and effects of work-related multiple stressors). The operator's performance is an outcome of the compatibility matching between individual human characteristics (capacities and limitations) and the requirements and affordances of both the technology

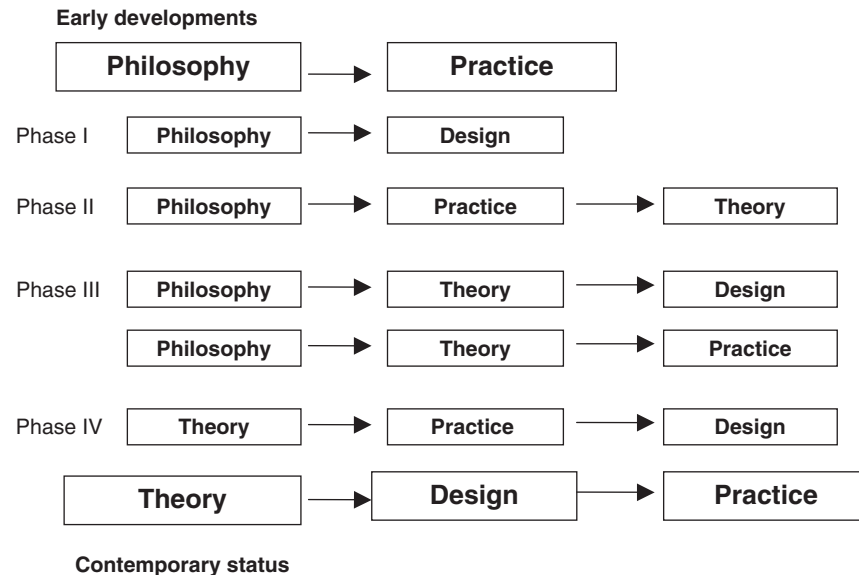

Figure 3   Evolution in development of HFE discipline (after Karwowski, 2005).

and environment. The quality of working life and the system (enterprise) performance is affected by matching the positive and negative outcomes of the complex compatibility relationships between the human operator, technology, and environment. Positive outcomes include such measures as work productivity, performance times, product quality, and subjective psychological (desirable) behavioral outcomes such as job satisfaction, employee morale, human well-being, and commitment. The negative outcomes include both human and system-related errors, loss of productivity, low quality, accidents, injuries, physiological stresses, and subjective psychological (undesirable) behavioral outcomes such as job dissatisfaction, job/occupational stress, and discomfort.

## 4  DISTINGUISHING FEATURES OF CONTEMPORARY HFE DISCIPLINE AND PROFESSION

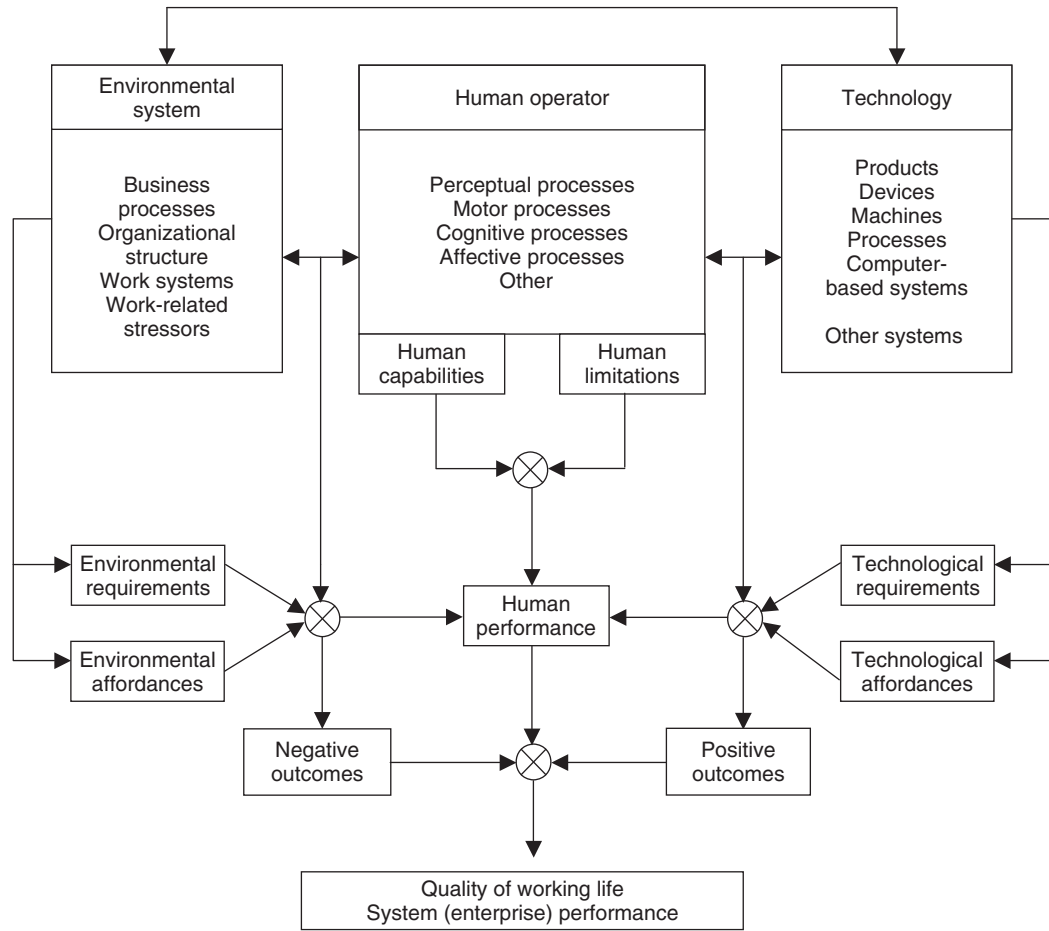
The main focus of the HFE discipline in the twenty-first century will be the design and management of systems that satisfy customer demands in terms of human compatibility requirements. Karwowski (2005) has discussed 10 characteristics of contemporary HFE discipline and profession. Some of the distinguishing features are as follows:

- HFE experiences continuing evolution of its "fit" philosophy, including diverse and ever-expanding human-centered design criteria (from safety to comfort, productivity, usability, or affective needs like job satisfaction or life happiness).
- HFE covers extremely diverse subject matters, similarly to medicine, engineering, and psychology (see Table 1).
- HFE deals with very complex phenomena that are not easily understood and cannot be simplified by making nondefendable assumptions about their nature.
- Historically, HFE has been developing from the "philosophy of fit" toward practice. Today, HFE is developing a sound theoretical basis for design and practical applications (see Figure 4).
- HFE attempts to "by-step" the need for the fundamental understanding of human−system interactions without separation from the consideration of knowledge utility for practical applications in the quest for immediate and useful solutions (also see Figure 5).
- HFE has limited recognition by decisionmakers, the general public, and politicians as to its value that it can bring to a global society at large, especially in the context of facilitating the socioeconomic development.
- HFE has a relatively limited professional educational base.
- The impact of HFE is affected by the ergonomics illiteracy of the students and professionals in other disciplines, the mass media, and the public at large.

Theoretical ergonomics is interested in the fundamental understanding of the interactions between people and their environments. Central to HFE interests is also an understanding of how human−system interactions should be designed. On the other hand, HFE also falls under the category of applied research. The taxonomy of research efforts with respect to the quest for a fundamental understanding and the consideration of use, originally proposed by Stokes (1997), allows for differentiation of the main categories of research dimensions as follows: (1) pure basic research, (2) use-inspired basic research, and (3) pure applied research. Figure 5 illustrates the interpretation of these categories for the HFE theory, design, and applications. Table 9 presents relevant specialties and subspecialties in HFE research as outlined by Meister (1999), who classified them into three main categories: (1) system/technology-oriented specialties, (2) process-oriented specialties, and (3) behaviorally oriented specialties. In addition, Table 10 presents a list of contemporary HFE research methods that can be used to advance the knowledge discovery and utilization through its practical applications.

## 5  PARADIGMS FOR ERGONOMICS DISCIPLINE

The paradigms for any scientific discipline include theory, abstraction, and design (Pearson and Young, 2002). Theory is a foundation of the mathematical sciences. Abstraction (modeling) is a foundation of the natural sciences, where progress is achieved by formulating hypotheses and systematically following the modeling process to verify and validate them. Design is the basis for engineering, where progress is achieved primarily by posing problems and systematically following the design process to construct systems that solve them.

In view of the above, Karwowski (2005) discussed the paradigms for HFE discipline: (1) ergonomics theory, (2) ergonomics abstraction, and (3) ergonomics design. Ergonomics theory is concerned with the ability to identify, describe, and evaluate human−system interactions. Ergonomics abstraction is concerned with the ability to use those interactions to make predictions that can be compared with the real world. Ergonomics design is concerned with the ability to implement knowledge about those interactions and use them to develop systems that satisfy customer needs and relevant human compatibility requirements. Furthermore, the pillars for any scientific discipline include a definition, a teaching paradigm, and an educational base (NRC, 2001). A definition of the ergonomics discipline and profession adopted by the IEA (2003) emphasizes fundamental questions and significant accomplishments, recognizing that the HFE field is constantly changing. A teaching paradigm for ergonomics should conform to established scientific standards, emphasize the development of competence in the field, and integrate theory, experimentation, design, and practice. Finally, an introductory course sequence in ergonomics should be based on the curriculum model and the disciplinary description.


Note: ⊗—Matching of compatibility relationships

**Figure 4**   Human–system compatibility approach to ergonomics (Karwowski, 2005).

**Figure 5**   Considerations of fundamental understanding and use in ergonomics research (Karwowski 2005).

**Table 9  Specialties and Subspecialties in HFE Research**

### *System/Technology-Oriented Specialties*

1.  Aerospace: civilian and military aviation and outer space activities.
2.  Automotive: automobiles, buses, railroads, transportation functions (e.g., highway design, traffic signs, ships).
3.  Communication: telephone, telegraph, radio, direct personnel communication in a technological context.
4.  Computers: anything associated with the hardware and software of computers.
5.  Consumer products: other than computers and automobiles, any commercial product sold to the general public (e.g., pens, watches, TV).
6.  Displays: equipment used to present information to operators (e.g., HMO, HUD, meters, scales).
7.  Environmental factors/design: the environment in which human–machine system functions are performed (e.g., offices, noise, lighting).
8.  Special environment: this turns out to be underwater.

### *Process-Oriented. Specialties*

*The emphasis is on how human functions are performed and methods of improving or analyzing that performance:*

1.  Biomechanics: human physical strength as it is manifested in such activities as lifting, pulling, and so on.
2.  Industrial ergonomics (IE): papers related primarily to manufacturing; processes and resultant problems (e.g., carpal tunnel syndrome).
3.  Methodology/measurement: papers that emphasize ways of answering HFE questions or solving HFE problems.
4.  Safety: closely related to IE but with a major emphasis on analysis and prevention of accidents.
5.  System design/development: papers related to the processes of analyzing, creating, and developing systems.
6.  Training: papers describing how personnel are taught to perform functions/tasks in the human–machine system.

### *Behaviorally Oriented Specialties*

1.  Aging: the effect of this process on technological performance.
2.  Human functions: emphasizes perceptual-motor and cognitive functions. The latter differs from training in the sense that training also involves cognition but is the process of implementing cognitive capabilities. (The HFE specialty called *cognitive ergonomics/decision making* has been categorized.)
3.  Visual performance: how people see. They differ from displays in that the latter relate to equipment for seeing, whereas the former deals with the human capability and function of seeing.

## 6  ERGONOMICS COMPETENCY AND LITERACY

As pointed out by the National Academy of Engineering (Pearson and Young, 2002), many consumer products and services promise to make people's lives easier, more enjoyable, more efficient, or healthier but very often do not deliver on this promise. Design of interactions with technological artifacts and work systems requires involvement of ergonomically competent people—people with ergonomics proficiency in a certain area, although not generally in other areas of application, similarly to medicine or engineering.

One of the critical issues in this context is the ability of users to understand the utility and limitations of technological artifacts. Ergonomics literacy prepares individuals to perform their roles in the workplace and outside the working environment. Ergonomically literate people can learn enough about how technological systems operate to protect themselves by making informed choices and making use of beneficial affordances of the artifacts and environment. People trained in ergonomics typically possess a high level of knowledge and skill related to one or more specific area of ergonomics application. Ergonomics literacy is a prerequisite to

ergonomics competency. The following can be proposed as dimensions for ergonomics literacy:

1.  *Ergonomics Knowledge and Skills*. An individual has the basic knowledge of the philosophy of human-centered design and principles for accommodating human limitations.
2.  *Ways of Thinking and Acting*. An individual seeks information about benefits and risks of artifacts and systems (consumer products, services, etc.) and participates in decisions about purchasing and use and/or development of artifacts/systems
3.  *Practical Ergonomics Capabilities*. An individual can identify and solve simple task (job)-related design problems at work or home and can apply basic concepts of ergonomics to make informed judgments about usability of artifacts and the related risks and benefits of their use.

Table 11 presents a list of 10 standards for ergonomics literacy which were proposed by Karwowski (2003) in parallel to a model of technological literacy reported by the NAE (Pearson and Young, 2002). Eight of these standards are related to developing an

understanding of the nature, scope, attributes, and role of the HFE discipline in modern society, while two of them refer to the need for developing the abilities to apply the ergonomics design process and evaluate the impact of artifacts on human safety and well-being.

## 7  ERGONOMICS DESIGN

Ergonomics is the design-oriented discipline. However, as discussed by Karwowski (2005), ergonomists do not design systems; rather HFE professionals design the interactions between the artifact systems and humans. One of the fundamental problems involved in such a design is that typically there are multiple functional system–human compatibility requirements that must be satisfied at the same time. In order to address this issue, structured design methods for complex human–artifact systems are needed. In such a perspective, ergonomics design can be defined in general as mapping from the human capabilities and limitations to system (technology–environment) requirements and affordances (Figure 6), or, more specifically, from system–human compatibility needs to relevant human–system interactions.

Suh (1990, 2001) proposed a framework for axiomatic design which utilizes four different domains that reflect mapping between the identified needs ("what one wants to achieve") and the ways to achieve them ("how to satisfy the stated needs"). These domains include (1) customer requirements (customer needs or desired attributes), (2) the functional domain (functional requirements and constraints), (3) the physical domain (physical design parameters), and (4) the processes domain (processes and resources). Karwowski (2003) conceptualized the above domains for ergonomics design purposes as illustrated in

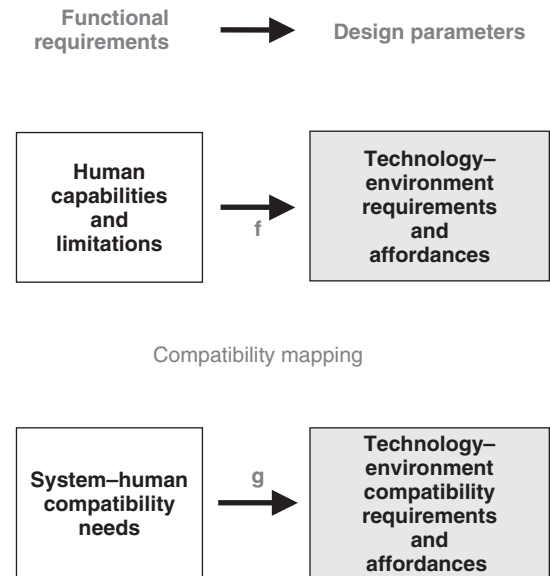

**Figure 6** Ergonomics design process: compatibility mapping (Karwowski 2005).

Figure 7 using the concept of compatibility requirements and compatibility mappings between the domains of (1) HFE requirements (goals in terms of human needs and system performance), (2) functional requirements and constraints expressed in terms of human capabilities and limitations, (3) the physical domain in terms of design of compatibility, expressed through the human–system interactions and specific work system design solutions, and (4) the processes domain, defined as management of compatibility (see Figure 8).

### 7.1  Axiomatic Design: Design Axioms

The axiomatic design process is described by the mapping process from functional requirements (FRs) to design parameters (DPs). The relationship between the two vectors FR and DP is as follows:

$$\{FR\} = [\mathbf{A}]\{DP\}$$

where $[\mathbf{A}]$ is the design matrix that characterizes the product design. The design matrix $[\mathbf{A}]$ for three functional domains (FRs) and three physical domains (DPs) is shown below:

$$[\mathbf{A}] = \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{bmatrix}$$

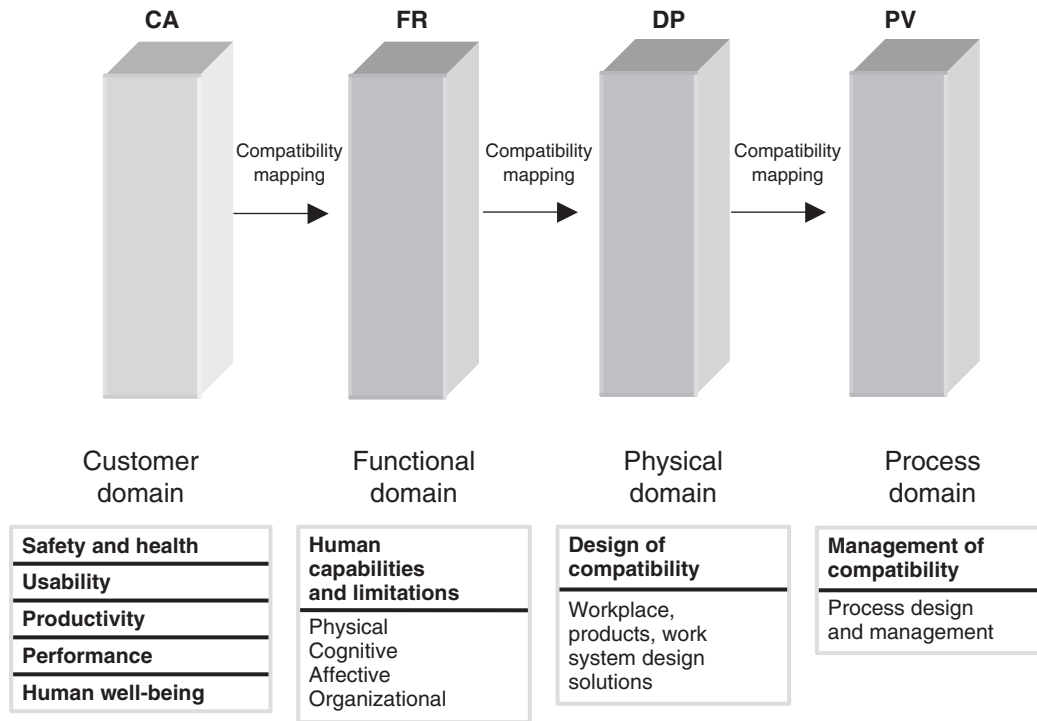
The following two design axioms, proposed by Suh (1991), are the basis for the formal methodology of design: (1) the independence axiom and (2) the information axiom.


**Figure 7**   Four domains of design in ergonomics (Karwowski, 2003).

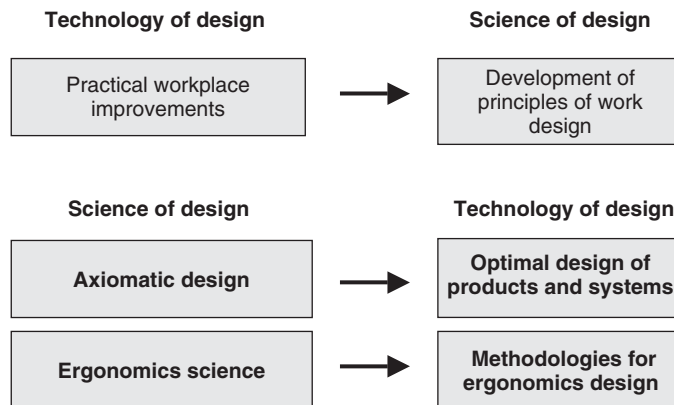

**Figure 8**   Axiomatic approach to ergonomics design (Karwowski, 2003).

### 7.1.1   Axiom 1: The Independence Axiom

This axiom stipulates a need for independence of the FRs, which are defined as the minimum set of independent requirements that characterize the design goals (defined by DPs).

### 7.1.2   Axiom 2: The Information Axiom

This axiom stipulates minimizing the information content of the design. Among those designs that satisfy the *independence axiom*, the design that has the smallest information content is the best design.

According to the second design axiom, the information content of the design should be minimized. The information content $I_i$ for a given functional requirement ($FR_i$) is defined in terms of the probability $P_i$ of satisfying $FR_i$:

$$I_i = \log_2(1/P_i) = -\log_2 P_i \text{ bits}$$

The information content will be additive when there are many functional requirements that must be satisfied simultaneously. In the general case of $m$ number of FRs, the information content for the entire system $I_{sys}$ is

$$I_{sys} = -\log_2 C_{\{m\}}$$

where $C_{\{m\}}$ is the joint probability that all $m$ FRs are satisfied.

The above axioms can be adapted for ergonomics design purposes as follows:

### 7.1.3 Axiom 1: The Independence Axiom

This axiom stipulates a need for independence of the functional compatibility requirements (FCRs), which are defined as the minimum set of independent compatibility requirements that characterize the design goals (defined by ergonomics design parameters, EDPs).

### 7.1.4 Axiom 2: The Human Incompatibility Axiom

This axiom stipulates a need to minimize the incompatibility content of the design. Among those designs that satisfy the independence axiom, the design that has the smallest incompatibility content is the best design.

As discussed by Karwowski (2001, 2003), in ergonomics design, the above axiom can be interpreted as follows. The human incompatibility content of the design $I_i$ for a given functional requirement (FR$_i$) is defined in terms of the compatibility $C_i$ index satisfying FR$_i$:

$$I_i = \log_2(1/C_i) = -\log_2 C_i \text{ ints}$$

where $I$ denotes the incompatibility content of a design.

### 7.2 Theory of Axiomatic Design in Ergonomics

As discussed by Karwowski 1991, 2001, 2003), a need to remove the system–human incompatibility (or ergonomics entropy) plays the central role in ergonomics design. In view of such discussion, the second axiomatic design axiom can be adopted for the purpose of ergonomics theory as follows.

The incompatibilty content of the design, $I_i$ for a given functional compatibility requirement (FCR$_i$), is defined in terms of the compatibility $C_i$ index that satisfies this FCR$_i$:

$$I_i = \log_2(1/C_i) = -\log_2 C_i \text{ [ints]}$$

where $I$ denotes the incompatibility content of a design, while the compatibility index $C_i$ [$0 < C < 1$] is defined depending on the specific design goals,that is, the applicable or relevant ergonomics design criterion used for system design or evaluation.

In order to minimize system–human incompatibility, one can (1) minimize exposure to the negative (undesirable) influence of a given design parameter on the system–human compatibility or (2) maximize the positive influence of the desirable design parameter (adaptability) on system–human compatibility. The first design scenario, that is, a need to minimize exposure to the negative (undesirable) influence of a given design parameter ($A_i$), typically occurs when $A_i$ exceeds some maximum exposure value of $R_i$, for example, when the compressive force on the human spine (lumbosacral joint) due to manual lifting of loads exceeds the accepted (maximum) reference value. It should be noted that if $A_i < R_i$, then $C$ can be set to 1, and the related incompatibility due to the considered design variable will be zero.

The second design scenario, that is, the need to maximize the positive influence (adaptability) of the desirable feature (design parameter $A_i$) on system human compatibility), typically occurs when $A_i$ is less than or below some desired or required value of $R_i$ (i.e., minimum reference value). For example, when the range of chair height adjustability is less than the recommended (reference) range of adjustability to accommodate 90% of the mixed (male/female) population. It should be noted that if $A_i > R_i$, then $C$ can be set to 1, and the related incompatibility due to the considered design variable will be zero. In both of the above described cases, the human–system incompatibility content can be assessed as discussed below.

1. *Ergonomics Design Criterion. Minimize exposure* when $A_i > R_i$.

The compatibility index $C_i$ is defined by the ratio $R_i/A_i$ where $R_i$ = maximum exposure (standard) for design parameter $i$ and $A_i$ = actual value of a given design parameter $i$:

$$C_i = R_i/A_i$$

and hence

$$I_i = -\log_2 C_i = -\log_2(R_i/A_i) = \log_2(A_i/R_i) \text{ ints}$$

Note that if $A_i < R_i$, then $C$ can be set to 1, and incompatibility content $I_i$ is zero.

2. *Ergonomics Design Criterion. Maximize adaptability* when $A_i < R_i$.

The compatibility index $C_i$ is defined by the ratio $A_i/R_i$, where $A_i$ = actual value of a given design parameter $i$ and $R_i$ = desired reference or required (ideal) design parameter standard $i$:

$$C_i = A_i/R_i$$

Hence

$$I_i = -\log_2 C_i = -\log_2(A_i/R_i) = \log_2(R_i/A_i) \text{ ints}$$

Note that if $A_i > R_i$, then $C$ can be set to 1 and incompatibility content $I_i$ is zero.

As discussed by Karwowski (2005), the proposed units of measurement for system–human incompatibility (ints) are parallel and numerically identical to the

measure of information (bits). The information content of the design in expressed in terms of the (ergonomics) incompatibility of design parameters with the optimal, ideal, or desired reference values, expressed in terms of ergonomics design parameters, such as range of table height or chair height adjustability, maximum acceptable load of lift, maximum compression on the spins, optimal number of choices, maximum number of hand repetitions per cycle time on a production line, minimum required decision time, and maximum heat load exposure per unit of time.

The general relationships between technology of design and science of design are illustrated in Figure 8. Furthermore, Figure 9 depicts such relationships for the HFE discipline. In the context of axiomatic design in ergonomics, the functional requirements are the human−system compatibility requirements, while the design parameters are the human−system interactions. Therefore, ergonomics design can be defined as mapping from the human−system compatibility requirements to the human−system interactions. More generally, HFE can be defined as the science of design, testing, evaluation, and management of human−system interactions according to the human−system compatibility requirements.

## 7.3  Axiomatic Design Approach in Ergonomics: Applications

Helander (1994, 1995) was first to provide a conceptualization of the second design axiom in ergonomics by considering selection of a chair based on the information content of specific chair design parameters. Recently, Karwowski (2003) introduced the concept of system incompatibility measurements and the measure on incompatibility for ergonomics design and evaluation. Furthermore, Karwowski (2003) has also illustrated an application of the first design axiom adapted to the needs of ergonomics design using an example of the design of the rear-light system utilized to provide information about application of brakes in a passenger car. The rear-light system is illustrated in Figure 10. In this highway safety-related example, the FRs of the rear-lighting (braking display) system were defined in terms

**Figure 10**  Illustration of redesigned rear-light system of an automobile.

of FRs and DPs as follows:

$$\begin{aligned}
\text{FR}_1 =\ & \text{Provide early warning to maximize lead} \\
& \text{response time (MLRT) (information} \\
& \text{about the car in front that is applying brakes)}
\end{aligned}$$

$$\text{FR}_2 = \text{Assure safe braking (ASB)}$$

The traditional (old) design solution is based on two DPs:

$$\text{DP}_1 = \text{Two rear brake lights on the sides (TRLS)}$$
$$\text{DP}_2 = \text{Efficient braking mechanism (EBM)}$$

The design matrix of the traditional rear-lighting system (TRLS) is as follows:

$$\begin{Bmatrix} \text{FR}_1 \\ \text{FR}_2 \end{Bmatrix} = \begin{pmatrix} \text{X} & 0 \\ \text{X} & \text{X} \end{pmatrix} \begin{Bmatrix} \text{DP}_1 \\ \text{DP}_2 \end{Bmatrix}$$

| MLRT | X | 0 | TRLS |
|------|---|---|------|
| ASB  | X | X | EBM  |

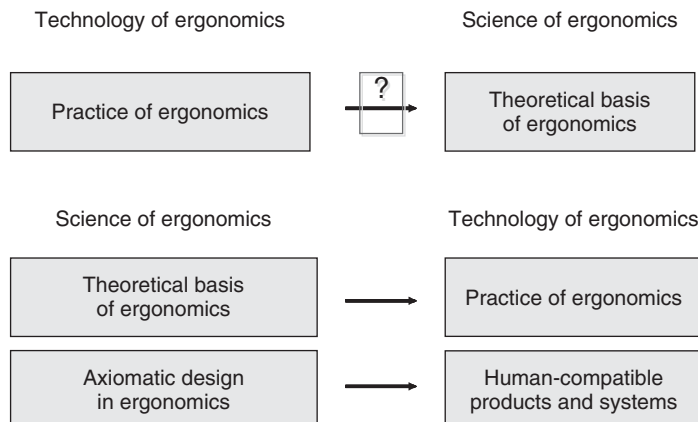

**Figure 9**   Science, technology, and design in ergonomics (Karwowski, 2003).

This rear-lighting warning system (old solution) can be classified as a *decoupled design* and is not an optimal design. The reason for such classification is that, even with the efficient braking mechanism, one cannot compensate for the lack of time in the driver's response to braking of the car in front due to a sudden traffic slowdown. In other words, this rear-lighting system does not provide early warning that would allow the driver to maximize his or her lead response time (MLRT) to braking.

The solution that was implemented two decades ago utilizes a new concept for the rear lighting of the braking system (NRLS). The new design is based on addition of the third braking light, positioned in the center and at a height that allows this light to be seen through the windshields of the car proceeding the car immediately in front. This new design solution has two DPs:

DP1 = A new rear-lighting system (NRLS)
DP2 = Efficient braking mechanism) (EBM) (the same as before)

The formal design classification of the new solution is an uncoupled design. The design matrix for this new design is as follows:

| MLRT | X | 0 | NRLS |
|------|---|---|------|
| ASB  | 0 | X | EBM  |

It should be noted that the original (traditional) rear-lighting system (TRLS) can be classified as decoupled design. This old design $[DP_{1,O}]$ does not compensate for the lack of early warning that would allow to maximize a driver's lead response time (MLRT) whenever braking is needed and, therefore, violates the second functional requirement ($FR_2$) of safe beaking. The design matrix for new system (NRLS) is an *uncoupled design* that satisfies the independence of functional requirements (independence axiom). This uncoupled design, $[DP_{1,N}]$, fulfills the requirement of maximizing lead response time (MLRT) whenever braking is needed and does not violate the $FR_2$ (safe braking requirement).

## 8 THEORETICAL ERGONOMICS: SYMVATOLOGY

It should be noted that the system–human interactions often represent complex phenomena with dynamic compatibility requirements. They are often nonlinear and can be unstable (chaotic) phenomena, the modeling of which requires a specialized approach. Karwowski (2001) indicated a need for symvatology as a corroborative science to ergonomics that can help in developing solid foundations for the ergonomics science. The proposed subdiscipline is called *symvatology*, or the science of the artifact–human (system) compatibility. Symvatology aims to discover laws of the artifact–human compatibility, proposes theories of the artifact–human compatibility, and develops a quantitative matrix for

measurement of such compatibility. Karwowski (2001) coined the term symvatology, by joining two Greek words: *symvatotis* (compatibility) and *logos* (logic, or reasoning about). Symvatology is the systematic study (which includes theory, analysis, design, implementation, and application) of interaction processes that define, transform, and control compatibility relationships between artifacts (systems) and people. An *artifact system* is defined as a set of all artifacts (meaning objects made by human work) as well as natural elements of the environment, and their interactions occurring in time and space afforded by nature. A human system is defined as the human (or humans) with all the characteristics (physical, perceptual, cognitive, emotional, etc.) which are relevant to an interaction with the artifact system.

To optimize both the human and system well-being and performance, system–human compatibility should be considered at all levels, including the physical, perceptual, cognitive, emotional, social, organizational, managerial, environmental, and political. This requires a way to measure the inputs and outputs that characterize the set of system–human interactions (Karwowski, 1991). The goal of quantifying artifact–human compatibility can only be realized if we understand its nature. Symvatology aims to observe, identify, describe, and perform empirical investigations and produce theoretical explanations of the natural phenomena of artifact–human compatibility. As such, symvatology should help to advance the progress of the ergonomics discipline by providing a methodology for the design for compatibility as well as the design of compatibility between artificial systems (technology) and humans. In the above perspective, the goal of ergonomics should be to optimize both the human and system well-being and their mutually dependent performance. As pointed out by Hancock (1997), it is not enough to assure the well-being of the human, as one must also optimize the well-being of a system (i.e., the artifacts-based technology and nature) to make the proper uses of life.

Due to the nature of the interactions, an artifact system is often a dynamic system with a high level of complexity, and it exhibits a nonlinear behavior. The *American Heritage Dictionary of English Language* (Morris, 1978) defines "complex" as consisting of interconnected or interwoven parts. Karwowski et al. (1988) proposed to represent the artifact–human system ($S$) as a construct which contains the human subsystem ($H$), an artifact subsystem ($A$), an environmental subsystem ($E$), and a set of interactions ($I$) occurring between different elements of these subsystems over time ($t$). In the above framework, compatibility is a dynamic, natural phenomenon that is affected by the artifact–human system structure, its inherent complexity, and its entropy or the level of incompatibility between the system's elements. Since the structure of system interactions ($I$) determines the complexity and related compatibility relationships in a given system, compatibility should be considered in relation to the system's complexity.

The system space, denoted here as an ordered set [(complexity, compatibility)], is defined by the four pairs as follows [(high, high), (high, low), (low, high), (low, low)]. Under the best scenario, that is, under the

most optimal state of system design, the artifact–human system exhibits high compatibility and low complexity levels. It should be noted that the transition from high to low level of system complexity does not necessarily lead to improved (higher) level of system compatibility. Also, it is often the case in most of the artifact–human systems that an improved (higher) system's compatibility can only be achieved at the expense of increasing the system's complexity.

As discussed by Karwowski et al. (1988), the lack of compatibility, or ergonomics incompatibility (EI), defined as degradation (disintegration) of the artifact–human system, is reflected in the system's measurable inefficiency and associated human losses. In order to express the innate relationship between the systems's complexity and compatibility, Karwowski et al. (1988, 1991) proposed the *complexity–incompatibility principle,* which can be stated as follows: *As the (artifact–human) system complexity increases, the incompatibility between the system elements, as expressed through their ergonomic interactions at all system levels, also increases, leading to greater ergonomic (nonreducible) entropy of the system and decreasing the potential for effective ergonomic intervention.* The above principle was illustrated by Karwowski (1995) using as an example the design of an office chair (see Figure 11). Karwowski (1992a) also discussed the complexity–compatibility paradigm in the context of organizational design. It should be noted that the above principle reflects the natural phenomena that others in the field have described in terms of difficulties

encountered in humans interacting with consumer products and technology in general. For example, according to Norman (1988), the paradox of technology is that added functionality to an artifact typically comes with the trade-off of increased complexity. These added complexities often lead to increase human difficulty and frustration when interacting with these artifacts. One of the reasons for the above is that technology which has more features also has less feedback. Moreover, Norman noted that the added complexity cannot be avoided when functions are added and can only be minimized with good design that follows natural mapping between the system elements (i.e., the control-display compatibility). Following Ashby's (1964) law of requisite variety, Karwowski (1995) proposed the corresponding law, called the "law of requisite complexity," which states that only design complexity can reduce system complexity. The above means that only the added complexity of the regulator (R = re/design), expressed by the system compatibility requirements (CR), can be used to reduce the ergonomics system entropy ($S$), that is, reduce overall artifact–human system incompatibility.

## 9   CONGRUENCE BETWEEN MANAGEMENT AND ERGONOMICS

Advanced technologies with which humans interact toady constitute complex systems that require a high level of integration from both the *design and management* perspectives. *Design integration* typically focuses on the interactions between hardware (computer-based

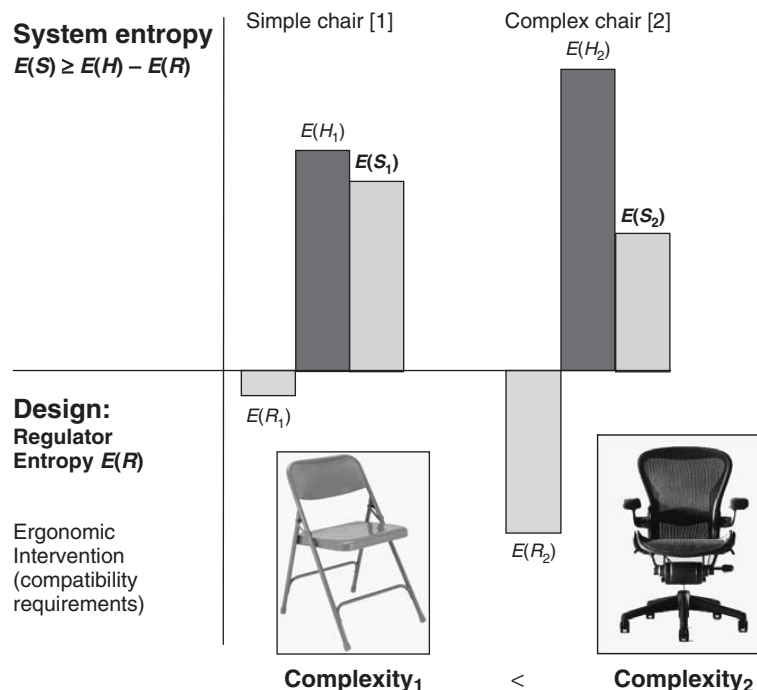

**Figure 11** System entropy determination: example of a chair design (after Karwowski, 1995).
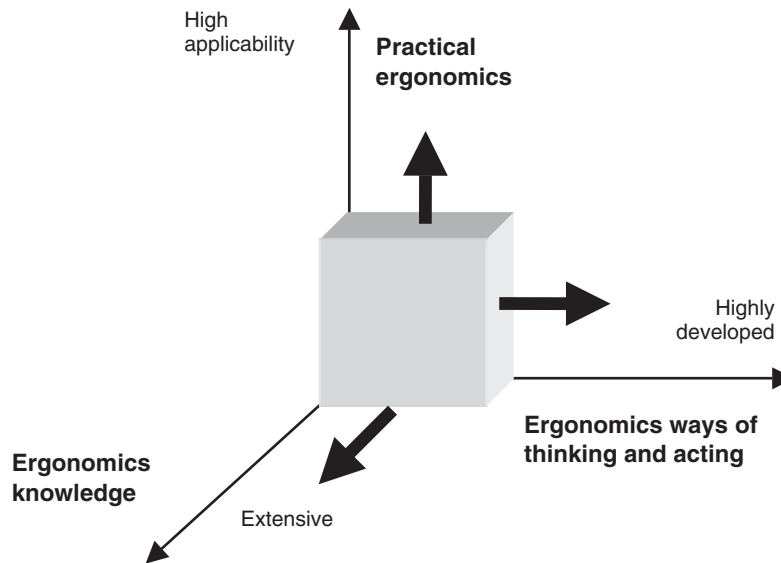

**Figure 12**  Desired goals for ergonomics literacy (Karwowski, 2003).

technology), organization (organizational structure), information system, and people (human skills, training, and expertise). *Management integration* refers to the interactions between various system elements across the process and product quality, workplace and work system design, occupational safety and health programs, and corporate environmental protection policies. As stated by Hamel (2007), "Probably for the first time since the Industrial Revolution, you cannot compete unless you are able to get the best out of people . . . ." Hamel also pointed out: "You cannot build a company that is fit for the future, unless you build a company that is fit for human beings." Unfortunately, the knowledge base of human factors and its principles of human-centered design have not yet been fully explored and applied in the area of business management. (See Figure 12.)

The scientific management originated with the work by Frederick W. Taylor (1911), who studied, among other problems, *how jobs were designed* and how workers could be trained to perform these jobs. The natural congruence between contemporary management and HFE can be described in the context of the respective definitions of these two disciplines. Management is defined today as a set of activities, including (1) planning and decision making, (2) organizing, (3) leading, and (4) controlling, directed at an organization's resources (human, financial, physical, and information) with the aim of achieving organizational goals in an efficient and effective manner (Griffin, 2001). The main elements of the management definition presented above and central to ergonomics are the following: (1) *organizing*, (2) *human resource planning*, and (3) *effective and efficient achievement of organizational goals*. In the description of these elements, the original terms proposed by the Griffin (2001) are applied in order to

ensure precision of the used concepts and terminology. *Organizing* is deciding which is the best way to group organizational elements. The *job design* is the basic building block of an organizational structure. Job design focuses on identification and determination of the tasks and activities for which the particular workers are responsible.

It should be noted that the basic ideas of management (i.e., planning and decision making, organizing, leading, and controlling) are also essential to HFE. An example of the mapping between the management knowledge (planning function) and human factors knowledge is shown in Figure 13. Specifically, common to management and ergonomics are the issues of job design and job analysis. Job design is widely considered to be the first building block of an organizational structure. Job analysis as a systematic analysis of jobs within an organization allows us to determine an individual's work-related responsibilities. The *human resource planning* is an integral part of the human resource management. The starting point for this business function is a *job analysis*, that is, a systematic analysis of the workplace in the organization. *Job analysis* consists of two parts: (1) *job description* and (2) *job specification*. Job description should include description of the task demands and the work environment conditions, such as work tools, materials, and machines needed to perform specific tasks. Job specification determines abilities, skills, and other worker characteristics necessary for *effective and efficient* tasks performance in a particular job.

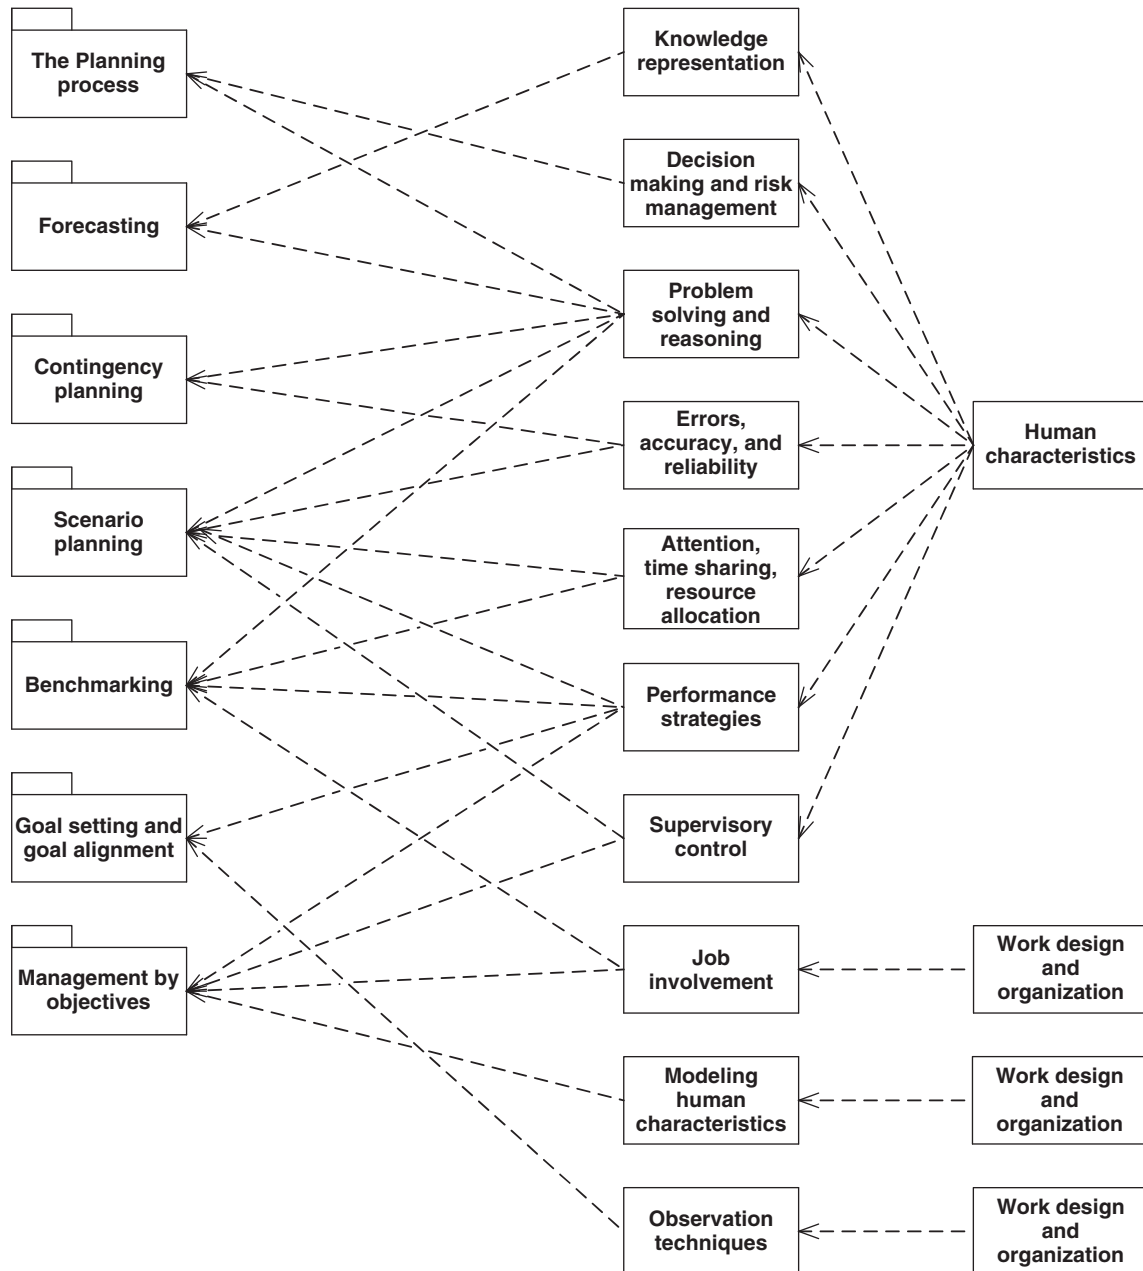
The discipline of management also considers important human factors that play a role in *achieving organizational goals in an effective and efficient way*. Such factors include (1) work stress in the context of individual workers' behavior and (2) human resource management in the context of safety and health


**Figure 13** Human factors knowledge mapping: planning processes (left side) related to organizational design as part of business management and relevant human characteristics (middle and right sides).

management. The work stress may be caused by the four categories of the organizational and individual factors: (1) decision related to the *task demands*; (2) *work environment demands*, including physical, perceptional, and cognitive task demands, as well as quality of the work environment, that is, adjustment of the tools and machines to the human characteristics and capabilities;

(3) *role demands* related to the relations with supervisor and co-workers; and (4) *interpersonal demands*, which can cause conflict between workers, for example, management style and group pressure. The human resource management includes provision of the safe work conditions and environment at each workstation, in the workplace, and in the entire organization.

It should also be noted that the elements of the management discipline described above, such as *job design, human resource planning* (job analysis and job specification), *work stress management,* and *safety and health management*, are essential components of the HFE subdiscipline often called industrial ergonomics. Industrial ergonomics, which investigates the human–system relationships at the individual workplace (workstation) level or at the work system level, embraces the knowledge that is also of central interest to management. From this point of view, industrial ergonomics in congruence with management is focusing on the organization and management at the workplace level (work system level) through the design and assessment (testing and evaluation) of job tasks, tools, machines, and work environments in order to adapt these to the capabilities and needs of the workers.

Another important subdiscipline of HFE with respect to the central focus of the management discipline is macroergonomics. According to Hendrick and Kleiner (2001), macroergonomics is concerned with the analysis, design, and evaluation of work systems. Work denotes any form of human effort or activity. System refers to *sociotechnical* systems, which range from a single individual to a complex multinational organization. A *work system* consists of people interacting with some form of (1) job design (work modules, tasks, knowledge, and skill requirements), (2) hardware (machines or tools) and/or software, (3) the internal environment (physical parameters and psychosocial factors), (4) the external environment (political, cultural, and economic factors), and (5) an organizational design (i.e., the work system's structure and processes used to accomplish desired functions).

The unique technology of HFE is the *human–system interface technology.* The human–system interface technology can be classified into five subparts, each with a related design focus (Hendrick, 1997; Hendrick & Kleiner, 2001):

1. *Human–machine* interface technology or hardware ergonomics
2. *Human–environment* interface technology or environmental ergonomics
3. *Human–software* interface technology or cognitive ergonomics
4. *Human–job* interface technology, or work design ergonomics
5. *Human–organization* interface technology or macroergonomics In this context, as disussed by (Hendrick and Kleiner, 2001), the HFE discipline discovers knowledge about human performance capabilities, limitations, and other human characteristics in order to develop human–system interface (HSI) technology, which includes the interface design principles, methods, and guidelines. Finally, the HFE profession applies the HSI technology to the design, analysis, test and evaluation, standardization, and control of systems.

## 10 HUMAN-CENTERED DESIGN OF SERVICE SYSTEMS

An important area of interest to the contemporary HFE discipline is the development and operation of service systems that employ today more than 60% of the workforce in the United States, Japan, and Germany (Salvendy and Karwowski, 2010). The major components in most service operations are people, infrastructure, and technology (Bitran and Pedrosa, 1998). Contemporary service systems can be characterized into four main dimensions (Fähnrich and Meiren, 2007):

- *Structure*: human, material, information, communication, technology, resources, and operating facilities
- *Processes*: process model, service provision
- *Outcomes*: product model, service content, consequences, quality, performance and standards
- *Markets*: requirement model, market requirements, and customer needs

Service system design extends the basic design concepts to include the experience that clients have with products and services. It also applies to the processes, strategies, and systems that are behind the experiences (Moritz, 2005). The key principles of customer-centered service system (CSS) design are characterized by the relationship between knowledge and technology. CSS involves the knowledge that is required to deliver the service, whether it is invested in the technology of the service or in the service provider (Hulshoff et al., 1998; McDermott et al., 2001).

Knowledge requirements in service systems design and modeling have been categorized into three main categories: knowledge based, knowledge embedded, and knowledge separated (McDermott et al., 2001). A knowledge-based service system such as teaching depends on customer knowledge to deliver the service. This knowledge may become embedded in a product that makes the services accessible to more people. An example of this is logistics providers, where the technology of package delivery is embedded in service system computers that schedule and route the delivery of packages. The delivery personnel contribute to critical components of both delivery and pickup. Their knowledge is crucial to satisfying customers and providing quality services. The CSS approach contributes to systems development processes rather than replaces them. Key principles of customer-centered service systems have been identified:

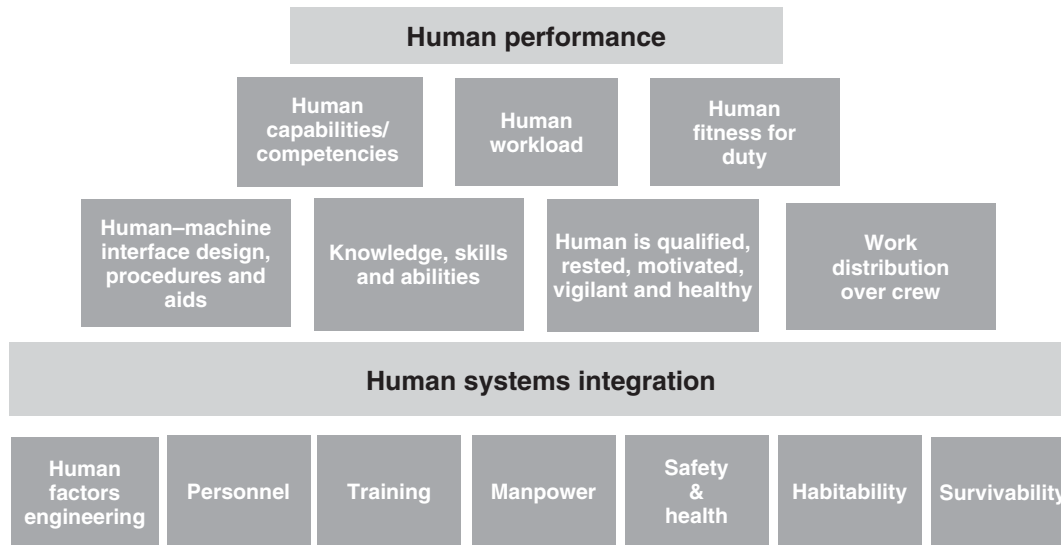
- *Clear Understanding of User and Task Requirements*. Key strengths of customer-centered service systems design are the spontaneous and active involvement of service users and the understanding of their task requirements. Involving end users will improve service system acceptance and increase commitment to the success of the new service.
- *Consistent Allocation of Functions between Users and Service System*. Allocation of


**Figure 14** Domains of human systems integration (adapted from Air Force, 2005).

functions should be based on full understanding of customer capabilities, limitations, and task demands.

- *Iterative Service System Design Approach*. Iterative service system design solutions include processing responses and feedback from service users after their use of proposed design solutions. Design solutions could range from simple paper prototypes to high-fidelity service systems mock-ups.

- *Multidisciplinary Design Teams*. Customer-centered service system design is a multitask collaborative process that involves multidisciplinary design teams. It is crucial that the service system design team comprise professionals and experts with suitable skills and interests in the proposed service system design. Such a team might include end users, service handlers (front-stage service system designers), managers, usability specialists, software engineers (back-stage service system designers), interaction designers, user experience architects, and training support professionals.

## 11 HUMAN–SYSTEMS INTEGRATION

The HFE knowledge is also being used for the purpose of human–systems integration (HSI), especially in the context of applying systems engineering to the design and development of large-scale, complex technological systems, such as those for the defense and space exploration industries (Malone and Carson, 2003; Handley and Smillie, 2008; Hardman et al., 2008; Folds et al., 2008). The knowledge management human domains have been identified internationally and are shown in Figure 14. These include human

factors engineering, manpower, personnel, training, safety and health hazards, habitability, and survivability. As discussed by Ahram and Karwowski (2009a, 2009b), these domains are the foundational human-centered domains of HSI and can be described as follows (Air Force, 2005, 2008, 2009):

**Manpower** Manpower addresses the number and type of personnel in the various occupational specialties required and potentially available to train, operate, maintain, and support the deployed system based on work and workload analyses. The manpower community promotes the pursuit of engineering designs that optimize the efficient and economic use of manpower, keeping human resource costs at affordable levels. Program managers and decision makers, who determine which manpower positions are required, must recognize the evolving demands on humans (cognitive, physical, and physiological) and consider the impact that technology can make on humans integrated into a system, both positive and negative.

**Personnel** The personnel domain considers the type of human knowledge, skills, abilities, experience levels, and human aptitudes (i.e., cognitive, physical, and sensory capabilities) required to operate, maintain, and support a system and the means to provide (recruit and retain) such people. System requirements drive personnel recruitment, testing, qualification, and selection. Personnel population characteristics can impact manpower and training as well as drive design requirements.

**Human Factors Engineering** Human factors engineering involves understanding and comprehensive integration of human capabilities (cognitive, physical, sensory, and team dynamics) into a system design, starting with conceptualization and continuing through system disposal. The primary concern for human factors engineering is to effectively integrate human–system interfaces to achieve optimal total system performance

(use, operation, maintenance, support, and sustainment). Human factors engineering, through comprehensive task analyses (including cognitive), helps define system functions and then allocates those functions to meet system requirements.

**Environment** Environment considers conditions within and around the system that affect the human's ability to function as part of the system. Steps taken to protect the total system (human, hardware, and software) from the environment as well as the environment (water, air, land, space, cyberspace, markets, organizations, and all living things and systems) from the systems design, development, manufacturing, operation, sustainment, and disposal activities are considered here. Environmental considerations may affect the concept of operations and requirements.

**Safety and Occupational Health** Safety promotes system design characteristics and procedures that minimize the potential for accidents or mishaps that cause death or injury to operators, maintainers, and support personnel as well as stakeholders and bystanders. The operation of the system itself is considered as well as prohibiting cascading failures in other systems. Using safety analyses and lessons learned from prior systems (if they exist), the safety community prompts design features to prevent safety hazards where possible and to manage safety hazards that cannot be avoided. The focus is on designs that have redundancy and, where an interface with humans exists, alerting the operators and users alike when problems arise and also help to avoid and recover from errors. Occupational health promotes system design features and procedures that minimize the risk of injury, acute or chronic illness, and disability and enhance job performance of personnel who operate, maintain, or support the system. The occupational health community seeks to prevent health hazards where possible and recommends personal protective equipment, protective enclosures, or mitigation measures where health hazards cannot be avoided. However, a balance must be found between providing too much information, thus increasing workload to unsafe levels, and mitigating minor concerns (i.e., providing too much information on faults such that managing this information becomes a task in of itself).

**Habitability** Habitability involves the characteristics of system living and working conditions such as lighting, ventilation, adequate space, vibration, noise, temperature control, availability of medical care, food and drink services, suitable sleeping quarters, sanitation, and personnel hygiene facilities. Such characteristics are necessary to sustain high levels of personnel morale, motivation, quality of life, safety, health, and comfort, contributing directly to personnel effectiveness and overall system performance. These habitability characteristics also directly impact personnel recruitment and retention.

**Survivability** Survivability addresses the characteristics of a system (e.g., life support, personal protective equipment, shielding, egress or ejection equipment, air bags, seat belts, electronic shielding) that reduce susceptibility of the total system to operational degradation or termination, to injury or loss of life, and to a partial or complete loss of the system or any of its components. These issues must be considered in the context of the full spectrum of anticipated operations and operational environments and for all people who will interact with the system (e.g., users/customers, operators, maintainers, or other support personnel). Adequate protection and escape systems must provide for personnel and system survivability when they are threatened with harm.

Malone and Carson (2003) stated the goal of the HSI paradigm as "to develop a system where the human and machine synergistically and interactively cooperate to conduct the mission." They state that the "low hanging fruit" of performance improvement lies in the human–machine interface block. The basic steps for the HSI approach can be summarized as follows (Karwowski and Ahram, 2009):

- *Human–Systems Integration Process*. Apply a standardized HSI approach that is integrated with systems processes.
- *Top-Down Requirements Analysis*. Conduct this type of analysis at the beginning and at appropriate points to decide which steps to take to optimize manpower and system performance.
- *Human–Systems Integration Strategy*. Incorporate HSI inputs into system processes throughout the life cycle, starting from the beginning of the concept and continuing through the operational life of the system.
- *Human–Systems Integration Plan*. Prepare and update this plan regularly to facilitate HSI activities.
- *Human–Systems Integration Risks*. Identify, prioritize, track, and mitigate factors that will adversely affect human performance.
- *Human–Systems Integration Metrics*. Implement practical metrics in specifications and operating procedures to evaluate progress continually.
- *Human Interfaces*. Assess the relationships between the individual and the equipment, between the individual and other individuals, and between the individual (or organization) and the organization to optimize physiological, cognitive, or sociotechnical operations.
- *Modeling*. Use simulation and modeling tools to evaluate trade-offs.

## 12 COMMITTEE ON HUMAN–SYSTEMS INTEGRATION OF THE NATIONAL RESEARCH COUNCIL

As described by the NRC (2010), the Committee on Human Factors was originally created in 1980 at the request of the U.S. Army, Navy, and Air Force to assist them in addressing various military issues. This committee was renamed in 2008 as the Committee on Human-Systems Integration (COHSI) and has expanded its scope of activities to include nonmilitary issues, such as human factors engineering, physical ergonomics, training, occupational health and safety, health care,

product design, and macroergonomics. The main objective of the committee is *to provide new perspectives on theoretical and methodological issues concerning the relationship of individuals and organizations to technology and the environment; identify critical issues in the design, test, evaluation, and use of new human-centered technologies; and advise committee sponsors on the research needed to expand the scientific and technical bases for effectively designing new technology and training employees*. Currently, the meetings and activities of the COHSI are sponsored by the Agency for Healthcare Research and Quality, Federal Aviation Administration, the Human Factors and Ergonomics Society, the National Institute on Disability and Rehabilitation Research, Office of Naval Research, the U.S. Army Research Laboratory, and the U.S. Air Force Research Laboratory.

## 13  THE INTERNATIONAL ERGONOMICS ASSOCIATION (WW.IEA.CC)

Over the last 30 years, ergonomics as a scientific discipline and as a profession has been rapidly growing, expanding its scope and breadth of theoretical inquiries, methodological basis, and practical applications (Meister 1997, 1999; Chapanis, 1999; Stanton and Young, 1999; Kuorinka, 2000; Karwowski, 2001; IEA 2003). As a profession, the field of ergonomics has seen development of formal organizational structures (i.e., the national and cross-national ergonomics societies and networks) in support of HFE discipline and professionals internationally. As of 2010, the IEA consisted of 47 member (federated) societies plus 2 affiliated societies and 3 IEA networks, representing over 18,000 HFE members worldwide (see Table 12). The main goals of

the IEA are to elaborate and advance the science and practice of ergonomics at an international level and to improve the quality of life by expanding the scope of ergonomics applications and contributions to the global society. A list of current IEA technical committees is shown in Table 13.

Some past IEA activities have focused on development of programs and guidelines in order to facilitate the discipline and profession of ergonomics worldwide. Examples of such activities include an international directory of ergonomics programs, core competencies in ergonomics, criteria for IEA endorsement of certifying bodies in professional ergonomics, guidelines for a process of endorsing a certification body in professional ergonomics, guidelines on standards for accreditation of ergonomics education programs at tertiary (university) level, or ergonomics quality in design (EQUID) programs. More information about these programs can be found on the IEA websire (www.ie.cc). In addition to the above, the IEA endorses scientific journals in the field. A list of the core HFE journals is given in Table 14. A complete classification of the core and related HFE journals was proposed by Dul and Karwowski (2004).

The IEA has also developed several actions for stimulating development of HFE in industrially developing countries (IDCs). Such actions include the following elements:

- Cooperating with international agencies such as the ILO (International Labour Organisation), WHO (World Health Organisation), and professional scientific associations with which the IEA has signed formal agreements
- Working with major publishers of ergonomics journals and texts to extend their access to

- federated societies, with particular focus on developing countries
- Development of support programs for developing countries to promote ergonomics and extend ergonomics training programs

- Promotion of workshops and training programs in developing countries through the supply of educational kits and visiting ergonomists
- Extending regional ergonomics "networks" of countries to countries with no ergonomics programs located in their region
- Supporting non-IEA member countries considering application for affiliation to the IEA in conjunction with the IEA Development Committee

## 14  FUTURE HFE CHALLENGES

The contemporary HFE discipline exhibits rapidly expanding application areas, continuing improvements in research methodologies, and increased contributions to fundamental knowledge as well as important applications to the needs of the society at large. For example, the subfield of neuroergonomics focuses on the neural control and brain manifestations of the perceptual, physical, cognitive, emotional, and so on, interrelationships in human work activities (Parasuraman, 2003). As the science of the brain and work environment, *neuroergonomics* aims to explore the premise of design of work to match the neural capacities and limitations of people. The potential benefits of this emerging branch of HFE are improvements of medical therapies and applications of more sophisticated workplace design principles. The near future will also see development of the entirely new HFE domain that can be called nanoergonomics. Nanoergonomics will address the issues of humans interacting with the devices and machines of extremely small dimensions and in general with the nanotechnology.

Finally, it should be noted that developments in technology and the socioeconomic dilemmas of the twenty-first century pose significant challenges for HFE discipline and profession. According to the report on major predictions for science and technology in the

twenty-first century published by the Japan Ministry of Education, Culture, Sports, Science and Technology MEXT (2006), several issues will affect the future of our civilization, including developments in genetics (creation of an artificial life, extensive outer space exploration); developments in cognitive sciences (human cognitive processes through artificial systems); a revolution in medicine (cell and organ regeneration, nanorobotics for diagnostics and therapy, superprosthesis, artificial photosynthesis of foods, elimination of human starvation and malnutrition, and safe genetic foods manipulation); full recycling of resources and reusable energy (biomass and nanotechnology); changes in human habitat (100% underground manufacturing, separation of human habitat from natural environments); clean-up of the negative effects of the twentieth century (natural sources of clean energy); communication, transport, and travel (automated transport systems, revolution in supersonic small aircraft and supersonic ocean travel, underwater ocean travel); and human safety (human error avoidance technology, control of the forces of nature, intelligent systems for safety in all forms of transport). The above issues will also affect the future direction in the development of human factors and ergonomics, as the discipline that focuses on the science, engineering, design, technology, and management of human-compatible systems.

# CHAPTER 2

# HUMAN FACTORS ENGINEERING AND SYSTEMS DESIGN

**Sara J. Czaja and Sankaran N. Nair**
**University of Miami Miller School of Medicine**
**Miami, Florida**

## 1 INTRODUCTION

### 1.1 Human Factors Engineering and the Systems Approach in Today's Environments

#### 1.1.1 Overview

*Human factors* is generally defined as the "scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and other methods to design in order to optimize human well-being and overall system performance" (International Ergonomics Association, 2010). The focus of human factors is on the application of knowledge about human abilities, limitations, behavioral patterns, and other characteristics to the design of person–machine systems. By definition, a person–machine system is a system which involves an interaction between people and other system components, such as hardware, software, tasks, environments, and work structures. The system may be simple, such as a human interacting with a hand tool, or it may be complex, such as an aviation system or a physician interacting with a complex computer display that is providing information about the status of a patient. The general objectives of human factors are to maximize human and system efficiency, health, safety, comfort, and quality of life (Sanders and McCormick, 1993; Wickens et al. 2004). In terms of research, this involves studying human performance to develop design principles, guidelines, methodologies, and tools for the design of the human–system interface. Research relevant to the field of human factors can range from basic, such as understanding the impact of aging on reaction time, to very applied, such as the understanding if multimodal cues enhance visual search performance in dynamic environments such as air traffic control. In terms of practice, human factors involves the application of these principles, guidelines, and tools to the actual design and evaluation of real-world systems and system components or the design of training programs and instructional materials that support the performance of tasks or the use of technology/equipment (Hendrick and Kleiner, 2001). In all instances human factors is concerned with optimizing the interaction between the human and the other systems components.

Given the focus on human performance within the context of tasks and environments, systems theory and the systems approach are fundamental to human factors engineering. Generally, systems theory argues for a unified nature of reality and the belief that the components of a system are meaningful only in terms of the general goals of the entire system. A basic tenet among systems theorists is that all systems are synergistic and that the whole is greater than the sum of its parts. This is in contrast to a reductionist approach, which focuses on a particular system component or element in isolation. The *reductionist* approach has traditionally been the "popular" approach to system design, where the focus has been on the physical or technical components of a system, with little regard for the behavioral component. In recent years the increased incidence of human error in the medical, transportation, safety, energy, and nuclear power environments and the resultant horrific consequences as well as the limited success of many technical developments have demonstrated the shortcomings of this approach and the need for a systems prospective.

As noted by Gorman and colleagues (2010), if there is a polarity between high technologies and humans that use them, errors can arise, especially if the system is asked to respond in a novel or unanticipated situation. A cogent example cited by the authors is the poor coordination of the system-level response following Hurricane Katrina. Other examples include adverse patient outcomes, oil spills (e.g., *Exxon Valdez*), and transportation incidents such as Flight 3407, the commercial commuter plane that crashed in the Buffalo, New York, area in 2009.

Implicit in the belief in systems theory is adoption of the systems approach. Generally, the systems approach considers the interaction among all of the components of a system relative to system goals when evaluating particular phenomena. Systems methodology represents a set of methods and tools applicable to (1) the analysis of systems and system problems; (2) the design, development, and deployment of systems; and (3) the management of systems and change in systems (Banathy and Jenlink, 2004). As noted by Sage and Rouse (2009), today's systems are often large scale and complex, and simply integrating individual subsystems is insufficient and does not typically result in a system that performs optimally. Instead, systems methodologies must be employed throughout the entire life cycle of the system. Further, systems engineering must use a variety of methodologies and analytical methods as well as knowledge from a multitude of disciplines.

Applied to the field of human factors, the systems concept implies that human performance must be evaluated in terms of the context of the system and that the efficiency of a system is determined by optimizing the performance of the human and the physical/technical components of the system. Further, optimization of human and system efficiency requires consideration of all major system components throughout the design process. Unfortunately, there has been a long tradition in the design and implementation of systems that places the primary emphasis on the technology components of the system without equal consideration of the person component (Gorman et al., 2010). A basic tenet of human factors is that design efforts that do not consider the human element will not achieve the maximum level of performance. For this reason, a discussion of the role of human factors in system design and evaluation is central to a handbook on human factors engineering. This is especially true in today's era of computerization and automation where systems are becoming increasingly large and complex and involve multiple components and interrelationships.

In this chapter we discuss the role of human factors engineering in system design. The focus is on the approaches and methodologies used by human factors engineers to integrate knowledge regarding human performance into the design process. The topic of system design is vast and encompasses many areas of specialization within human factors. Thus, we introduce several concepts that are covered in depth in other chapters of the handbook. Prior to discussing the design process, a summary of changes in today's systems and a brief history of the systems approach are provided. Our overall intent in the chapter is to provide an overview of the system design process and to demonstrate the importance of human factors to systems design. Further, we introduce new approaches to system design that are being applied to complex, integrated systems.

## 1.1.2 Changes in Work and Organizational Systems

Work organizations and social environments have changed enormously over the past decade, and these changes will continue as technology and demographic/social patterns evolve. Technology by its nature is dynamic, and continual developments in technology are changing work processes, the content of jobs, where work is performed, and the delivery of education and training. These changes will continue as new technologies emerge and we continue to move toward a service sector economy. For example, telework, where work is performed outside of the workplace and oftentimes in the home, is increasing on both a full- and part-time basis. In addition, technology-mediated learning, or "e-learning," is emerging as the preferred method for training employees (Czaja and Sharit, 2009).

Systems and organizations are also changing dramatically due to the growth of new organizational structures, new management practices, and technology. Changes include a shift from vertically integrated business organizations to less vertically integrated, specialized firms. Another shift is to decentralized management and collaborative work arrangements and team work across distributed organizational systems. Because of the complexity of tasks involved in complex systems, multi-operator teams are often preferred as the skills and abilities of a team can exceed the capabilities and workload constraints of individual operators (Salas et al., 2008). In these cases effective collaboration among the group members is challenging and requires a balance between efficiency and participatory involvement of as many stakeholders. In this regard, technology, such group support systems, has helped make it possible for organizations to use very large and diverse groups to solve problems. However, collaborative technology systems do not address all of the issues facing large groups such as meeting scheduling and information overload (de Vreede et al., 2010). Further, in many work domains, such as air traffic management and safety-critical domains, group members with different roles and responsibilities are distributed physically. There is also a shift towards knowledge-based organizations where intellectual capital is an important organizational asset. Together, these changes in work structures and processes result in an increased demand for more highly skilled workers who have a broader scope of knowledge and skills in decision making and knowledge management.

Also, in many domains such as the military, health care, and communication, there is an increased concern with "systems of systems" where different systems originally designed for their own purposes are integrated to produce a new and complex large system. The challenge associated with systems of systems has given rise to the discipline of human systems integration (HSI), which is a comprehensive multidisciplinary management and technical approach for ensuring consideration of

the person in all stages of the system life cycle. HSI includes manpower, personnel, training, environment, safety, health, human factors engineering, habitability, and survivability. It is also concerned with the design process and the development of tools and methods that help to ensure that stakeholders and designers work together to ensure that the abilities, limitations, and needs of users are considered in all phases of the design cycle. HSI has been largely employed in military systems (Pew and Mavor, 2007; Liu et al., 2009).

The demographics of the population are also changing. As depicted in Figure 1, the number of older adults in the United States is dramatically increasing. Of particular significance is the increase in the number of people aged 85+ years. The aging of the population has vast implications for the design of systems. For example, increases in the number of older people coupled with a shrinking labor pool due to a decline in fertility rates will threaten economic growth, living standards, and pension and health benefit financing. To this end, current changes in pension policies favor extending working life, and many industries are looking to older workers to address the emerging problem of labor and skill shortages due to the large number of older employees who are leaving the workforce and the smaller pool of available workers. Many adults in their middle and older years are choosing to remain in the workforce longer or return to work because of concerns about retirement income, health care benefits, or a desire to remain productive and socially engaged. Together, these trends suggest an increase in the number of older workers in the upcoming decades (Figure 2). These trends are paralleled in other countries. In the European Union (EU), the aging of the workforce and supporting social structures are a major

concern, and a major goal for the countries in the EU is to increase the employment rate of people aged 55–64 years (Ilmarinen, 2009). Overall, these trends imply that organizations will need to focus on strategies to accommodate an increasingly older workforce. Thus there is a great need for understanding the capabilities, limitations, and preferences of older adults with respect to current jobs, work scheduling, and training. There are also many unanswered questions regarding the impact of aging and an older workforce on team functioning and processes. This is an important consideration given the current focus on collaborative work. The aging of the population also has implications for system design within other domains such as transportation and health care.

The number of women in the labor force has also been increasing steadily, which also has implications for job and workplace design. For example, many women are involved in caregiving for an older relative or friend. Current estimates indicate that about 22% of adults in the United States are engaged in some form of caregiving. Most informal caregivers currently work either full time or part time, and these caregivers (∼59–75%) are typically middle-aged women at the peak of their earning power (Family Caregiving Alliance, 2010). As noted by Schulz and Martire (2009), increases in both labor force participation rates of women and the number of people who need informal care raise important questions about how effectively the work and caregiver roles can be combined and what strategies can be used to optimize work and caregiving scenarios. Finally, due to the globalization of trade and commerce, many systems include people from a variety of ethnic and cultural backgrounds. As noted by Strauch (2010), ethnic and

**Figure 1** U.S. historical and projected older adult population as percentage of the total population: 1900–2050 (Hobbs and Stoops, 2002; U.S. Census Bureau, 2008).
**Figure 2**   Projected labor force participation rates of older adults, 1986–2016 (Toossi, 2007).

cultural values vary with respect to work practices, communication, and family. Cultural/ethnic values are also dynamic and change over time. If ethnic/cultural factors are not considered in systems design and operations, there may be breakdowns in system team performance and overall system efficiency. To date, there is limited information on how cultural factors affect issues such as team work, communication, and the overall operations of systems. In general, all of the aforementioned issues underscore the need for a more human factors involvement in systems design.

## 1.2   Brief History of the Systems Approach and Human Factors Engineering

The systems concept was initially a philosophy associated with thinkers such as Hegel, who recognized that the whole is more than the sum of its parts. It was also a fundamental concept among Gestalt psychologists, who recognized the importance of "objectness" or wholeness to human perception. The idea of a general systems theory was developed by Bertalanffy in the late 1930s and developed further by Ashby in the 1940s (Banathy and Jenlink, 2004). The systems approach, which evolved from systems thinking, was developed initially in the biological sciences and refined by communication engineers in the 1940s. Adoption of this approach was bolstered during World War II when it was recognized that military systems were becoming too complex for humans to operate successfully. This discovery gave rise to the emergence of the field of human factors engineering and its emphasis on human–machine systems.

Sheridan (2002) classified the progress of human factors and the study of human–machine systems into three phases: phase A (knobs and dials), phase B (borrowed engineering models), and phase C (human–computer interaction). The initial time period, phase A, gave birth to the concept of human–machine systems. The focus of human factors engineers was primarily on aircraft (civilian and military) and weapon systems, with limited applications in the automotive and communication industries. Following World War II there was an appreciation of the need to continue to develop human factors. The initial focus of this effort was on the design of displays and controls and workstations for defense systems. In this era, human factors study was often equated with the study of knobs and dials. During phase B the field began to evolve beyond knobs and dials when human factors engineers recognized the applicability of system engineering models to the study of human performance. During the 1960s, systems theory became a dominant way of thinking within engineering, and human factors engineers began to use modeling techniques, such as control theory, to predict human–system performance. A number of investigators were concerned with developing models of human performance and applying these models to system design. At the same time, the application of human factors expanded beyond the military, and many companies began to establish human factors groups. The concept of the human–machine system also expanded as human factors engineers became involved with the design of consumer products and workplaces.

Phase C refers to the era of human–computer interaction. Advances in computing power and automation have changed the nature of human–machine systems dramatically, resulting in new challenges for human factors engineers and system designers. In many work domains the deployment of computers and automation has changed the nature of the demands placed on the worker. In essence, people are doing less physical work and are interacting mentally with computers and automated systems, with an emphasis on perceiving, attending, thinking, decision making, and problem solving (Rasmussen et al., 1994; Sheridan 2002; Proctor and Vu, 2010). The presence of computers and other forms

of communications technologies has become ubiquitous in most work systems. One of the most dramatic changes has been the development of the Internet, which allows increased access to vast amounts of information by a wide variety of users as well as greater interconnectivity than ever before across time zones and distances. Access to the Internet places greater demands on information processing, and information management and concerns about privacy and information security have become important issues within the fields of human factors and human–computer interaction (Proctor and Vu, 2010). Phase C is continuing to grow at a rapid pace and human factors engineers are confronted with many new types of technology and work systems, such as artificial intelligence agents, human supervisory control, and virtual reality. For example, robots are increasingly being introduced into military, space, aviation, and medical domains and research is being conducted on how to optimize human–robot teams. Issues being investigated include strategies for maximizing communication such as using gesture or gaze and how to optimally coordinate human–robot behavior. Ongoing research is also examining how theories and models of natural human interactions can be applied to robotic systems (e.g., Shah and Breazeal, 2010). Clearly, these types of systems present new challenges for system designers and human factors specialists.

To design today's work systems effectively, we need to apply knowledge regarding human information-processing capabilities to the design process. The need for this type of knowledge has created a greater emphasis on issues related to human cognition within the field of human factors and has led to the emergence of cognitive engineering (Woods, 1988). Cognitive engineering focuses on complex, cognitive thinking and knowledge-related aspects of human performance, whether carried out by humans or by machine agents (Wickens et al., 2004). It is closely aligned with the field of cognitive science and artificial intelligence. With the emphasis on team work, the concept of team cognition has emerged, which refers to the interaction between intraindividual and interindividual cognitive processes and applies the conceptual tools of cognitive science to a team or group as opposed to the individual. More recently, theories of macrocognition have been developed to guide complex collaborative processes or knowledge-based performance in nonroutinized, novel situations. It emphasizes expertise out of context and teams going beyond routine methods of performing and generating new performance processes to deal with novel situations (Fiore et al., 2010). Another new construct that has emerged is neuroergonomics, which involves the study of the mechanisms that underlie human information processing through methods used in cognitive neuroscience. These methods include neuroimaging techniques such as functional magnetic resonance imaging (fMRI), electroencephalography (EEG), and event-related potentials (ERPs). These techniques have been applied to assessment workload in complex tasks and mental workload and vigilance (Parasuraman and Wilson, 2008; Proctor and Vu; 2010).

Further need for new approaches to system design comes from the changing nature of the design process. Developments in technology and automation have not only increased the complexities of the types of systems that are being designed but have also changed the design process itself and the way designers think, act, and communicate. System design is an extremely complex process that proceeds over relatively long time periods in an atmosphere of uncertainty (Meister, 2000; Sage and Rouse, 2009). The process is influenced by many factors, some of which are behavioral and some of which are physical, technical, and organizational (Table 1). As noted, design also involves interaction among many people with different types and levels of knowledge and diverse backgrounds. At the most basic level, this interaction involves engineers from many different specialties; however, in reality it also involves the users of the system being designed and organizational representatives. Further, system design often takes place under time constraints in turbulent economic and social markets. Design also involves the use of many different tools and technologies. For example, human performance models are often used to aid the design process. In this regard, there have been three major trends in the development of human performance models: manual control models, network models, and cognitive process models. Today, in many instances sophisticated models of human behavior are simulated in virtual environments to evaluate human system integration. In these instances a digital or numerical manikin is used to model human processes in an attempt to take into account factors, such as human behavior, that influence system reliability early in the design process (Lämkull et al., 2007; Fass and Leiber, 2009). These types of modeling techniques are being deployed in the aircraft and air traffic control systems as well as in the automotive and military industries. Currently, many models are complex and difficult to use without training. There is a strong need within the human factors community to improve the quality and usability of these models and to ensure that practitioners have the requisite skills to use these models (Pew, 2008).

Overall, it has become apparent that we cannot restrict the application of human factors to the design of specific jobs, workplaces, or human–machine interfaces; instead we must broaden our view of system design and consider broader sociotechnical issues. In other words, design of today's systems requires the adoption of a more *macroergonomic approach*, a top-down sociotechnical system approach to design that is concerned with the human–organizational interface and represents a broad perspective to systems design. Sociotechnical systems integrate people and social and technical elements to accomplish system objectives. Thus, people within these systems must demonstrate both social and technical skills and have an awareness of the broader environment to function effectively (Carayon, 2006). As illustrated throughout this chapter, a number of important trends are related to the organization and design of work systems that underscore the need for a macroergonomic approach, including (1) rapid

**Table 1  Design Process**

### *Elements*

1. Design specification
2. Design history (e.g., predecessor system data and analyses)
3. Design components transferred from a predecessor system
4. Design goals (technological and idiosyncratic)

### *Processes*

1. Analysis of design goals (performed by both designers and human factors ergonomics specialists)
2. Determination of design problem parameters (both)
3. Search for information to understand the design problem and parameters (both)
4. Behavioral analysis of functions and tasks (specialist only)
5. Transformation of behavioral information into physical surrogates (specialist only)
6. Development and evaluation of alternative solution to the design problem (both, mostly designers)
7. Selection of one design solution to be followed by detailed design (both, mostly designers)
8. Design of the human–machine interface, human–computer interface, human–robot interface (any may be primary)
9. Evaluation and testing of design outputs (both)
10. Determination of system status and development progress (both)

### *Factors Affecting Design*

1. Nature of the design problem and of the system, equipment, or product to be designed
2. Availability of needed relevant information
3. Strategies for solution of design problem (information-processing methods)
4. Idiosyncratic factors (designer/specialist intelligence, training, experience, skill, personality)
5. Multidisciplinary nature of the team
6. Environmental constraints and characteristics
7. Project organization and management

*Source*: Adapted from Meister (2000).

developments in technology, (2) demographic shifts, (3) changes in the value system of the workforce, (4) world competition, (5) an increased concern for safety and the resulting increase in ergonomics-based litigations, and (6) the failure of traditional microergonomics (Hendrick and Kleiner, 2001; Kleiner, 2008).

In sum, the nature of human–machine systems has changed drastically since the era of knobs and dials, presenting new challenges and opportunities for human factors engineers. We are faced not only with designing and evaluating new types of systems and a wider variety of systems (e.g., health care systems, living environments) but also with many different types of user populations. Many people with limited technical background and of varying ages are operating complex technology-based systems, which raises many new issues for system designers. For example, older workers may require different types of training or different work schedules to interact effectively with new technology, or operators with a limited technical background may require a different type of interface than those who are more experienced. Emergence of these types of issues reinforces the need to include human factors in system design. In the following section we present a general model of a system that will serve as background to a discussion of the system design process.

## 2  DEFINITION OF A SYSTEM

### 2.1  General System Characteristics

A *system* is an aggregation of elements organized in some structure (usually, hierarchical) to accomplish system goals and objectives. All systems have the following characteristics: interaction of elements, structure, purpose, and goals and inputs and outputs. A system is usually composed of humans and machines and has a definable structure and organization and external boundaries that separate it from elements outside the system. All the elements within a system interact and function to achieve system goals. Further, each system component has an effect on the other components. It is through the system inputs and outputs that the elements of a system interact and communicate. Systems also exist within an environment (physical and social), and the characteristics of this environment have an impact on the structure and the overall effectiveness of the system (Meister, 1989, 1991). For example, to be responsive to today's highly competitive and unstable environment, systems have to be flexible and dynamic. This creates the need for changes in organizational structures. Formal, hierarchical organizations do not effectively support distributed decision making and flexible processes.

Generally, all systems have the following components: (1) elements (personnel, equipment, procedures); (2) conversion processes (processes that result in changes in system states); (3) inputs or resources (personnel abilities, technical data); (4) outputs (e.g., number of units produced); (5) an environment (physical and social and organizational); (6) purpose and functions (the starting point in system development); (7) attributes (e.g., reliability); (8) components and programs; (9) management, agents, and decision makers; and (10) structure. These components must be considered in the design and evaluation of every system. For example, the nature of the system inputs has a significant impact on the ability of a system to produce the desired outputs. Inputs that are complex, ambiguous, or unanticipated may lead to errors or time delays in information processing, which in turn may lead to inaccurate or inappropriate responses. If there is conflicting or confusing information on a patient's chart, a physician might have difficulty diagnosing the illness and prescribing the appropriate course of treatment.

There are various ways in which systems are classified. Systems can be distinguished according to degree of automation, functions and tasks, feedback mechanisms, system class, hierarchical levels, and combinations of system elements (Meister, 1991). A basic distinction between open- and closed-loop systems is usually made on the basis of the nature of a system's feedback mechanisms. *Closed-loop systems* perform a process that requires continuous control and feedback for error correction. Feedback mechanisms exist that provide continuous information regarding the difference between the actual and the desired states of the system. In contrast, *open-loop systems* do not use feedback

for continuous control; when activated, no further control is executed. However, feedback can be used to improve future operations of the system (Sanders and McCormick, 1993). The distinction between open- and closed-loop systems is important, as they require different design strategies.

We are also able to describe different classes of systems. For example, we can distinguish at a very general level among educational systems, production systems, maintenance systems and health care systems, transportation systems, communication systems, and military systems. Within each of these systems we can also identify subsystems, such as the social system or the technical system. Complex systems generally contain a number of subsystems. Finally, we are able to distinguish systems according to components or elements. For example, we can distinguish among machine systems, human systems (biological systems), and human–machine systems and more recently human–robot systems and collaborative team or group systems.

## 2.2 Person–Machine Systems

A person–machine system is some combination of humans and machines that interact to achieve the goals of a system. These systems are characterized by elements that interact, structure, goals, conversion processes, inputs, and outputs. Further, they exist in an environment and have internal and external boundaries. A simple model of a human–machine system is presented in Figure 3. This general systems model applies to person–machine systems; inputs are received and processed and outputs are produced through the interaction of the system components. A more complex

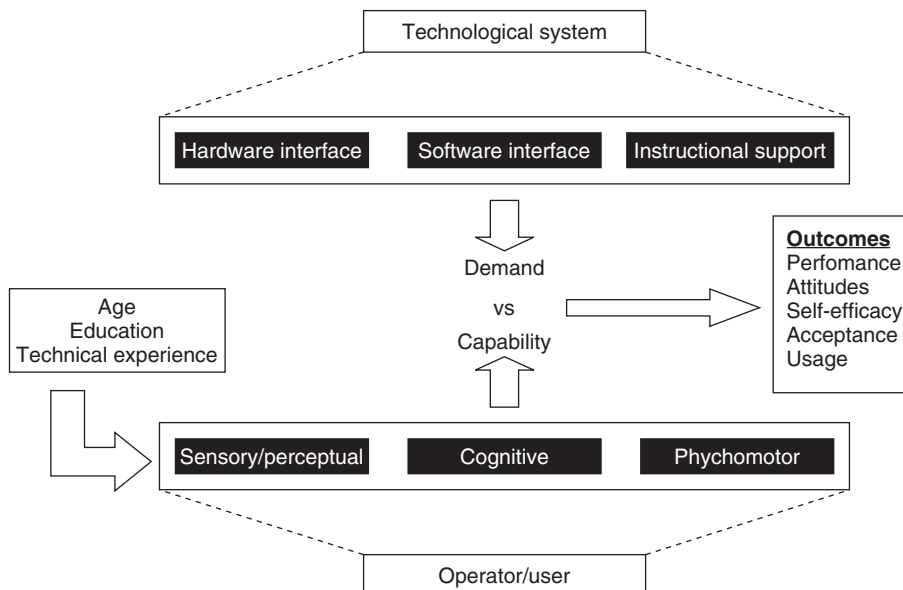

**Figure 3**  Example of human–machine system.
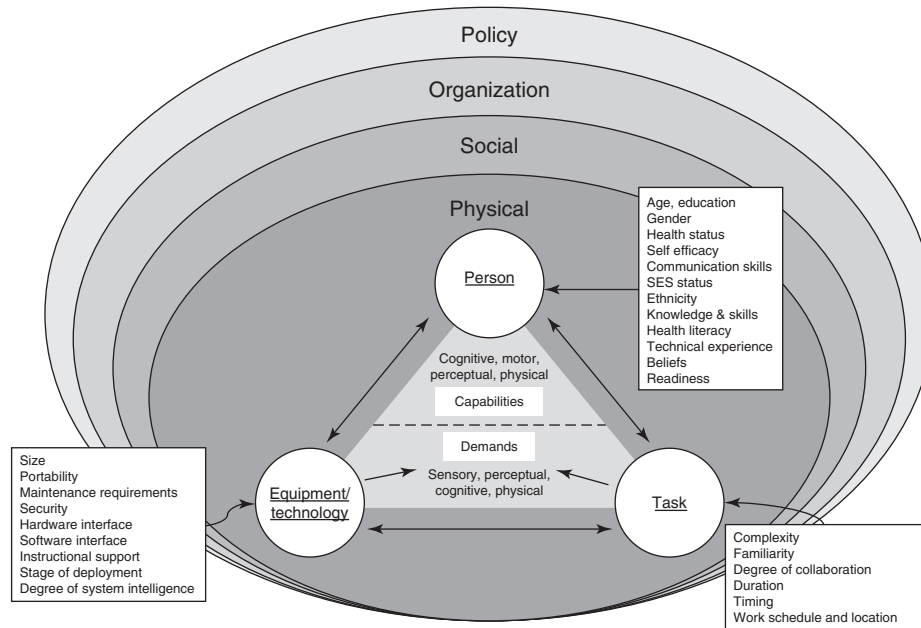

**Figure 4** Human factors model of person–task–equipment system.

model which integrates social and environmental components and is more representative of today's socio-technical systems is presented in Figure 4.

With the emergence of computer and automation technologies, the nature of person–machine systems has changed dramatically. For example, display technology has changed, and information can be presented in a wide variety of formats using multimedia approaches. Control functions have also changed, and humans can even speak commands. In addition, as noted earlier, with the advent of the Internet a vast amount of information on a wide variety of topics is available at an unprecedented rate and communication is taking on new forms with the advent of applications email and instant messaging. Perhaps more important, machines have become more intelligent and capable of performing tasks formerly restricted to humans. Prior to the development of intelligent machines, the model of the human–machine interface was formed around a control relationship in which the machine was under human control. In current human–machine systems (which involve some form of advanced technology), the machine is intelligent and capable of extending the capabilities of the human. Computer/automation systems can now perform routine, elementary tasks and complex computations, suggest ways to perform tasks, or engage in reasoning or decision making. In these instances, the human–machine interface can no longer be conceptualized in terms of a control relationship where the human controls the machine. A more accurate representation is a partnership where the human and the machine are engaged in two-way cognitive interaction. Also, in today's workplace human–computer interaction tasks often involve networks among groups of individuals.

For example, in aircraft piloting, the introduction of the flight management system (FMS) has dramatically changed the tasks of the pilot. The FMS is capable of providing the pilot with advice on navigation, weather patterns, airport traffic patterns, and other topics and is also capable of detecting and diagnosing abnormalities. The job of the pilot has become that of a process manager, and in essence the workspace of the pilot has become a desk; there is limited manual control of the flight system (Sheridan, 2002). Further the Next Generation Air Transportation System (NextGen) project is transforming the air transportation system in the United States through the incorporation of modern technologies. This will also have vast implications for pilots and air traffic controllers who will be assuming vast changes in job demands, roles, and responsibilities (http://www.jpdo.gov; Proctor and Vu, 2010). Rapidly advancing technologies such as image-guided navigation systems are being designed to support minimally invasive surgical procedures. Initially these systems, which represent a partial automation system for some aspects of a surgeon's task, were largely used in neurosurgery; however, they are increasingly being used in other surgical fields such as orthopedics. As discussed by Manzey and colleagues (2009), these tools are helpful for surgeons and have resulted in performance improvements. However, there are several human factors issues such as mental workload and training that need to be considered prior to their implementation. Other types of systems such as automotive systems are also incorporating new computer, communication, and control technologies that change the way that operators interact with these systems and raise new design concerns. With respect to automobiles, a number of issues related to driver

safety are emerging: For example, are maps and route information systems a decision aid or a distraction?

Similar issues are emerging in other domains. For example, flexible manufacturing systems represent some combination of automatic, computer-based, and human control. In these systems the operators largely assume the role of a supervisory controller and must plan and manage the manufacturing operation. Issues regarding function allocation are critical within these systems, as is the provision of adequate cognitive and technical support to the humans. Computers now offer the potential of assisting humans in the performance of cognitive activities, such as decision making, and a question arises as to what level of machine power should be deployed to assist human performance so that the overall performance of the system is maximized. This question has added complexity, as in most complex systems the problem is not restricted to one operator but to two or more operators who cooperate and have access to different databases. Today's automated systems are becoming even more complex with more decision elements, multiple controller set points, more rules, and more distributed objective functions and goals. Further, different parts of the system, both human and machine, may attempt to pursue different goals, and these goals may be in conflict. This is commonly referred to as the *mixed-initiative problem*, in which mixed human initiatives combine with mixed automation initiatives. Most systems of this type are supervised by teams of people in which the operator is part of a decision-making team of people who together with the automated system control the process (Sheridan, 2002). The mixed-initiative problem presents a particular challenge for system designers and human factors engineers.

Obviously, there are many different types of human–machine systems, and they vary greatly in size, structure, complexity, and so on. Although the emphasis in this chapter is on work systems where computerization is an integral system component, we should not restrict our conceptualization of systems to large, complex technological systems in production or process environments. We also need to consider other types of systems, such as a person using an appliance within a living environment, a physician interacting with a heart monitor in an intensive care unit, or an older person driving an automobile within a highway environment or using a telemedicine device within a home setting. In all cases, the overall performance of the system will be improved with the application of human factors engineering to system design.

New challenges for system design also arise from the evolution of virtual environments (VEs). Designers of these systems need to consider characteristics unique to VE systems, such as the design of navigational techniques, object selection and manipulation mechanisms, and the integration of visual, auditory, and haptic system outputs. Designers of these types of systems must enhance presence, immersion, and system comfort while minimizing consequences such as motion sickness. VE user interfaces are fundamentally different from traditional user interfaces with unique input–output devices, perspectives, and physiological interactions. As noted virtual human modeling is commonly used in the design of many systems to prevent changes late in the design process and enhance design efficiency.

Thus, in today's world, person–machine systems, which increasingly involve machine intelligence, can take many forms, depending on the technology involved and the function allocation between human and machine. Figure 5 presents the extremes of various degrees of automation and the complexity of various task scenarios. The lower left represents a system in which the human is left to perform completely predictable and, in most cases, "leftover tasks." In contrast, the upper right represents ideally intelligent automation where automated systems are deployed to maximal efficiency—a state

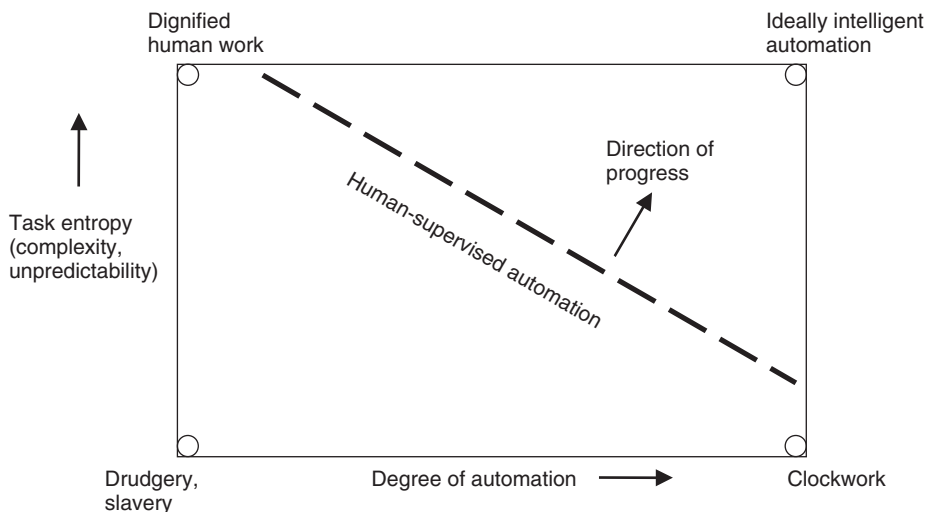

**Figure 5** Progress of human-supervised automation (Sheridan, 2002).

not attainable in the foreseeable future. The lower right also represents an effective use of full automation, and the upper left represents the most effective deployment of humans—working on undefined and unpredictable problems. As discussed by Sheridan (2002), few real situations occur at these extremes; most human-automated systems represent some trade-off of these options, which gradually progress toward the upper right—ideally, intelligent automation. Clearly, specification of the human–machine relationship is an important design decision. The relationship must be such that the abilities of both the human and machine components are maximized, as is cooperation among these components. Too often, technology is viewed as a panacea and implemented without sufficient attention to human and organizational issues.

The impact of the changing nature of person–machine systems on the system design process and current approaches to system design is discussed in a later section. However, before this topic is addressed, concepts of system and human reliability are introduced because these concepts are important to a discussion of system design and evaluation.

### 2.3 System Reliability

*System reliability* refers to the dependability of performance of the system, subsystem, or system component in carrying out its intended function for a specified period of time. Reliability is usually expressed as the probability of successful performance; therefore, for the probability estimate to be meaningful, the criteria for successful performance must be specified (Proctor and Van Zandt, 1994; Sheridan, 2008). The overall reliability of a system depends on the reliability of the individual components and how they are combined within a system. The reliability of a component is the probability that it does not fail and is defined as $r$, where $r = 1 − p$; $p$ represents the probability of failure.

Generally, components in a system are arranged in series, in parallel, or some combination of both. For total performance of the system to be satisfactory, if the components are arranged in series, they must all operate adequately. In this case, if the component failures are independent of each other, system reliability is the product of the reliability of the individual components. Further, as more components are added to a system, the reliability of the system decreases unless the reliability of these components is equal to 1.0. The reliability of the overall system can only be as great as that of the least reliable component.

In parallel systems, two or more components perform the same function such that successful performance of the system requires that only one component operate successfully. This is often referred to as *system redundancy*; the additional components provide redundancy to guard against system failure. For these types of systems, adding components in parallel increases the reliability of the system. If all of the components are equally reliable, system reliability is determined by calculating the probability that at least one component remains functional and considering the reliability of each of the parallel subsystems. Parallel redundancy is often provided for

human functions because the human component within a system is the least reliable.

### 2.4 Human Reliability

*Human reliability* is the probability that each human component of the system will perform successfully for an extended period of time and is defined as 1 minus the operator error probability (Proctor and Van Zandt, 1994). The study of human error has become an increasingly important research concern because it has become apparent that the control of human error is necessary for the successful operation of complex, integrated systems. The incidence of human error has risen dramatically over the past few years with many disastrous consequences. It has been estimated that human error is the primary cause of most major accidents and incidents in complex systems such as process control, aviation, and the health care environments (e.g., Wickens and Hollands, 2000; Morrow et al., 2006). In fact, human error has become a significant topic within the health care domain in efforts to improve human safety and decrease litigation and health insurance costs. The topic of human error is discussed in detail elsewhere in this handbook. It is discussed briefly in this chapter because the analysis of human error has important implications for system design. It is generally recognized that many errors that people make are the result of poor system design or organizational structure, and the error is usually only one in a lengthy and complex chain of breakdowns.

Due to the prevalence of human error and the enormous and often costly consequences, the study of human error has become an important focus within human factors engineering and in fact has emerged as a well-defined discipline. In recent years a number of techniques have emerged to study human error. Generally, these techniques fall into two categories, quantitative techniques and qualitative techniques. *Quantitative techniques* attempt to predict the likelihood of human error for the development of risk assessment for the entire system. These techniques can provide useful insights into human factors deficiencies in system design and thus can be used to identify areas where human factors knowledge needs to be incorporated. However, there are shortcomings associated with these techniques, such as limitations in providing precise estimates of human performance abilities, especially for cognitive processes (Wickens, 1992). Further, designers are not able to identify all of the contingencies of the work process.

*Qualitative techniques* emphasize the causal element of human error and attempt to develop an understanding of the causal events and factors contributing to human error. Clearly, when using these approaches, the circumstances under which human error is observed and the resultant causal explanation for error occurrence have important implications for system design. If the causal explanation stops at the level of the operator, remedial measures might encompass better training or supervision; for example, a common solution for back injuries is to provide operators with training on "how to lift," overlooking opportunities for other, perhaps more effective,

changes in the system, such as modifications in management, work procedures, work planning, or resources.

As noted, analyses of many major accident events indicate that the root cause of these events can be traced to latent failures and organizational errors. In other words, human errors and their resulting consequences usually result from inadequacies in system design. An example is the crash at Dryden Airport in Ontario. The analysis of this accident revealed that the accident was linked to organizational failings such as poor training, lack of management commitment to safety, and inadequate maintenance and regulatory procedures (Reason, 1995). These findings indicate that when analyzing human error it is important to look at the entire system and the organizational context in which the error occurred.

Several researchers have developed taxonomies for classifying human errors into categories. These taxonomies are useful, as they help identify the source of human error and strategies that might be effective in coping with error. Different taxonomies emphasize different aspects of human performance. For example, some taxonomies emphasize human actions, whereas others emphasize information-processing aspects of behavior. Rasmussen and colleagues (Rasmussen, 1982; Rasmussen et al., 1994) developed a taxonomy of human errors from analyses of human involvement in failures in complex processes. This schema is based on a decomposition of mental processes and states involved in erroneous behavior. For the analysis, the events of the causal chain are followed backward from the observed accidental event through mechanisms involved at each stage. The taxonomy is based on an analysis of the work system and considers the context in which the error occurred (e.g., workload, work procedures, shift requirements). This taxonomy has been applied to the analysis of work systems and has proven to be useful for understanding the nature of human involvement in accident events.

Reason (1990, 1995) has developed a similar scheme for examining the etiology of human error for the design and analysis of complex work systems. The model is based on a systems approach and describes a pathway for identifying the organizational causes of human error. The model includes two interrelated causal sequences for error events: (1) an active failure pathway where the failure originates in top management decisions and proceeds through error-producing conditions in various workplaces to unsafe acts committed by workers at the immediate human–machine interface and (2) a latent failure pathway that runs directly from the organizational processes to deficiencies in the system's defenses. The model can be used to assess organizational safety health in order to develop proactive measures for remediating system difficulties and as an investigation technique for identifying the root causes of system breakdowns.

The implications of error analysis for system design depend on the nature of the error as well as the nature of the system. Errors and accidents have multiple causes, and different types of errors require different remedial measures. For example, if an error involves deviations from normal procedures in a well-structured technical system, it is possible to derive a corrective action for a particular aspect of an interface or task element. This might involve redesign of equipment or of some work procedure to minimize the potential for the error occurrence. However, in complex dynamic work systems it is often difficult or undesirable to eliminate the incidence of human error completely. In these types of systems, there are many possible strategies for achieving system goals; thus, it is not possible to specify precise procedures for performing tasks. Instead, operators must be creative and flexible and engage in exploratory behavior in order to respond to the changing demands of the system. Further, designers are not able to anticipate the entire set of possible events; thus, it is difficult to build in mechanisms to cope with these events. This makes inevitable a certain amount of error.

Several researchers (Rouse and Morris, 1987; Rasmussen et al., 1994) advocate the design of *error-tolerant systems*, where the system tolerates the occurrence of errors but avoids the consequences; there is a means to control the impact of error on system performance. Design of these interfaces requires an understanding of the work domain and the acceptable boundaries of behavior and modeling the cognitive activity of operators dealing with incidents in a dynamic environment. A simple example of this type of design would be a computer system which holds a record of a file so that it is not lost permanently if an operator mistakenly deletes the files. A more sophisticated example would be an intelligent monitoring system which is capable of varying levels of intervention.

Rouse and Morris (1987) describe an error-tolerant system that provides three levels of support. Two levels involve feedback (current state and future state) and rely on an operator's ability to perceive his or her own errors and act appropriately. The third level involves *intelligent monitoring*, that is, online identification and error control. They propose an architecture for the development of this type of system that is based on an operator-centered design philosophy and involves incremental support and automation. Rasmussen and Vincente (1989) have developed a framework for an interface that supports recovery from human errors. The framework, called *ecological interface design*, is based on an analysis of the work system. This approach is described in more detail in a later section.

## 3 SYSTEM DESIGN PROCESS

### 3.1 Approaches to System Design

System design is usually depicted as a highly structured and formalized process characterized by stages in which various activities occur. These activities vary as a function of system requirements, but they generally involve planning, designing, testing, and evaluating. More details regarding these activities are given in a subsequent section. Generally, system design is characterized as a top-down process that proceeds, in an interactive fashion, from broad molar functions to progressively more molecular tasks and subtasks. It is also a time-driven

process and is constrained by cost, resources, and organizational and environmental requirements. The overall goal of system design is to develop an entity that is capable of transforming inputs into outputs to accomplish specified goals and objectives.

In recent years, within the realm of system design, a great deal of attention has been given to the design philosophy and the resulting design architecture as it has become apparent that new design approaches are required to design modern complex systems. The design and analysis of such systems cannot be based on design models developed for systems characterized by a stable environment and stable task procedures. Instead, the design approach is concerned with supplying resources to people who operate in a dynamic work space, engage in collaborative relationships, use a variety of technologies, and often need to adapt their behavioral patterns to changing environmental conditions. In other words, a structural perspective whereby we describe the behavior of the system in terms of cause-and-effect patterns and arrange system elements in cause-and-effect chains is no longer adequate.

### 3.1.1  Models of System Design

The traditional view of the system design process is that it is a linear sequence of activities where the output of each stage serves as input to the next stage. The stages generally proceed from the conceptual level to physical design through implementation and evaluation. Human factors inputs are generally considered in the design and evaluation stages (Eason, 1991). The general characteristics of this approach are that it represents a reductionist approach where various components are designed in isolation and made to fit together; it is dominated by technological considerations where humans are considered secondary components. The focus is on fitting the person to the system, and different components of the system are developed on the basis of narrow functional perspectives (Kidd, 1992; Liker and Majchrzak, 1994). Generally, this approach has dominated the design of overall work systems, such as manufacturing systems, as well as the design of the human−machine interface. For example, the emphasis in the design of human−computer systems has largely been on the individual level of the human−computer interaction without much attention to task and environmental factors that may affect performance. To date too much attention has been on the microergonomic aspects of design without sufficient attention to social and organizational issues (Hendrick and Kleiner, 2001; Kleiner, 2008). The implementation of computers of automation into most work systems, coupled with the enhanced capabilities of technological systems, has created a need for new approaches to system design. As discussed, there are many instances where technology has failed to achieve its potential, resulting in failures in system performance with adverse and often disastrous consequences. These events have demonstrated that the traditional design approach is no longer adequate. A brief overview of these approaches and some other design approaches will be presented to provide some examples of alternative approaches to system design and demonstrate

methodologies and concepts that can be applied to the design of current human−machine systems. This will be followed by a discussion of the specification application of human factors engineering to design activities.

### 3.1.2  Alternative Approaches to System Design

**Sociotechnical Systems Approach** The sociotechnical systems approach, which evolved from work conducted at the Tavistock Institute, represents a complete design process for the analysis, design, and implementation of systems. The approach is based on open systems theory and emphasizes the fit between social and technical systems and the environment. This approach includes methods for analyzing the environment, the social system, and the technical system. The overall design objective is the joint optimization of the social and technical systems (Pasmore, 1988). Some drawbacks associated with sociotechnical design are that the design principles are often vague and there is often an overemphasis on the social system without sufficient emphasis on the design of the technical system.

Clegg (2000) recently presented a set of sociotechnical principles to guide system design. The principles are intended for the design of new systems that involve new technologies and modern management practices. The principles are organized into three interrelated categories: metaprinciples, content principles, and process principles. *Metaprinciples* are intended to demonstrate a world view of design, *content principles* focus on more specific aspects of the content of the new designs, and *process principles* are concerned with the design process. The principles also provide a potential for evaluative purposes. They are based on a macroergonomic perspective.

The central focus of macroergonomics is on interfacing organizational design with the technology employed in the system to optimize human−system functioning. Macroergonomics considers the human−organization−environment−machine interface, as opposed to microergonomics, which focuses on the human−machine interface. Macroergonomics is considered to be the driving force for microergonomics. Macroergonomics concepts have been applied successfully to manufacturing, service, and health care organizations as well as to the design of computer-based information systems (Hendrick and Kleiner, 2001; Kleiner, 2008).

**Participatory Ergonomics** Participatory ergonomics is the application of ergonomic principles and concepts to the design process by people who are part of the work group and users of the system. These people are typically assisted by ergonomic experts who serve as trainers and resource centers. The overall goal of participatory design is to capitalize on the knowledge of users and to incorporate their needs and concerns into the design process. Methods, such as focus groups, quality circles, and inventories, have been developed to maximize the value of user participation. Participatory ergonomics has been applied to the design of jobs and workplaces and to the design of products. For example, the quality circle approach was adopted by a refrigerator

manufacturing company that needed a systemwide method for assessing the issues of aging workers. The assembly line for medium-sized refrigerators was chosen as an area for job redesign. The project redesign team involved workers from the line as well as other staff members. The team was instructed with respect to the principles of ergonomics and design for older workers. The solution, proposed by the team, for improving the assembly line resulted in improved performance and also allowed older workers to continue to perform the task (Imada et al., 1986). The design of current personal computer systems also typically involves user participation. Representative users participate in usability studies. In general, participatory ergonomics does not represent a design process because it does not consider broader system design issues but rather focuses on individual components. However, the benefits of user participation should not be overlooked and should be a fundamental aspect of system design.

**User-Centered Design** The user-centered design approach represents an approach where human factors are of central concern within the design process. It is based on an open-systems model and considers the human and technical subsystems within the context of the broader environment. User-centered approaches propose general specifications for system design, such as that the system must maximize user involvement at the task level and the system should be designed to support cooperative work and allow users to maintain control over operations (Liker and Majchrzak, 1994). Essentially, this design approach incorporates user requirements, user goals, and user tasks as early as possible into the design of a system, when the design is still relatively flexible and changes can be made at least cost.

Eason (1989) has developed a detailed process for user-centered design in which a system is developed in an evolutionary incremental fashion and development of the social system complements development of the technical system. Eason maintains that the technical system should follow the design of jobs and the design of the technical system must involve user participation and consider criteria for four factors: functionality, usability, user acceptance, and organizational acceptance. Once these criteria are identified, alternative design solutions are developed and evaluated. There are different philosophies with respect to the nature of user involvement. Eason emphasizes user involvement throughout the design process, whereas with other models the users are considered sources of data and the emphasis is on translating knowledge about users into practice. Advocates of the user participation approach argue that users should participate in the choice between alternatives because they have to live with the results. Advocates of the knowledge approach express concern about the ability of users to make informed judgments. Eason (1991) maintains that designers and users can form a partnership where both can play an effective role. A number of methods are used in user-centered design, including checklists and guidelines, observations, interviews, focus groups, and task analysis.

**Computer-Supported Design** The design of complex technical systems involves the interpretation and integration of vast amounts of technical information. Further, design activities are typically constrained by time and resources and involve the contributions of many persons with varying backgrounds and levels of technical expertise. In this regard, computer-based design support tools have emerged to aid designers and support the design of effective systems. These systems are capable of offering a variety of supports, including information retrieval, information management, and information transformation. The type of support warranted depends on the needs and expertise of the designer (Rouse, 1987). A common example of this type of support is a computer-aided design/computer-aided manufacturing (CAD/CAM) system.

There are many issues surrounding the development and deployment of computer-based design support tools, including specification of the appropriate level of support, determination of optimal ways to characterize the design problem and the type of knowledge most useful to designers, and the identification of factors that influence the acceptance of these tools. A discussion of these issues is beyond the scope of this chapter. Refer to Rouse and Boff (1987a,b) for an excellent review of this topic.

**Ecological Interface Design** Ecological interface design (EID) is a theoretical framework for designing human–computer interfaces for complex sociotechnical systems (Rasmussen et al., 1994; Vincente, 2002). The primary aim of EID is to support knowledge workers who are required to engage in adaptive problem solving in order to respond to novelty and change in system demands. EID is based on a cognitive systems engineering approach and involves an analysis of the work domain and the cognitive characteristics and behavior tendencies of the individual. Analysis of the work domain is based on an abstraction hierarchy (means–end analysis) (Rasmussen, 1986) and relates to the specification of information content. The skills–rules–knowledge taxonomy (Rasmussen, 1983) is used to derive inferences for how information should be presented. The aims of EID are to support the entire range of activities that confront operators, including familiar, unfamiliar, and unanticipated events, without contributing to the difficulty of the task.

EID has been applied to a variety of domains, such as process control, aviation, software engineering, and medicine, and has been shown to improve performance over that achieved by more traditional design approaches. However, there are still some challenges confronting the widespread use of EID in the industry. These challenges include the time and effort required to analyze the work domain, choice of the interface form, and the difficulty of integrating EID with the design of other components of a system (Vincente, 2002).

## 3.2 Incorporating Human Factors in System Design

One problem faced by human factors engineers in system design is convincing project managers, engineers, and designers of the value of incorporating human factors knowledge and expertise into the system design process. In many instances, human factors issues are

ignored or human factors activities are restricted to the evaluation stage. This is referred to as the "too little, too late" phenomenon (Lim et al., 1992). Restricting human factors inputs to the evaluation stage limits the utility and effectiveness of human factors contributions. Either the contributions are ignored because it would be too costly or time consuming to alter the design of the system ("too late") or minor alterations are made to the design to pay lip service to human issues ("too little"). In either case there is limited realization of human factors contributions. For human factors to be effective, human factors engineers need to be involved throughout the design process.

There are a variety of reasons why human factors engineers are not considered as equal partners in a design team. One reason is that other team members (e.g., designers, engineers) have misconceptions about the potential contributions of human factors and the importance of human issues. They perceive, for example, that humans are flexible and can adapt to system requirements or that accommodating human issues will compromise the technical system. Another reason is that sometimes human factors inputs are of limited value to designers (Meister, 1989; Chapanis, 1995). The inputs are either so specific that they apply to a particular design situation and not to the design process in question or vague and overly general. For example, a design guideline which specifies that "older people need larger characters on computer screens" is of little value. How does one define "larger characters"? Obviously, the type of input required depends on the nature of the design problem. Design of a kitchen to accommodate people in wheelchairs requires precise information, such as counter height dimensions or required turning space. In contrast, guidelines for designing intelligent interfaces need to be expressed at the cognitive task level, independent of a particular technology (Woods and Roth, 1988). Thus, one important task for human factors engineers is to ensure that design inputs are in a form that is usable and useful to designers. Williges and colleagues (1992) demonstrate how integrated empirical models can be used as quantitative design guidelines. Their approach involved integrating data from four sequential experiments and developing a model for the design of a telephone-based information system.

To ensure that human factors will be applied to system design systematically, we need to market the potential contributions of human factors to engineers, project managers, and designers. One approach is to use case studies, relevant to the design problem, that illustrate the benefits of human factors. Case studies of this nature can be found in technical journals (e.g., *Applied Ergonomics*, *Ergonomics in Design*) and technical reports. Another approach is to perform a cost–benefit analysis. Estimating the costs and benefits associated with human factors is difficult because it is difficult to isolate the contribution of human factors relative to other variables, baseline measures of performance are unavailable, or performance improvements are hard to quantify and link to system improvements. There are methods available to conduct this type of analysis.

## 3.3 Applications of Human Factors to System Design Process

System design can be conceptualized as a problem-solving process that involves the formulation of the problem, the generation of solutions to the problem, analysis of these alternatives, and selection of the most effective alternative (Rouse, 1985). There are various ways to classify the various stages in system design. Meister (1989), on the basis of a military framework, distinguishes among four phases:

1. *System Planning*. The need for the system is identified and system objectives are defined.
2. *Preliminary Design*. Alternative system concepts are identified, and prototypes are developed and tested.
3. *Detail Design*. Full-scale engineering is developed.
4. *Production and Testing*. The system is built and undergoes testing and evaluation.

To maximize system effectiveness, human factors engineers need to be involved in all phases of the process. In addition to human factors engineers, a representative sample of operators (users) should also be included.

The basic role of human factors in system design is the application of behavioral principles, data, and methods to the design process. Within this role, human factors get involved in a number of activities. These activities include specifying inputs for job, equipment and interface design, human performance criteria, operator selection and training, and inputs regarding testing and evaluation. The nature of these activities is discussed at a general level in the next section. Most of these issues are discussed in detail in subsequent chapters. The intent of this discussion is to highlight the nature of human factors involvement in the design process.

### 3.3.1 System Planning

During system planning, the need for the system is established and the goals and objectives and performance specifications of the system are identified. Performance specifications define what a system must do to meet its objectives and the constraints under which the system will operate. These specifications determine the system's performance requirements. Human factors should be a part of the system planning process. The major role of human factors engineers during this phase is to ensure that human issues are considered in the specification of design requirements and the statement of system goals and objectives. This includes understanding personnel requirements, general performance requirements, the intended users of the system, user needs, and the relationship of system objectives relative to these needs.

### 3.3.2 System Design

System design encompasses both preliminary design and detailed design. During this phase of the process, alternative design concepts are identified and tested

and a detailed model of the system is developed. To ensure adequate consideration of human issues during this phase, the involvement of human factors engineers is critical. The major human factors activities include (1) function allocation, (2) task analysis, (3) job design, (4) interface design, (5) design of support materials, and (6) workplace design. The primary role of the human factors engineer is to ensure joint optimization of the human and technical systems.

**Function Allocation** Function allocation is a critical step in work system design. This is especially true in today's work systems, as machines are becoming more and more capable of performing tasks once restricted to humans. A number of studies have shown (e.g., Morris et al., 1985; Sharit et al., 1987) that proper allocation of functions between humans and machines results in improvements in overall system performance.

Function allocation involves formulating a functional description of a system and subsequent allocation of functions among system components. A frequent approach to function allocation is to base allocation decisions on machine capabilities and to automate wherever possible. Although this approach may appear expedient, there are several drawbacks. In most systems not all tasks can be automated, and thus some tasks must be performed by humans. These tasks are typically "leftover" tasks. Allocating them to humans generally leads to problems of underload, inattention, and job dissatisfaction. A related problem is that automated systems fail and humans have to take over. This can be problematic if the humans are out of the loop or if their skills have become rusty due to disuse. In essence the machine-based allocation strategy is inadequate. As discussed previously, there are numerous examples of technocentered design. It has become clear that a better approach is complementary where functions are allocated so that human operators are complemented by technical systems. This approach involves identifying how to couple humans and machines to maximize system performance. In this regard, there is much research aimed at developing methods to guide function allocation decisions. These methods include lists (e.g., Fitts's list), computer simulation packages, and general guidelines for function allocation (e.g., Price, 1985).

The traditional static approach (humans are better at . . . ) to function allocation has been challenged and dynamic allocation approaches have been developed. With dynamic allocation, responsibility for a task at any particular instance is allocated to the component most capable at that point in time. Hou et al. (1993) developed a framework to allocate functions between humans and computers for inspection tasks. Their framework represents a dynamic allocation framework and provides *for* a quantitative evaluation of the allocation strategy chosen. Morris et al. (1985) investigated the use of a dynamic adaptive allocation approach within an aerial search environment. They found that the adaptive approach resulted in an overall improvement in system performance. Similar to this approach is the adaptive automation approach. This approach involves invoking some form of automation as a function of the person's momentary needs (e.g., transient increase in workload or fatigue). The intent of this approach is to optimize the control of human–machine systems in varying environments. To date, few studies have examined the benefit of this approach. However, several important issues have emerged in the design of these types of systems, such as what aspect of the task should be adapted and who should make the decision to implement or remove automation.

**Task Analysis** Task analysis is also a central activity in system design. Task analysis helps ensure that human performance requirements match operators' (users') needs and capabilities and that the system can be operated in a safe and efficient manner. The output of a task analysis is also essential to the design of the interface, workplaces, support materials, training programs, and test and evaluation procedures.

A task analysis is generally performed after function allocation decisions are made; however, sometimes the results of the task analysis alter function allocation decisions. A task analysis usually consists of two phases: a task description and a task analysis. A *task description* involves a detailed decomposition of functions into tasks which are further decomposed into subtasks or steps. A *task analysis* specifies the physical and cognitive demands associated with each of these subtasks.

A number of methods are available for conducting task analysis. Commonly used methods include flow process charts, critical task analysis, and hierarchical task analysis. Techniques for collecting task data include documentation review, surveys and questionnaires, interviews, observation, and verbal protocols.

As the demands of tasks have changed and become more cognitive in nature, methods have been developed for performing *cognitive task analysis*, which attempts to describe the knowledge and cognitive processes involved in human performance in particular task domains. The results of a cognitive task analysis are important to the design of interfaces for intelligent machines. A common approach used to carry out a cognitive task analysis is a goal–means decomposition. This approach involves an analysis of the work domain to identify the cognitive demands inherent in a particular situation and building a model that relates these cognitive demands to situational demands (Roth et al., 1992). Another approach involves the use of cognitive simulation.

**Job Design** The type of work that a person performs is largely a function of job design. Jobs involve more than tasks and include work content, distribution of work, and work roles. Essentially, a job represents a person's prescribed role within an organization. *Job design* involves determining how tasks will be grouped together, how work will be coordinated among individuals, and how people will be rewarded for their performance (Davis and Wacker, 1987). To design jobs effectively, consideration must be given to workload requirements and to the psychosocial aspects of work (people's needs and expectations). This consideration is especially important in automated work systems, where the skills and potential contributions of humans are often overlooked.

In terms of workload, the primary concern is that work requirements are commensurate with human abilities and individuals are not placed in situations of underload or overload, as both situations can lead to performance decrements, job dissatisfaction, and stress. Both the physical and mental demands of a task need to be considered. There are well-established methods for evaluating the physical demands of tasks and for determination of work and rest schedules. The concept of mental workload is more esoteric. This issue has received a great deal of attention in the literature, and a variety of methods have been developed to evaluate the mental demands associated with a task.

Consideration of operator characteristics is also an essential element of job design, as the workforce is becoming more heterogeneous. For example, older workers may need different work/rest schedules than younger workers or may be unsuited to certain types of tasks. Those who are physically challenged may also require different job specifications.

In terms of psychosocial considerations, a number of studies have identified critical job dimensions. Generally, these dimensions include task variety, task identity, feedback, autonomy, task significance, opportunity to use skills, and challenge. As far as possible, these characteristics should be designed into jobs. Davis and Wacker (1987) have developed a quality-of-working-life-criteria checklist which lists job dimensions important to the satisfaction of individual needs. These dimensions relate to the physical environment, institutional rights and privileges, job content, internal social relations, external social relations, and career path.

A number of approaches to job design have been identified. These include work simplification, job enrichment, job enlargement, job rotation, and teamwork design. The method chosen should depend on the actual design problem, work conditions, and individuals. However, it is generally accepted that the work simplification approach does not lead to optimal job design.

**Interface Design** Interface design involves specification of the nature of the human–machine interaction, that is, the means by which the human is connected to the machine. During this stage of design, the human factors specialist typically works closely with engineers and designers. The role of human factors is to provide the design team with information regarding the human performance implications of design alternatives. This generally involves three major activities: (1) gathering and interpreting human performance data, (2) conducting attribute evaluations of suggested designs, and (3) human performance testing (Sanders and McCormick, 1993). Human performance testing typically involves building mock-ups and prototypes and testing them with a sample of users. This type of testing can be expensive and time consuming. Recently, the development of rapid prototyping tools has made it possible to speed up and compress this process. These tools have been used primarily in the testing of computer interfaces; however, they can be applied to a variety of situations.

Interface design encompasses the design of both the physical and cognitive components of the interface and includes the design and layout of controls and displays, information content, and information representation. Physical components include factors such as type of control or input device, size and shape of controls, control location, and visual and auditory specifications (e.g., character size, character contrast, labeling, signal rate, signal frequency).

Cognitive components refer to the information-processing aspects of the interface (e.g., information content, information layout). As machines have become more intelligent, much of the focus of interface design has been on the cognitive aspects of the interface: Issues of concern include determination of the optimal level of machine support, identification of the type of information that users need, determination of how this information should be presented, and identification of methodologies to analyze work domains and cognitive activities. The central concern is developing interfaces that best support human task performance. In this regard, a number of approaches have evolved for interface design. Ecological interface design (Rasmussen and Vincente, 1989) is an example of a recent design method.

There are a variety of sources of data on the characteristics of human performance that can serve as inputs to the design process. These include handbooks, textbooks, standards [e.g., American National Standards Institute (ANSI)], and technical journals. There are also a variety of models of human performance, including cognitive models (e.g., GOMS; Card et al., 1983), control theory models, and engineering models. These models can be useful in terms of predicting the effects of design parameters on human performance outcomes. As discussed previously, it is the responsibility of the human factors engineer to make sure that information regarding human performance is in a form that is useful to designers. It is also important when using these data to consider the nature of the task, the task environment, and the user population.

**Design of Support Materials** This phase of the design process includes identifying and developing materials that facilitate the user's interaction with the system. These materials include job aids, instructional materials, and training devices and programs. All too often this phase of the design process is neglected or given little attention. A common example is the cumbersome manuals that accompany software packages or VCRs.

Support materials should not be used as a substitute for good design, however; the design of effective support materials is an important part of the system design process. Users typically need training and support to interact successfully with new technologies and complex systems. To maximize their effectiveness, human factors principles need to be applied to the design of instructional materials, job aids, and training programs. Guidelines are available for the design of instructional materials and job aids. Bailey (1982) provides a thorough discussion of these issues. A great deal has also been written on the design of training programs.

**Design of Work Environment** The design of the work environment is an important aspect of work system design. Systems exist within a context, and

the characteristics of this context affect overall system performance. The primary concern of workplace design is to ensure that the work environment supports the operator and activity performance and allows the worker to perform tasks in an efficient, comfortable, and safe manner. Important issues include workplace and equipment layout, furnishings, reach dimensions, clearance dimensions, visual dimensions, and the design of the ambient environment. There are numerous sources of information related to workplace design and evaluation that can be used to guide this process. These issues are also covered in detail in other chapters of this handbook.

### 3.4 Test and Evaluation

Test and evaluation are critical aspects of system design and usually take place throughout the system design process. Test and evaluation provide a means for continuous improvement during system development. Human factors inputs are essential to the testing and evaluation of systems. The primary role of human factors is to assess the impact of system design features on human performance outputs, including objective outputs such as speed and accuracy of performance and workload, and subjective outputs such as comfort and user satisfaction. Human factors specialists are also interested in ascertaining the impact of human performance on overall system performance. Issues related to the evaluation and assessment of system effectiveness are covered in detail in Chapters 41.

Because the evaluation of systems and system components involves measurement of human performance in operational terms (relative to the system or subsystem in question), human factors engineers face a number of challenges when evaluating systems. Generally, the standards of generalizability are higher for human factors research, as the research results must be extended to real-world systems (Kantowitz, 1992). At the same time, it is often difficult to achieve an appropriate level of control. Unfortunately, in many instances the utility of a test and the evaluation results are limited because of deficiencies in the test and evaluation procedures (Bitner, 1992).

In this regard, there are three key issues that need to be addressed when developing methods for evaluating system effectiveness: (1) subject representativeness, (2) variable representativeness, and (3) setting representativeness (Kantowitz, 1992). *Subject representativeness* refers to the extent to which subjects tested in the research study represent the population to which the research results apply. In most cases, the sample involved in system evaluation should represent the population of interest on relevant characteristics. *Variable representativeness* refers to the extent that the study variables are representative of the research question. It is important to select variables that capture the essential issues being assessed in the research study. *Setting representativeness* is the degree of congruence between the test situation in which the research is performed and the target situation in which the research must be applied. The important issue is the comparability of the

psychological processes captured in these situations, not necessarily physical fidelity.

A variety of techniques are available for conducting human factors research, including experimental methods, observational methods, surveys and questionnaires, and audits. There is no single preferred method; each has its associated strengths and weaknesses. The method one chooses depends on the nature of the research question. It is generally desirable to use several methods in conjunction.

## 4 CONCLUSIONS

System design and development represent an important area of application for human factors engineers. System performance will be improved by consideration of behavioral issues. Although much has been written on system design, our knowledge of this topic is far from complete. The changing nature and complexity of systems coupled with the increased diversity of end users present new challenges for human factors specialists and afford many research opportunities. The goals of this chapter were to summarize some of the current issues in system design and to illustrate the important role of human factors engineers within the system design process. Further, the chapter provides a framework for many of the topics addressed in this handbook.

*Whether performing a simple skill like standing and looking, or something more exotic . . . , your perceptual experiences are fundamentally multisensory.*

L. D. Rosenblum (2010)

## 1 INTRODUCTION

Human–machine interaction, as all other interactions of persons with their environment, involves a continuous exchange of information between the operator(s) and the machine. The operator provides input to the machine, which acts on this input and displays information back to the operator regarding its status and the consequences of the input. The operator must process this information, decide what, if any, controlling actions are needed, and then provide new input to the machine. One important facet of this exchange of information between the machine and the operator is the displaying of information from the machine as input to the operator. All such information must enter through the operator's senses and be organized and recognized accurately to ensure correct communication of the displayed information. Thus, an understanding of how people sense and perceive is essential for display design. An effective display is consistent with the characteristics and limitations of the human sensory and perceptual systems. These systems are also involved intimately in both the control of human interactions with the environment and the actions taken to operate machines. However, because the selection and control of action are the topics of Chapter 4, in this chapter we focus primarily on the nature of sensation and perception. Similarly, because other chapters focus on the applied topics of motion and vibration (Chapter 22), noise (Chapter 23), illumination (Chapter 24), and displays (Chapter 42), we concentrate primarily on the nature of sensory and perceptual processes and the general implications for human factors and ergonomics.

Many classifications of sensory systems exist, but most commonly, distinctions are made between five sensory modalities: vision, audition, olfaction, gustation, and somasthesis. The vestibular system, which provides the sense of balance, is also of importance in many areas of human factors and ergonomics. Although the peripheral aspects of these sensory systems are distinct, the senses interact extensively in creating our perceptual experiences, as implied by Rosenblum's (2010) quote with which the chapter begins.

All sensory systems extract information about four characteristics of stimulation: (1) the sensory modality and submodalities (e.g., touch as opposed to pain), (2) the stimulus intensity, (3) the duration of the stimulation, and (4) its location (Gardner and Martin, 2000). Each system has receptors that are sensitive to some aspect of the physical environment. These receptors are responsible for sensory transduction, or the conversion of physical stimulus energy into electrochemical energy in the nervous system. Their properties are a major factor determining the sensitivity to stimulation. After sensory transduction, the sensory information for each sense is encoded in the activity of neurons and travels to
**Figure 1** Primary sensory receiving areas (visual, auditory, and somatosensory) of the cerebral cortex and other important landmarks and areas. (From Schiffman, 1996.)

the brain via specialized, structured pathways consisting of highly interconnected networks of neurons. For most modalities, two or more pathways operate in parallel to analyze and convey different types of information from the sensory signal. The pathways project to primary receiving areas in the cerebral cortex (see Figure 1), in most cases after passing through relay areas in the thalamus. From the primary receiving area, the pathways then project to many other areas within the brain.

Each neuron in the sensory pathways is composed of a cell body, dendrites at the input side, and an axon with branches at the output side. Most neurons fire in an all-or-none manner, sending spike, or action, potentials down the axon away from the cell body. The rate at which a neuron fires varies as a function of the input that the neuron is receiving from other neurons (or directly from sensory receptors) at its dendrites. Most neurons exhibit a baseline firing rate in the absence of stimulation, usually on the order of 5–10 spikes/s, and information is signaled by deviations above or below this baseline rate. The speed of transmission of a spike along the fiber varies across different types of neurons, ranging from 20 to 100 m/s. Immediately after an action potential occurs, the neuron is in a refractory state in which another action potential cannot be generated. This sets an upper limit on the firing rate of about 1000 spikes/s.

Transmission between neurons occurs at small gaps, called *synapses*, between the axonal endings of one neuron and the dendrites of another. Communication at the synapse takes place by means of transmitter substances that have an excitatory effect of increasing the firing rate of the neuron or an inhibitory effect of decreasing the firing rate. Because as many as several hundred neurons may have synapses with the dendrites of a specific neuron, whether the firing rate will increase or decrease is a function of the sum of the excitatory and inhibitory inputs that the neuron is receiving. Which specific neurons provide excitatory and inhibitory inputs

will determine the patterns of stimulation to which the neuron will be sensitive (i.e., to which the firing rate will increase or decrease from baseline). The patterns may be rather general (e.g., an increase in illumination) or quite specific (e.g., a pair of lines at a particular angle moving in a particular direction). In general, increases in stimulus intensity result in increased firing rates for individual neurons and in a larger population of neurons that respond to the stimulus. Thus, intensity is coded by firing rate (as well as possibly relative timing of spike potentials) and population codes.

The study of sensation and perception involves not only the anatomy and physiology of the sensory systems but also behavioral measures of perception. Psychophysical data obtained from tasks in which observers are asked to detect, discriminate, rate, or recognize stimuli provide information about how the properties of the sensory systems relate to what is perceived. Behavioral measures also provide considerable information about the functions of the higher level brain processes involved in perception. The sensory information must be interpreted and organized by these higher level processes, which include mental representations, decision making, and inference. Thus, perceptual experiments provide evidence about how the input from the various senses is organized into a coherent percept.

## 2 METHODS FOR INVESTIGATING SENSATION AND PERCEPTION

Many methods have been, and can be, used to obtain data relevant to understanding sensation and perception (see, e.g., Scharff, 2003). The most basic distinction is between methods that involve anatomy and physiology as opposed to methods that involve behavioral responses. Because the former are not of much direct use in human factors and ergonomics, we do not cover them in as much detail as we do the latter.

## 2.1 Anatomical and Physiological Methods

A variety of specific techniques exist for analyzing and mapping out the pathways associated with sensation and perception. These include injecting tracer substances into the neurons, classifying neurons in terms of the size of their cell bodies and characteristics of their dendritic trees, and lesioning areas of the brain (see Wandell, 1995). Such techniques have provided a relatively detailed understanding of the sensory pathways.

One particular technique that has produced a wealth of information about the functional properties of specific neurons in the sensory pathways and their associated regions in the brain is *single-cell recording*. Such recording is typically performed on a monkey, cat, or other nonhuman species; an electrode is inserted that is sufficiently small to record only the activity of a single neuron. The responsivity of this neuron to various features of stimulation can be examined to gain some understanding of the neuron's role in the sensory system. By systematic examination of the responsivities of neurons in a given region, it has been possible to determine much about the way that sensory input is coded. In our discussion of sensory systems, we will have the opportunity to refer to the results of single-cell recordings.

Neuropsychological and psychophysiological investigations of humans have been used increasingly in recent years to evaluate issues pertaining to information processing. Neuropsychological studies typically examine patients who have some specific neurological disorder associated with lesions in particular parts of the brain. Several striking phenomena have been observed that enhance our understanding of higher level vision (Farah, 2000). One example is visual neglect, in which a person with a lesion in the right cerebral hemisphere, often in a region called the *right posterior parietal lobe*, fails to detect or respond to stimuli in the left visual field (Mort et al., 2003). This is in contrast to people with damage to regions of the temporal lobe, who have difficulty recognizing stimuli (Milner and Goodale, 1995). These and other results have provided evidence that a dorsal system, also called the *parietal pathway*, determines where something is (and how to act on it), whereas a ventral system, also called the *temporal pathway*, determines what that something is (Merigan and Maunsell, 1993).

A widely used psychophysiological method involves the measurement of *event-related potentials* (ERPs) (Handy, 2005). To record ERPs, electrodes attached to a person's scalp measure voltage variations in the electroencephalogram (EEG), which reflects the summed electrical activity of neuron populations as recorded at various sites on the scalp. An ERP is those changes that involve the brain's response to a particular event, usually onset of a stimulus. ERPs provide good temporal resolution, but the spatial resolution is not very high. Those ERP components occurring within 100 ms after onset of a stimulus are sensory components that reflect transmission of sensory information to, and its arrival at, the sensory cortex. The latencies for these components differ across sensory modalities. Later components reflect other aspects of information processing. For example, a negative component called

*mismatch negativity* is evident in the ERP about 200 ms after presentation of a stimulus event other than the one that is most likely. It is present regardless of whether the stimulus is in an attended stream of stimuli or an unattended stream, suggesting that it reflects an automatic detection of physical deviance. The latency of a positive component called the *P*300 is thought to reflect stimulus evaluation time, that is, the time to update the perceiver's current model of the physical environment.

During the past 15 years, use of functional neuroimaging techniques such as *functional magnetic resonance imaging* (fMRI) and *positron emission tomography* (PET), which provide insight into the spatial organization of brain functions, has become widespread (Kanwisher and Duncan, 2004; Hall, 2010). Both fMRI and PET provide images of the neural activity in different areas of the brain by measuring the volume of blood flow, which increases as the activity in an area increases. They have good spatial resolution, but the temporal resolution is not as good as that of ERPs. By comparing measurements taken during a control period to those taken while certain stimuli are present or tasks performed, the brain-imaging techniques can be used to identify which areas of the brain are involved in the processing of different types of stimuli and tasks.

Electrophysiological and functional imaging methods, as well as other psychophysiological techniques, provide tools that can be used to address many issues of concern in human factors. Among other things, these methods can be used to determine whether a particular experimental phenomenon has its locus in processes associated with sensation and perception or with those involving subsequent response selection and execution. Because of this diagnosticity, it has been suggested that psychophysiological measures may be applied to provide precise measurement of dynamic changes in mental workload (e.g., Wilson, 2002) and to other problems in human factors (Kramer and Weber, 2000). The term *neuroergonomics* is used to refer to a neuroscience approach to ergonomics (e.g., Lees et al., 2010).

## 2.2 Psychophysical Methods

The more direct concern in human factors and ergonomics is with behavioral measures, because our interest is primarily with what people can and cannot perceive and with evaluating specific perceptual issues in applied settings. Because many of the methods used for obtaining behavioral measures can be applied to evaluating aspects of displays and other human factors concerns, we cover them in some detail. The reader is referred to textbooks on psychophysical methods by Gescheider (1997) and Kingdom and Prins (2010) and to chapters by Schiffman (2003) and Rose (2006) for more thorough coverage.

### 2.2.1 Psychophysical Measures of Sensitivity

**Classical Threshold Methods** The goal of one class of psychophysical methods is to obtain some estimate of sensitivity to detecting either the presence of some stimulation or differences between stimuli. The classical methods were based on the concept of a threshold, with an *absolute threshold* representing the minimum amount

**Table 1  Determination of Sensory Threshold by Method of Limits Using Alternating Ascending (A) and Descending (D) Series**

| Stimulus Intensity (Arbitrary Units) | A | D | A | D | A | D | A | D | A | D |
|---|---|---|---|---|---|---|---|---|---|---|
| 15 |  |  |  |  |  | Y |  |  |  |  |

| Transition points[a] | 9.5 | 8.5 | 8.5 | 9.5 | 10.5 | 9.5 | 9.5 | 7.5 | 8.5 | 9.5 |

[a]Mean threshold value = 9.1.

of stimulation necessary for an observer to tell that a stimulus was presented on a trial, and a *difference threshold* representing the minimal amount of difference in stimulation along some dimension required to tell that a comparison stimulus differs from a standard stimulus. Fechner (1860) developed several techniques for finding absolute thresholds, with the methods of limits and constant stimuli being among the most widely used.

To find a threshold using the *method of limits*, equally spaced stimulus values along the dimension of interest (e.g., magnitude of stimulation) that bracket the threshold are selected (see Table 1). In alternating series, the stimuli are presented in ascending or descending order, beginning each time from a different, randomly chosen starting value below or above the threshold. For the ascending order, the first response typically would be, "No, I do not detect the stimulus." The procedure is repeated, incrementing the stimulus value each time, until the observer's response changes to "yes," and the average of that stimulus value and the last one to which a "no" response was given is taken as the threshold for that series. A descending series is conducted in the same manner, but from a stimulus above threshold, until the response changes from yes to no. The thresholds for the individual series are then averaged to produce the final threshold estimate. A particularly efficient variation of the method of limits is the *staircase* method (Cornsweet, 1962). For this method, rather than having distinct ascending and descending series started from randomly selected values below and above threshold, only a single continuous series is conducted in which the direction of the stimulus sequence—ascending or descending—is reversed when the observer's response changes. The threshold is then taken to be the average of the stimulus

values at which these transitions occur. The staircase method has the virtue of bracketing the threshold closely, thus minimizing the number of stimulus presentations that is needed to obtain a certain number of response transitions on which to base the threshold estimate.

The *method of constant stimuli* differs from the method of limits primarily in that the different stimulus values are presented randomly, with each stimulus value presented many different times. The basic data in this case are the percentage of yes responses for each stimulus value. These typically plot as an S-shaped psychophysical function (see Figure 2). The threshold is taken to be the estimated stimulus value for which the percentage of yes responses would have been 50%.

Both the methods of limits and constant stimuli can be extended to difference thresholds in a straightforward manner (see Gescheider, 1997). The most common extension is to use stimulus values for the comparison stimulus that range from being distinctly less than that of the standard stimulus to being distinctly greater. For the method of limits, ascending and descending series are conducted in which the observer responds "less," then "equal," and then "greater" as the magnitude of the comparison increases, or vice versa as it decreases, The average stimulus value for which the responses shift from less to equal is the lower threshold, and from equal to greater is the upper threshold, The difference between these two values is called the *interval of uncertainty*, and the difference threshold is found by dividing the interval of uncertainty by 2. The midpoint of this interval is the point of subjective equality, and the difference between this point and the true value of the standard stimulus reflects the constant error, or the influence of any factors that cause the observer to overestimate or underestimate
**Figure 2** Typical S-shaped psychophysical function obtained with the method of constant stimuli. The absolute threshold is the stimulus intensity estimated to be detected 50% of the time. (From Schiffman, 1996.)

systematically the value of the comparison in relation to that of the standard.

When the method of constant stimuli is used to obtain difference thresholds, the order in which the standard and comparison are presented is varied, and the observer judges which stimulus is greater than the other. The basic data then are the percentages of "greater" responses for each value of the comparison stimulus. The stimulus value corresponding to the 50th percentile is taken as the point of subjective equality. The difference between that stimulus value and the one corresponding to the 25th percentile is taken as the lower difference threshold, and the difference between the subjectively equal value and the stimulus value corresponding to the 75th percentile is the upper threshold: The two values are averaged to get a single estimate of the difference threshold.

Although threshold methods are often used to investigate basic sensory processes, variants can be used to investigate applied problems as well. Shang and Bishop (2000) argued that the concept of visual threshold is of value for measuring and monitoring landscape attributes. They measured three types of different thresholds—detection, recognition, and visual impact (changes in visual quality as a consequence of landscape modification)—for two types of objects, a transmission tower and an oil refinery tank, as a function of size, contrast, and landscape type. Shang and Bishop were able to obtain thresholds of high reliability and concluded that a visual variable that combined the effects of contrast and size, which they called *contrast weighted visual size*, was the best predictor of all three thresholds.

***Signal Detection Methods*** Although many variants of the classical methods are still used, they are not

as popular as they once were. The primary reason is that the threshold measures confound perceptual sensitivity, which they are intended to measure, with response criterion or bias (e.g., willingness to say yes), which they are not intended to measure. The threshold estimates can also be influenced by numerous other extraneous factors, although the impact of most of these factors can be minimized with appropriate control procedures. Alternatives to the classical methods, signal detection methods, have come to be preferred in many situations because they contain the means for separating sensitivity and response bias. Authoritative references for signal detection methods and theory include Green and Swets (1966), Macmillan and Creelman (2005), and Wickens (2001). Macmillan (2002) provides a briefer introduction to its principles and assumptions.

The typical signal detection experiment differs from the typical threshold experiment in that only a single stimulus value is presented for a series of trials, and the observer must discriminate trials on which the stimulus was not presented (noise trials) from trials on which it was (signal-plus-noise, or signal, trials). Thus, the signal detection experiment is much like a true–false test in that it is objective; the accuracy of the observer's responses with respect to the state of the world can be determined. If the observer says yes most of the time on signal trials and no most of the time on noise trials, we know that the observer was able to discriminate between the two states of the world. If, on the other hand, the proportion of yes responses is equal on signal and noise trials, we know that the observer could not discriminate between them. Similarly, we can determine whether the observer has a bias to say one response or the other by considering the relative frequencies of yes and no responses regardless of the state of the world. If half of the trials included the signal and half did not, yet the observer said yes 70% of the time, we know that the observer had a bias to say yes.

Signal detection methods allow two basic measures to be computed, one corresponding to discriminability (or *sensitivity)* and the other to *response bias*. Thus, the key advantage of the signal detection methods is that they allow the extraction of a pure measure of perceptual sensitivity separate from any response bias that exists, rather than combining the two in a single measure, as in the threshold techniques. There are many alternative measures of sensitivity (Swets, 1986) and bias (Macmillan and Creelman, 1990), based on a variety of psychophysical models and assumptions. We will base our discussion around signal detection theory and the two most widely used measures of sensitivity and bias, $d'$ and $\beta$. Sorkin (1999) describes how signal detection measures can be calculated using spreadsheet application programs such as Excel.

Signal detection theory assumes that the sensory effect of a signal or noise presentation on any given trial can be characterized as a point along a continuum of evidence indicating that the signal was in fact presented. Across trials, the evidence will vary, such that for either type of trial it will sometimes be higher (or lower) than at other times. For computation of $d'$ and $\beta$, it is assumed that the resulting distribution of
**Figure 3** Equal-variance, normal probability distributions for noise and signal-plus-noise distributions on sensory continuum, with depiction of proportion of false alarms, proportion of hits, and computation of $d'$. Bottom panel shows both distributions on a single continuum. (From Proctor and Van Zandt, 2008.)

values is normal (i.e., bell shaped and symmetric), or Gaussian, for both the signal and noise trials and that the variances for the two distributions are equal (see Figure 3). To the extent that the signal is discriminable from the noise, the distribution for the signal trials should be shifted to the right (i.e., higher on the continuum of evidence values) relative to that for the noise trials. The measure $d'$ is therefore the distance between the means of the signal and noise distributions, in standard deviation units. That is,

$$d' = \frac{\mu_s - \mu_n}{\sigma}$$

where $\mu_s$ is the mean of the signal distribution, $\mu_n$ is the mean of the noise distribution, and $\sigma$ is the standard deviation of both distributions. The assumption is that the observer will respond yes whenever the evidence value on any trial exceeds a criterion. The measure of $\beta$, which is expressed by the formula

$$\beta = \frac{f_s(C)}{f_n(C)}$$

where $C$ is the criterion and $f_s$ and $f_n$ are the heights of the signal and noise distributions, respectively, is the likelihood ratio for the two distributions at the criterion. It indicates the placement of this criterion with respect

to the distributions and thus reflects the relative bias to respond yes or no.

Computation of $d'$ and $\beta$ is relatively straightforward. The placement of the distributions with respect to the criterion can be determined as follows. The *hit rate* is the proportion of signal trials on which the observer correctly said yes; this can be depicted graphically by placing the criterion with respect to the signal distribution so that the proportion of the distribution exceeding it corresponds to the hit rate. The *false-alarm rate* is the proportion of noise trials on which the observer incorrectly said yes. This corresponds to the proportion of the noise distribution that exceeds the criterion; when the noise distribution is placed so that the proportion exceeding the criterion is the false-alarm rate, relative positions of the signal and noise distributions are depicted. Sensitivity, as measured by $d'$, is the difference between the means of the signal and noise distributions, and this difference can be found by separately calculating the distance of the criterion from each of the respective means and then combining those two distances. Computationally, this involves converting the false-alarm rate and hit rate into standard normal $z$ scores. If the criterion is located between the two means, $d'$ is the sum of the two $z$ scores. If the criterion is located outside that range, the smaller of the two $z$ scores must be subtracted from the larger to obtain $d'$. The likelihood ratio measure of bias, $\beta$, can be found from the hit and false-alarm rates by using a $z$ table that specifies the height of the distribution for each $z$ value. When $\beta$ is 1.0, no bias exists to give one or the other response. A value of $\beta$ greater than 1.0 indicates a bias to respond no, whereas a bias less than 1.0 indicates a bias to respond yes.

Although $\beta$ has been used most often as the measure of bias to accompany $d'$, several investigations have indicated that an alternative bias measure, $C$, is better (Snodgrass and Corwin, 1988; Macmillan and Creelman, 1990; Corwin, 1994), where $C$ is a measure of criterion location rather than likelihood ratio. Specifically,

$$C = -0.5[z(H) + z(F)]$$

where $H$ is the hit rate and $F$ the false-alarm rate. Here $C$ is superior to $\beta$ on several grounds, including that it is less affected by the level of accuracy than is $\beta$ and will yield a meaningful measure of bias when accuracy is near chance.

For a given $d'$, the possible combinations of hit rates and false-alarm rates that the observer could produce through adopting different criteria can be depicted in a *receiver operating characteristic* (ROC) curve (see Figure 4). The farther an ROC is from the diagonal that extends from hit and false-alarm rates of 0–1, which represents chance performance (i.e., $d'$ of 0), the greater the sensitivity. The procedure described above yields only a single point on the ROC, but in many cases it is advantageous to examine performance under several criteria settings, so that the form of the complete ROC is evident (Swets, 1986). One advantage is that the estimate of sensitivity will be more reliable when it is based on several points along the ROC than when it is based on
**Figure 4** ROC curves showing the possible hit and false-alarm rates for different sensitivities. (From Proctor and Van Zandt, 2008.)

only one. Another is that the empirical ROC can be compared to the ROC implied by the psychophysical model that underlies a particular measure of sensitivity to determine whether serious deviations occur. For example, when enough points are obtained to estimate complete ROC curves, it is possible to evaluate the assumptions of equal-variance, normal distributions on which the measures of $d'$ and $\beta$ are based. When plotted on $z$-score coordinates, the ROC curve will be linear with a slope of 1.0 if both assumptions are supported; deviations from a slope of 1.0 mean that one distribution is more variable than the other, whereas systematic deviations from linearity indicate that assumption of normality is violated. If either of these deviations is present, alternative measures of sensitivity and bias that do not rely on the assumptions of normality and equal variance should be used.

For cases in which a complete ROC curve is desired, several procedures exist for varying response criteria. The relative payoff structure may be varied across blocks of trials to make one or the other response more preferable; similarly, instructions may be varied regarding how the observer is to respond when uncertain. Another way to vary response criteria is to manipulate the relative probabilities of the signal-and-noise trials; the response criterion should be conservative when signal trials are rare and become increasingly more liberal as the signal trials become increasingly more likely. One of the most efficient techniques is to use rating scales (e.g., from 1, meaning very sure that the signal was not present, to 5, meaning very sure that it was present) rather than yes–no responses. The ratings are then treated as a series of criteria, ranging from high to low, and hit and false-alarm rates are calculated with respect to each. Eng (2006) provides an online program

for plotting an ROC curve and calculating summary statistics.

Signal detection methods are powerful tools for investigating basic and applied problems pertaining not only to sensation and perception but also to many other areas in which an observer's response must be based on probabilistic information, such as distinguishing normal from abnormal X rays (Manning and Leach, 2002) or detecting whether severe weather will occur within the next hour (Harvey, 2003). Although most work on signal detection theory has involved discriminations along a single psychological continuum, it has been extended also to situations in which multidimensional stimuli are presumed to produce values on multiple psychological continua such as color and shape (e.g., Macmillan, 2002). Such analyses have the benefit of allowing evaluation of whether the stimulus dimensions are processed in perceptually separable and independent manners and whether the decisions for each dimension are also separable. As these examples illustrate, signal detection methods can be extremely effective when used with discretion.

### 2.2.2 Psychophysical Scaling

Another concern in psychophysics is to construct scales for the relation between physical intensity and perceived magnitude (see Marks and Gescheider, 2002, for a review). One way to build such scales is to do so from discriminative responses to stimuli that differ only slightly. Fechner (1860) established procedures for constructing psychophysical scales from difference thresholds. Later, Thurstone (1927) proposed a method for constructing a scale from paired comparison procedures in which each stimulus is compared to all others. Thurstonian scaling methods can even be used for complex stimuli for which physical values are not known. Work on scaling in this tradition continues to this day in what is called Fechnarian multidimensional scaling (Dzhafarov and Colonius, 2005), which "borrows from Fechner the fundamental idea of computing subjective dissimilarities among stimuli from the observers' ability to tell apart very similar stimuli" (p. 3).

An alternative way to construct scales is to use direct methods that require some type of magnitude judgment (see, e.g., Bolanowski and Gescheider, 1991, for an overview). Stevens (1975) established methods for obtaining direct magnitude judgments. The technique of *magnitude estimation* is the most widely used. With this procedure, the observer is either presented a standard stimulus and told that its sensation is a particular numerical value (modulus) or allowed to choose his or her own modulus. Stimuli of different magnitudes are then presented randomly, and the observer is to assign values to them proportional to their perceived magnitudes. These values then provide a direct scale relating physical magnitude to perceived magnitude. A technique called *magnitude production* can also be used, in which the observer is instructed to adjust the value of a stimulus to be a particular magnitude. Variations of magnitude estimation and production have been used to measure such things as emotional stress (Holmes and Rahe, 1967) and pleasantness of voice quality for normal

speakers and persons with a range of vocal pathology (Eadie and Doyle, 2002). Furthermore, Walker (2002) provided evidence that magnitude estimation can be used as a design tool in the development of data sonifications, that is, representations of data by sound. Within physical ergonomics, Borg's (1998) RPE (ratings for perceived exertion) and CR-10 (category ratio, 10 categories) scales are used to measure magnitude of perceived exertion and discomfort, respectively, in situations where physical activity is required.

Baird and Berglund (1989) coined the term *environmental psychophysics* for the application of psychophysical methods such as magnitude estimation to applied problems of the type examined by Berglund (1991) that are associated with odorous air pollution and community noise. As Berglund puts it: "The method of ratio scaling developed by S. S. Stevens (1956) is a contribution to environmental science that ranks as good and important as most methods from physics or chemistry" (p. 141). When any measurement technique developed for laboratory research is applied to problems outside the laboratory, special measurement issues may arise. In the case of environmental psychophysics, the environmental stimulus of concern typically is complex and multisensory, diffuse, and naturally varying, presented against an uncontrollable background. The most serious measurement problem is that often it is not possible to obtain repeated measurements from a given observer under different magnitude concentrations, necessitating that a scale be derived from judgments of different observers at different points in time.

Because differences exist in the way that people assign magnitude numbers to stimuli, each person's scale must be calibrated properly. Berglund and her colleagues have developed what they call the *master scaling procedure* to accomplish this purpose. The procedure has observers make magnitude judgments for several values of a referent stimulus as well as for the environmental stimulus. Each observer's power function for the referent stimulus is transformed to a single master function (this is much like converting different normal distributions to the standard normal distribution for comparison). The appropriate transformation for each observer is then applied to her or his magnitude judgment for the environmental stimulus so that all such judgments are in terms of the master scale.

### 2.2.3  Other Techniques

Many other techniques have been used to investigate issues in sensation and perception. Most important are methods that use response times either instead of or in conjunction with response accuracy (see Welford, 1980; Van Zandt, 2002). Reaction time methods have a history of use approximately as long as that of the classical psychophysical methods, dating back to Donders (1868), but their use has been particularly widespread since about 1950. Simple reaction times require the observer to respond as quickly as possible with a single response (e.g., a keypress) whenever a stimulus event occurs. Alternative hypotheses of various factors that affect detection of the stimulus and the decision to respond, such as the locus of influence of visual masking

and whether the detection of two signals presented simultaneously can be conceived of as an independent race, can be evaluated using simple reaction times.

Decision processes play an even larger role in go–no go tasks, where responses must be made to some stimuli but not to others, and in choice–reaction tasks, where there is more than one possible stimulus and more than one possible response and the stimulus must be identified if the correct response is to be made. Methods such as the *additive factors logic* (Sternberg, 1969) can be used to isolate perceptual and decisional factors. This logic proposes that two variables whose effects are additive affect different processing stages, but two variables whose effects are interactive affect the same processing stage. Variables that interact with marker variables whose effects can be assumed to be in perceptual processes, but not with marker variables whose effects are on response selection or programming, can be assigned a perceptual locus. Analyses based on the distributions of reaction times have gained in popularity in recent years. Van Zandt (2002) provides MATLAB code for performing such analyses.

## 3  SENSORY SYSTEMS AND BASIC PERCEPTUAL PHENOMENA

The ways in which the sensory systems encode information have implications not only for the structure and function of the sensory pathways but ultimately also for the nature of human perception. They also place restrictions on the design of displays. Displays must be designed to satisfy known properties of sensory encoding (e.g., visual information that would be legible if presented in central vision will not be legible if the display were presented in the visual periphery), but they do not need to exceed the capabilities of sensory encoding. The sensory information that is encoded also must be represented in the nervous system. The nature of this representation also has profound implications for perception.

### 3.1  Vision

#### 3.1.1  Visual System

The sensory receptors in the eye are sensitive to energy within a limited range of the electromagnetic spectrum. One way of characterizing such energy is as continuous waves of different wavelengths. The visible spectrum ranges from wavelengths of approximately 370 nm (billionths of a meter) to 730 nm. Any energy outside this range, such as ultraviolet rays, will not be detected because they have no effect on the receptors. Light can also be characterized in terms of small units of energy called *photons*. Describing light in terms of wavelength is important for some aspects of perception, such as color vision, whereas for others it is more useful to treat it in terms of photons. As with any system in which light energy is used to create a representation of the physical world, the light must be focused and a clear image created. In the case of the eye, the image is focused on the photoreceptors located on the retina, which lines the back wall of the eye.
**Figure 5** Structure of the human eye. (From Schiffman, 1996.)

***Focusing System*** Light enters the eye (see Figure 5) through the cornea, a transparent layer that acts as a lens of fixed optical power and provides the majority of the focusing. The remainder of the focusing is accomplished by the crystalline lens, whose power varies automatically as a function of the distance from the observer of the object that is being fixated. Beyond a distance of approximately 6 m, the far point, the lens is relatively flat; for distances closer than the far point, muscles attached to the lens cause it to become progressively more spherical the closer the fixated object is to the observer, thus increasing its refractive power. The reason why this process, called *accommodation*, is needed is that without an increase in optical power for close objects their images would be focused at a point beyond the retina and the retinal image would be out of focus. Accommodation is effective for distances as close as 20 cm (the near point), but the extent of accommodation, and the speed at which it occurs, decreases with increasing age, with the near point receding to approximately 100 cm by age 60. This decrease in accommodative capability, called *presbyopia*, can be corrected with reading glasses. Other imperfections of the lens system—*myopia*, where the focal point is in front of the receptors; *hyperopia*, where the focal point is behind the receptors; and *astigmatism*, where certain orientations are out of focus while others are not—also typically are treated with glasses.

Between the cornea and the lens, the light passes through the pupil, an opening in the center of the iris that can vary in size from 2 to 8 mm. The pupil size is large when the light level is low, to maximize the amount of light that gets into the eye, and small when the light level is high, to minimize the imperfections in imaging that arise when light passes through the extreme periphery of the lens system. One additional consequence of these changes in image quality as a function of pupil size is that the *depth of field*, or the distance in front of or behind a fixated object at which

the images of other objects will be in focus also, will be greatest when the pupil size is 2 mm and decrease as pupil size increases, at least up to intermediate diameters (Marcos et al., 1999). In other words, under conditions of low illumination, accommodation must be more precise and work that requires high acuity, such as reading, can be fatiguing (Randle, 1988). When required to accommodate to near stimuli, adults show accommodative pupil restrictions that increase the depth of field. This tendency for restriction in pupil size is much weaker for children (Gislén et al., 2008; the children in their study were 9–10 years of age), most likely due to the superior accommodative range of their lenses.

If the eyes fixate on an object at a distance of approximately 6 m or farther, the lines of sight are parallel. As the object is moved progressively closer, the eyes turn inward and the lines of sight converge. Thus, the degree of *vergence* of the eyes varies systematically as a function of the distance of the object being fixated. The near point for vergence is approximately 5 cm, and if an object closer than that is fixated, the images at the two eyes will not be fused and a double image will be seen.

The natural resting states for accommodation and vergence, called *dark focus* and *dark vergence*, respectively, are intermediate to the near and far points (Leibowitz and Owens, 1975; Andre, 2003; Jaschinski et al., 2007). One view for which there is considerable support is that dark focus and vergence provide zero reference points about which accommodative and vergence effort varies (Ebenholtz, 1992). A practical implication of this is that less eye fatigue will occur if a person working at a visual display screen for long periods of time is positioned at a distance that corresponds approximately to the dark focus and vergence points. As with most other human characteristics of concern in human factors and ergonomics, considerable individual differences in dark focus and vergence exist. People with far dark-vergence postures tend to position themselves

farther away from the display screen than will those with closer postures (Heuer et al., 1989), and they also show more visual fatigue when required to perform close visual work (Jaschinski-Kruza, 1991).

**Retina** If the focusing system is working properly, the image will be focused on the retina, which lines the back wall of the eye. Objects in the left visual field will be imaged on the right hemi-retina and objects in the right visual field on the left hemi-retina; objects above the point of fixation will be imaged on the lower half of the retina, and vice versa for objects below fixation. The retina contains the photoreceptors that transduce the light energy into a neural signal; their spatial arrangement limits our ability to perceive spatial pattern (see Figure 6). There also are two layers of neurons, and their associated blood vessels, that process the retinal image before information about it is sent along the optic nerve to the brain. These neural layers are in the light path between the lens and the photoreceptors and thus degrade to some extent the clarity of the image at the receptors.

There are two major types of photoreceptors, *rods* and *cones*, with three subtypes of cones. All photoreceptors contain light-sensitive photopigments in their outer segments that operate in basically the same manner. Photons of light are absorbed by the photopigment when they strike it, starting a reaction that leads to the generation of a neural signal. As light is absorbed, the photopigment becomes insensitive and is said to be *bleached*. It must go through a process of regeneration before it is functional again. Because the rod and cone photopigments differ in their absolute sensitivities to light energy, as well as in their differential sensitivities to light across the visual spectrum, the rods and cones have different roles in perception.

Rods are involved primarily in vision under very low levels of illumination, what is called *scotopic vision*. All rods contain the same photopigment, rhodopsin, which is highly sensitive to light. Its spectral sensitivity function shows it to be maximally sensitive to light around 500 nm and to a lesser degree to other wavelengths. One consequence of there being only one rod photopigment is that we cannot perceive color under scotopic conditions. The reason for this is easy to understand. The rods will respond relatively more to stimulation of 500 nm than they will to 560-nm stimulation of equal intensity. However, if the intensity of the 560-nm stimulus is increased, a point would be reached at which the rods responded equally to the two stimuli. In other words, with one photopigment, there is no basis for distinguishing among the wavelength differences associated with color differences from intensity differences.

Cones are responsible for vision in daylight, or what is known as *photopic vision*. Cone photopigments are less sensitive to light than rhodopsin, and hence cones are operative at levels of illumination at which the rod photopigment has been effectively fully bleached. Also, because there are three types of cones, each containing a different photopigment, cones provide color vision. As explained previously, there must be more than one photopigment type if differences in the wavelength of stimulation are to be distinguished from differences in intensity. The spectral sensitivity functions for each of the three cone photopigments span broad ranges of the visual spectrum, but their peak sensitivities are located at different wavelengths. The peak sensitivities are approximately 440 nm for the short-wavelength ("blue") cones, 540 nm for the middle-wavelength ("green") cones, and 565 nm for the long-wavelength ("red") cones. Monochromatic light of a particular wavelength will produce a pattern of activity for the three cone types that is unique from the patterns produced by other wavelengths, allowing each to be distinguished perceptually.

The retina contains two landmarks that are important for visual perception. The first of these is the optic disk, which is located on the nasal side of the retina. This is the region where the optic nerve, composed of the nerve fibers from the neurons in the retina, exits the eye. The significant point is that there are no photoreceptors in this region, which is why it is sometimes called the *blind spot*. We do not normally notice the blind spot because (1) the blind spot for one of the eyes corresponds to part of the normal visual field for the other eye and (2) with monocular viewing, the perceptual system fills it in with fabricated images based on visual attributes from nearby regions of the visual field (Araragi et al., 2009). How this filling in occurs has been the subject of considerable investigation, with evidence from physiological studies and computational modeling suggesting that the filling in is induced by neurons in the primary visual cortex through slow conductive paths of horizontal connections in the primary visual cortex and fast feed-forward/feedback paths by way of the visual association cortex (Matsumoto and Komatsu, 2005; Satoh and Usui, 2008). If the image of an object falls only partly on the blind spot, the filling in from the surrounding region will cause the object to appear complete. However, if the image of an object falls entirely within the blind spot, this filling in will cause the object to not be perceived.

The second landmark is the *fovea*, which is a small indentation about the size of a pinhead on which the image of an object at the point of fixation will fall. The fovea is the region of the retina in which visual acuity is highest. Its physical appearance is due primarily to the fact that the neural layers are pulled away, thus allowing the light a straight path to the receptors. Moreover, the fovea contains only cones, which are densely packed in this region.

As shown in Figure 6, the photoreceptors synapse with bipolar cells, which in turn synapse with ganglion cells; the latter cells are the output neurons of the retina, with their axons making up the optic nerve. In addition, horizontal cells and amacrine cells provide interconnections across the retina. The number of ganglion cells is much less than the number of photoreceptors, so considerable convergence of the activity of individual receptors occurs. The neural signals generated by the rods and cones are maintained in distinct pathways until reaching the ganglion cells (Kolb, 1994). In the fovea, each cone has input into more than one ganglion cell. However, convergence is the rule outside the fovea, being an increasing function of distance from

Rods                    Cones

**Figure 6**   Neural structures and interconnections of vertebrate retina. (From Dowling and Boycott, 1966.)

the fovea. Overall, the average convergence is 120:1 for rods as compared to 6:1 for cones. The degree of convergence has two opposing perceptual consequences. Where there is little or no convergence, as in the neurons carrying signals from the fovea, the pattern of stimulation at the retina is maintained effectively complete, thus maximizing spatial detail. When there is considerable convergence, as for the rods, the activity of many photoreceptors in the region is pooled together, optimizing sensitivity to light at the cost of detail. Thus,

the wiring of the photoreceptors is consistent with the fact that the rods operate when light energy is at a premium but the cones operate when it is not.

The ganglion cells show several interesting properties pertinent to perception. When single-cell recording techniques are used to measure their receptive fields (i.e., the regions on the retina that when stimulated produce a response in the cell), these fields are found to have a circular, center-surround relation for most cells. If light presented in a circular, center region causes an increase in the firing rate of the neuron, light presented in a surrounding ring region will cause a decrease in the firing rate, or vice versa. What this means is that the ganglion cells are tuned to respond primarily to discontinuities in the light pattern within their receptive fields. If the light energy across the entire receptive field is increased, there will be little if any effect on the firing rate. In short, the information extracted and signaled by these neurons is based principally on contrast, which is important for perceiving objects in the visual scene, and not on absolute intensity, which will vary as a function of the amount of illumination. Not surprisingly, the average receptive field size is larger for ganglion cells receiving their input from rods than for those receiving it solely from cones and increases with increasing distance from the fovea.

Although most ganglion cells have the center-surround receptive field organization, two pathways can be distinguished on the basis of other properties. The ganglion cells in the *parvocellular pathway* have small cell bodies and relatively dense dendritic fields. Many of these ganglion cells, called midget cells, receive their input from the fovea. They have relatively small receptive fields, show a sustained response as long as stimulation is present in the receptive field, and have a relatively slow speed of transmission. The ganglion cells in the *magnocellular pathway* have larger cell bodies and sparse dendritic trees. They have their receptive fields at locations across the retina, have relatively large receptive fields, show a transient response to stimulation that dissipates if the stimulus remains on, have a fast speed of transmission, and are sensitive to motion. Because of these unique characteristics and the fact that these channels are kept separated later in the visual pathways, it has been thought that they contribute distinct information to perception. The parvocellular pathway is presumed to be responsible for pattern perception and the magnocellular pathway for high-temporal-frequency information, such as in motion perception and perception of flicker. The view that different aspects of the sensory stimulus are analyzed in specialized neural pathways has received considerable support in recent years.

**Visual Pathways**  The optic nerve from each eye splits at what is called the *optic chiasma* (see Figure 7). The fibers conveying information from the nasal halves of the retinas cross over and go to the opposite sides of the brain, whereas the fibers conveying information from the temporal halves do not cross over. Functionally, the significance of this is that for both eyes input from the right visual field is sent to the left half of the brain and

input from the left visual field is sent to the right half. A relatively small subset of the fibers (approximately 10%) splits off from the main tract and the fibers go to structures in the brain stem, the tectum, and then the pulvinar nucleus of the thalamus. This *tectopulvinar pathway* is involved in localization of objects and the control of eye movements.

Approximately 90% of the fibers continue on the primary *geniculostriate pathway*, where the first synapse is at the lateral geniculate nucleus (LGN). The distinction between the parvocellular and magnocellular pathways is maintained here. The LGN is composed of six layers, four parvocellular and two magnocellular, each of which receives input from only a single eye. Hence, at this level the input from the two eyes has yet to be combined. Each layer is laid out in a retinotopic map that provides a spatial representation of the retina. In other respects, the receptive field structure of the LGN neurons is similar to that of the ganglion cells. The LGN also receives input from the visual cortex, both directly and indirectly, by way of a thalamic structure called the reticular nucleus that surrounds the LGN (Briggs and Usrey, 2011). This feedback likely modulates the activity in the LGN, allowing the communication between the visual cortex and LGN to be bidirectional.

From the LGN, the fibers go to the primary visual cortex, which is located in the posterior cortex. This region is also called the *striate cortex* (because of its stripes), *area 17*, or *area V1*. The visual cortex consists of six layers. The fibers from the LGN have their synapses in the fourth layer from the outside, with the parvocellular neurons sending their input to one layer $(4C\beta)$ and the magnocellular neurons to another $(4C\alpha)$, and they also have collateral projections to different parts of layer 6. The neurons in these layers then send their output to other layers. In layer 4 the neurons have circular-surround receptive fields, but in other layers, they have more complex patterns of sensitivity. Also, whereas layer 4 neurons receive input from one or the other eye, in other layers most neurons respond to some extent to stimulation at either eye.

A distinction can be made between simple cells and complex cells (e.g., Hubel and Wiesel, 1977). The responses of simple cells to shapes can be determined from their responses to small spots of light (e.g., if the receptive field for the neuron is plotted using spots of light, the neuron will be most sensitive to a stimulus shape that corresponds with that receptive field), whereas those for complex cells cannot be. Simple cells have center-surround receptive fields, but they are more linear than circular; this means that they are orientation selective and will respond optimally to bars in an orientation that corresponds with that of the receptive field. Complex cells have similar linear receptive fields and so are also orientation selective, but they are movement sensitive as well. These cells respond optimally not only when the bar is at the appropriate orientation but also when it is moving. Some cells, which receive input from the magnocellular pathway, are also directionally sensitive: they respond optimally to movement in a particular direction. Certain cells, called *hypercomplex cells*, are sensitive to the length of
**Figure 7** Human visual system showing projection of visual fields through the system. (From Schiffman, 1996.)

the bar so that they will not respond if the bar is too long. Some neurons in the visual cortex are also sensitive to disparities in the images at each eye and to motion velocity. In short, the neurons of the visual cortex analyze the sensory input for basic features that provide the information on which higher level processes operate.

The cortex is composed of columns and hypercolumns arranged in a spatiotopic manner. Within a single column, all of the cells except for those in layer 4 will have the same preferred orientation. The next column will respond to stimulation at the same location on the retina but will have a preferred orientation

that is approximately $10°$ different than that of the first column. As we proceed through a group of about 20 columns, called a *hypercolumn*, the preferred orientation will rotate $180°$. The next hypercolumn will show the same arrangement, but for stimulation at a location on the retina that is adjacent to that of the first. A relatively larger portion of the neural machinery in the visual cortex is devoted to the fovea, which is to be expected because it is the region for which detail is being represented.

Two cortical areas, V2 (the first visual association area) and MT (medial temporal), receive input from

V1 (Briggs and Usrey, 2010). Part of the V2 neurons also project to MT, but another part goes to cortical area V4, making up the dorsal (where) and ventral (what) streams, respectively. Barber (1990) found that visual abilities pertaining to detection, identification, acquisition, and tracking of aircraft in air defense simulations clustered into subgroups consistent with the hypothesis that different aspects of visual perception are mediated by these distinct subsystems in the brain.

### 3.1.2 Basic Visual Perception

***Brightness***   Brightness is that aspect of visual perception that corresponds most closely to the intensity of stimulation. To specify the effective intensity of a stimulus, photometric measures, which are calibrated to reflect human spectral sensitivity, should be used. A photometer can be used to measure either *illuminance*, that is, the amount of light falling on a surface, or *luminance*, that is, the amount of light generated by a surface. To measure illuminance, an illuminance probe is attached to the photometer and placed on the illuminated surface. The resulting measure of illuminance is in lumens per square meter ($lm/m^2$) or lux (lx). To measure luminance, a lens with a small aperture is attached to the photometer and focused onto the surface from a distance. The resulting measure of luminance is in candelas per square meter ($cd/m^2$). Although measures with a photometer are suitable with most displays, the relatively new technology of laser-based video projectors requires an alternative method, because each pixel produces light for too brief of a time for accurate photometric measurement (Doucet et al., 2010).

Judgments of brightness are related to intensity by the power function

$$B = aI^{0.33}$$

where $B$ is brightness, $a$ is a constant, and $I$ is the physical intensity. However, brightness is not determined by intensity alone but also by several other factors. For example, at brief exposures on the order of 100 ms or less and for small stimuli, temporal and spatial summation occurs. That is, a stimulus of the same physical intensity will look brighter if its exposure duration is increased or if its size is increased.

One of the most striking influences on brightness perception and sensitivity to light is the level of *dark adaptation*. When a person first enters a dark room, he or she is relatively insensitive to light energy. However, with time, dark adaptation occurs and sensitivity increases drastically. The time course of dark adaptation is approximately 30 min. Over the first couple of minutes, the absolute threshold for light decreases and then levels off. However, after approximately 8 min in the dark, it begins decreasing again, approaching a maximum around the 30-min point. After 30 min in the dark, lights can be seen that were of too low intensity to be visible initially, and stimuli that appeared dim now seem much brighter. Dark adaptation reflects primarily regeneration into a maximally light-sensitive state of the cone photopigments and then the rod photopigment. Jackson et al. (1999) reported a dramatic slowing in the rod-mediated component of dark adaptation that may contribute to increased night vision problems experienced by older adults. After becoming dark adapted, vision may be impaired momentarily when the person returns to photopic viewing conditions. Providing gradually changing light intensity in regions where light intensity would normally change abruptly, such as at the entrances and exits of tunnels, may help minimize such impairment (e.g., Oyama, 1987).

The brightness of a monochromatic stimulus of constant intensity will vary as a function of its wavelength because the photopigments are differentially sensitive to light of different wavelengths. The scotopic spectral sensitivity function is shifted toward the short-wavelength end of the spectrum, relative to the photopic function. Consequently, if two stimuli, one short wavelength and one long, appear equally bright at photopic levels, the short-wavelength stimulus will appear brighter at scotopic levels, a phenomenon called the *Purkinje shift*. Little light adaptation will occur when high levels of long-wavelength light are present because the sensitivity of the rods to long-wavelength light is low. Thus, it is customary to use red light sources to provide high illumination for situations in which a person needs to remain dark adapted.

It is common practice to distinguish between brightness and lightness as two different aspects of perception (Blakeslee et al., 2008): *Judgments of brightness* are of the apparent luminance of a stimulus, whereas *judgments of lightness* are of perceived achromatic color along a black-to-white dimension (i.e., apparent reflectance). Both the brightness and lightness of an object are greatly influenced by the surrounding context. *Lightness contrast* is a phenomenon where the intensity of a surrounding area influences the lightness of a stimulus. The effects can be quite dramatic, with a stimulus of intermediate reflectance ranging in appearance from white to dark gray or black as the reflectance of the surround is increased from low to high. The more common phenomenon of *lightness constancy* occurs when the level of illumination is increased across the entire visual field. In this case, the absolute amount of light reflected to the eye by an object may be quite different, but the percept remains constant. Basically, lightness follows a constant-ratio rule (Wallach, 1972): Lightness will remain the same if the ratio of light energy for a stimulus relative to its surround remains constant. Lightness constancy holds for a broad range of ratios and across a variety of situations, with brightness constancy obtained under a more restricted set of viewing conditions (Jacobsen and Gilchrist, 1988; Arend, 1993).

Although low-level mechanisms early in the sensory system probably contribute at least in part to constancy and contrast, more complex higher level brain mechanisms apparently do as well. Particularly compelling are demonstrations showing that the lightness and brightness of an object can vary greatly simply as a function of organizational and depth cues. Agostini and Proffitt (1993) demonstrated lightness contrast as a function of whether a target gray circle was organized perceptually with black or white circles, even though the inducing circles were not in close proximity to the target. Gilchrist
**Figure 8** Effect of perceived shading on brightness judgments. The patches $a_1$ and $a_2$ are the same shade of gray, but $a_1$ appears much darker than $a_2$. (Reprinted with permission from Adelson, 1993. Copyright 1993 by the American Association for the Advancement of Science.)

(1977) used depth cues to cause a piece of white paper to be perceived incorrectly as in a back chamber that was highly illuminated or correctly as in a front chamber that was dimly illuminated. When perceived as in the front chamber, the paper was seen as white; however, when perceived as in the back chamber, the paper appeared to be almost black. Adelson (1993) showed that such effects are not restricted to lightness but also occur for brightness judgments. For example, when instructed to adjust the luminance of square $a_1$ in Figure 8 to equal that of square $a_2$, observers set the luminance of $a_1$ to be 70% higher than that of $a_2$. Thus, even relatively "sensory" judgments such as brightness are affected by higher order organizational factors.

***Visual Acuity and Sensitivity to Spatial Frequency*** *Visual acuity* refers to the ability to perceive detail. Acuity is highest in the fovea, and it decreases with increasing eccentricities due in part to the progressively greater convergence of activity from the sensory receptors that occurs in the peripheral retina. Distinctions can be made between different types of acuity. *Identification acuity* is the most commonly measured, using a Snellen eye chart that contains rows of letters that become progressively smaller. The smallest row for which the observer can identify the letters is used as the indicator of acuity. Regarded as normal, 20/20 vision means that the person being tested is able to identify at a distance of 20 ft letters of a size that a person with normal vision is expected to identify. A person with 20/100 vision can identify letters at 20 ft only as large as those that a person with normal vision could at 100 ft. *Vernier acuity* is a person's ability to discriminate between broken and unbroken lines, and *resolution acuity* is the ability to distinguish gratings from a stimulus

that covers the same area but is of the same average intensity throughout. All of these measures are variants of *static acuity*, in that they are based on static displays. *Dynamic acuity* refers to the ability to resolve detail when there is relative motion between the stimulus and the observer. Dynamic acuity is usually poorer than static acuity (Morgan et al., 1983), partly due to an inability to keep a moving image within the fovea (Murphy, 1978). A concern in measuring acuity is that the types are not perfectly correlated, and thus an acuity measure of one type may not be a good predictor of ability to perform a task whose acuity requirements are of a different type. For example, the elderly show typically little loss of identification acuity as measured by a standard test, but they seem to have impaired acuity in dynamic situations and at low levels of illumination (Kosnik et al., 1990; Sturr et al., 1990). Thus, performance on a dynamic acuity test may be a better predictor of driving performance for elderly persons (Wood, 2002). In a step toward making assessment of dynamic acuity more routine, Smither and Kennedy (2010) have developed and evaluated a prototype of an automated, portable dynamic visual acuity system using a low-energy laser.

Spatial contrast sensitivity has been shown to provide an alternative, more detailed way for characterizing acuity. A *spatial contrast sensitivity function* can be generated by obtaining threshold contrast values for discriminating sine-wave gratings (for which the bars change gradually rather than sharply from light to dark) of different spatial frequencies from a homogeneous field. The contrast sensitivity function for a typical adult shows maximum sensitivity at a spatial frequency of about three to five cycles per degree of visual angle, with relatively sharp drop-offs at high and low spatial frequencies. Basically what this means is that we are not extremely sensitive to very fine or course gratings. Because high spatial frequencies relate to the ability to perceive detail and low to intermediate frequencies to the more global characteristics of visual stimuli, tests of acuity based on contrast sensitivity may be more analytic concerning aspects of performance that are necessary for performing specific tasks. For example, Evans and Ginsburg (1982) found contrast sensitivity at intermediate and low spatial frequencies to predict the detectability of stop signs in night driving, and contrast sensitivity measures have also been shown to predict performance of flight-related tasks (Gibb et al., 2010). A main difficulty for use of contrast sensitivity functions for practical applications is the long time required to perform such a test. Lesmes et al. (2010) have developed and performed initial validation tests of a quick method that requires only 25 trials to construct a relatively accurate function.

Of concern in human factors and ergonomics is temporal acuity. Because many light sources and displays present flickering stimulation, we need to be aware of the rates of stimulation beyond which flicker will not be perceptible. The *critical flicker frequency* is the highest rate of flicker at which it can be perceived. Numerous factors influence the critical frequency, including stimulus size, retinal location, and level of

surrounding illumination. The critical flicker frequency can be as high as 60 Hz for large stimuli of high intensity, but it typically is less. You may have noticed that the flicker of a computer display screen is perceptible when you are not looking directly at it as a consequence of the greater temporal sensitivity in the peripheral retina.

***Color Vision and Color Specification***    Color is used in many ways to display visual information. Color can be used, as in television and movies, to provide a representation that corresponds to the colors that would be seen if one were physically present at the location that is depicted. Color is also used to highlight and emphasize as well as to code different categories of displayed information. In situations such as these, we want to be sure that the colors are perceived as intended.

In a color-mixing study, the observer is asked to adjust the amounts of component light sources to match the hue of a comparison stimulus. Human color vision is *trichromatic*, which means that any spectral hue can be matched by a combination of three primary colors, one each from the short-, middle-, and long-wavelength positions of the spectrum. This trichromaticity is a direct consequence of having three types of cones that contain photopigments with distinct spectral sensitivity functions. The pattern of activity generated in the three cone systems will determine what hue is perceived. A specific pattern can be determined by a monochromatic light source of a particular wavelength or by a combination of light sources of different wavelengths. As long as the relative amounts of activation in the three cone systems are the same for different physical stimuli, they will be perceived as being of the same hue. This fact is used in the design of color television sets and computer monitors, for which all colors are generated from combinations of pixels of three different colors.

Another phenomenon of additive color mixing is that blue and yellow, when mixed in approximately equal amounts, yield an achromatic (e.g., white) hue, as do red and green. This stands in contrast to the fact that combinations involving one hue from each of the two complementary pairs are seen as combinations of the two hues. For example, when blue and green are combined additively in similar amounts, the resulting stimulus appears blue-green. The pairs that yield an achromatic additive mixture are called *complementary colors*. That these hues have a special relation is evident in other situations as well. When a background is one of the hues from a pair of complementary colors, it will tend to induce the complementary hue in a stimulus that would otherwise be perceived as a neutral gray or white. Similarly, if a background of one hue is viewed for awhile and then the gaze is shifted to a background of a neutral color, an afterimage of the complementary hue will be seen.

The complementary color relations also appear to have a basis in the visual system, but in the neural pathways rather than in the sensory receptors. That is, considerable evidence indicates that output from the cones is rewired into opponent processes at the level of the ganglion cells and beyond. If a neuron's firing rate increases when a blue stimulus is presented, it decreases when a yellow stimulus is presented. Similarly, if a neuron's firing rate increases to a red stimulus, it decreases to a green stimulus. The pairings in the opponent cells always involve blue with yellow and red with green. Thus, a wide range of color appearance phenomena can be explained by the view that the sensory receptors operate trichromatically, but this information is subsequently recoded into an opponent format in the sensory pathways.

The basic color-mixing phenomena are depicted in color appearance systems. A *color circle* can be formed by curving the visual spectrum, as done originally by Isaac Newton. The center of the circle represents white, and its rim represents the spectral colors. A line drawn from a particular location on the rim to the center depicts saturation, the amount of hue that is present. For example, if one picks a monochromatic light source that appears red, points on the line represent progressively decreasing amounts of red as one moves along it to the center. The appearance for a mixture of two spectral colors can be approximated by drawing a chord that connects the two colors. If the two are mixed in equal amounts, the point at the center corresponds to the mixture; if the percentages are unequal, the point is shifted accordingly toward the higher percentage spectral color. The hue for the mixture point can be determined by drawing a diagonal through it; its hue corresponds to that of the spectral hue at the rim, and its saturation corresponds to the proximity to the rim.

The color circle is too imprecise to be used to specify color stimuli, but a system much like it, the CIE (Commission Internationale de l'Éclairage) system, is the most widely used color specification system. The CIE provided a standardized set of color-matching functions, $x(\lambda)$, $y(\lambda)$, and $z(\lambda)$, called the *XYZ tristimulus coordinate system* (see Figure 9). The tristimulus values for a monochromatic stimulus can be used to determine the proportions of three wavelengths ($X$, $Y$, and $Z$, corresponding to red, green, and blue, respectively) needed to match it. For example, the $X$, $Y$, and $Z$ tristimulus values for a 500-nm stimulus are 0.0049, 0.3230, and 0.2720. The proportion of $X$ primary can be determined by dividing the tristimulus value for $X$ by the combined values for $X$ plus $Y$ plus $Z$. The proportion of $Y$ primary can be determined in like manner, and the proportion of $Z$ primary is simply 1 minus the $X$ and $Y$ proportions. The spectral stimulus of 500 nm thus has the following proportions: $x = 0.008$, $y = 0.539$, and $z = 0.453$.

The *CIE color space*, shown in Figure 9, is triangular rather than circular. Location in the space is specified according to the $x$ and $y$ color coordinates. Only $x$ and $y$ are used as the coordinates for the space because $x$, $y$, and $z$ sum to 1.0. The spectral stimulus of 500 nm would be located on the rim of the triangle, in the upper left of the figure. Saturation decreases as proximity to the rim decreases, to an achromatic point labeled $C$ in Figure 9. The color of a stimulus can be specified precisely by using the tristimulus values for each component spectral frequency or approximately by determining the coordinates at the location approximating its appearance.
**Figure 9**   CIE color space. The abscissa and ordinate indicate the *x* and *y* values, respectively.

Another widely used color specification system is the *Munsell Book of Colors*. This classification scheme is also a variant of the color circle, but adding in a third dimension that corresponds to lightness. In the Munsell notation, the word *hue* is used as normal, but the words *value* and *chroma* are used to refer to lightness and saturation, respectively. The book contains sheets of color samples organized according to their values on the three dimensions of hue, value, and chroma. Color can be specified by reporting the values of the sample that most closely match those of the stimulus of interest.

When using a colored stimulus, one important consideration is its location in the visual field (Gegenfurtner and Sharpe, 1999). The distribution of cones varies across the retina, resulting in variations in color perception at different retinal locations. For example, because short-wavelength cones are absent in the fovea and only sparsely distributed throughout the periphery, very small blue stimuli imaged in the fovea will be seen as achromatic and the blue component in mixtures will have little impact on the perceived hue. Cones of all three types

decrease in density with increasing eccentricity, with the consequence that color perception becomes less sensitive and stimuli must be larger in order for color to be perceived. Red and green discrimination extends only $20°-30°$ into the periphery, whereas yellow and blue can be seen up to $40°-60°$ peripherally. Color vision is completely absent beyond that point.

Another consideration is that a significant portion of the population has *color blindness*, or, more generally, color vision deficiency. The most common type of color blindness is dichromatic vision. It is a gender-linked trait, with most dichromats being males. The name arises from the fact that such a person can match any spectral hue with a combination of only two primaries; in most cases this disorder can be attributed to a missing cone photopigment. The names *tritanopia, deuteranopia*, and *protanopia* refer to missing the short-, middle-, or long-wavelength pigment, respectively. The latter two types (commonly known as red–green color blindness) are much more prevalent than the former. The point to keep in mind is that color-blind persons

are not able to distinguish all of the colors that a person with trichromatic vision can. Specifically, people with red–green color blindness cannot differentiate middle and long wavelengths (520–700 nm), and the resulting perception is composed of short (blue) versus longer (yellow) wavelength hues. O'Brien et al. (2002) found that the inability to discriminate colors in certain ranges of the spectrum reduces their conspicuity (i.e., the ability to attract attention). Deuteranopes performed significantly worse than trichromats at detecting red, orange, and green color-coded traffic control devices in briefly flashed displays, but not at detecting yellow and blue color-coded signs. Testing for color vision is of importance for certain occupations, such as being an aircraft pilot, where a deficiency in color vision may lead to a crash. Tests for color deficiencies include the Ishihara plates, which require differences in color to be perceived if test patterns are to be identified, and the Farnsworth–Munsell 100-hue test, in which colored caps are to be arranged in a continuous series about four anchor point colors (Wandell, 1995). Because individuals who have some color deficiency but are not severely deficient may be able to pass one test, for example, with the Ishihara plates, multiple color vision tests seem to be necessary to detect lesser color deficiencies (Gibb et al., 2010).

## 3.2 Audition

### 3.2.1 Auditory System

The sensory receptors for hearing are sensitive to sound waves, which are moment-to-moment fluctuations in air pressure about the atmospheric level. These fluctuations are produced by mechanical disturbances, such as a stereo speaker moving in response to signals that it is receiving from a music source and amplifier. As the speaker moves forward and then back, the disturbances in the air go through phases of compression, in which the density of molecules—and hence the air pressure—is increased, and rarefaction, in which the

density and air pressure decrease. With a pure tone, such as that made by a tuning fork, these changes follow a sinusoidal pattern. The frequency of the oscillations (i.e., the number of oscillations per second) is the primary determinant of the sound's pitch, and the amplitude or intensity is the primary determinant of loudness. Intensity is usually specified in *decibels* (dB), which is $20 \log (p/p_0)$, where $p$ is the pressure corresponding to the sound and $p_0$ is the standard value of 20 µPa. When two or more pure tones are combined, the resulting sound wave will be an additive combination of the components. In that case, not only frequency and amplitude become important but also the phase relationships between the components, that is, whether the phases of the cycles for each are matched or mismatched. The wave patterns for most sounds encountered in the world are quite complex, but they can be characterized in terms of component sine waves by means of a Fourier analysis. The auditory system must perform something like a Fourier analysis, since we are capable to a large extent of extracting the component frequencies that make up a complex sound signal, so that the pitches of the component tones are heard.

***Ear*** A sound wave propagates outward from its source at the speed of sound (344 m/s), with the amplitude proportional to $1/(\text{distance})^2$. It is the cyclical air pressure changes at the ear as the sound wave propagates past the observer that starts the sensory process. The outer ear (see Figure 10), consisting of the pinna and the auditory canal, serves to funnel the sound into the middle ear; the pinna will amplify or attenuate some sounds as a function of the direction from which they come and their frequency, and the auditory canal amplifies sounds in the range of approximately 1–2 kHz. A flexible membrane, called the *eardrum* or *tympanic membrane*, separates the outer and middle ears. The pressure in the middle ear is maintained at the atmospheric level by means of the Eustachian tube, which opens into the throat, so any deviations

**Figure 10**    Structure of the human ear. (From Schiffman, 1996.)

from this pressure in the outer ear will result in a pressure differential that causes the eardrum to move. Consequently, the eardrum vibrates in a manner that mimics the sound wave that is affecting it. However, changes in altitude, such as those occurring during flight, can produce a pressure differential that impairs hearing until that differential is eliminated, which cannot occur readily if the Eustachian tube is blocked by infection or other causes.

Because the inner ear contains fluid, there is an impedance mismatch between it and the air that would greatly reduce the fluid movement if the eardrum acted on it directly. This impedance mismatch is overcome by a lever system of three bones (the ossicles) in the middle ear: the *malleus, incus,* and *stapes*. The malleus is attached to the eardrum and is connected to the stapes by the incus. The stapes has a footplate that is attached to a much smaller membrane, the oval window, which is at the boundary of the middle ear and the cochlea, the part of the inner ear that is important for hearing. Thus, when the eardrum moves in response to sound, the ossicles move, and the stapes produces movement of the oval window. Muscles attached to the ossicles tighten when sounds exceed 80 dB, thus protecting the inner ear to some extent from loud sounds by lessening their impact. However, because this acoustic reflex takes between 10 and 150 ms to occur, depending on the intensity of the sound, it does not provide protection from percussive sounds such as gunshots.

The *cochlea* is a fluid-filled, spiral structure (see Figure 11). It consists of three chambers, the vestibular and tympanic canals, and the cochlear duct, which separates them except at a small hole at the apex called the *helicotrema*. Part of the wall separating the cochlear duct from the tympanic canal is a flexible membrane called the *basilar membrane*. This membrane is narrower and stiffer nearer the oval window than it is nearer the helicotrema. The organ of Corti, the receptor organ that transduces the pressure changes to neural impulses, sits on the basilar membrane in the cochlear duct. It contains two groups of hair cells whose cilia project into the fluid in the cochlear duct and either touch or approach the tectorial membrane, which is inflexible. When fluid motion occurs in the inner ear, the basilar membrane vibrates, causing the cilia of the hair cells to be bent. It is this bending of the hair cells that initiates a neural signal. One group of hair cells, the inner cells, consists of a single row of approximately 3500 cells; the other group, the outer cells, is composed of approximately 12,000 hair cells arranged in three to five rows. The inner hair cells are mainly responsible for the transmission of sound information from the cochlea to the brain; the outer hair cells act as a cochlear amplifier, increasing the movement of the basilar membrane at frequencies contained in the sounds being received (Hackney, 2010). Permanent hearing loss most often is due to hair cell damage that results from excessive exposure to loud sounds or to certain drugs.

Sound causes a wave to move from the base of the basilar membrane, at the end near the oval window, to its apex. Because the width and thickness of the basilar membrane vary along its length, the magnitude of the displacement produced by this traveling wave at different locations will vary. For low-frequency sounds, the greatest movement is produced near the apex; as the frequency increases, the point of maximal displacement shifts toward the base. Thus, not only does the frequency with which the basilar membrane vibrates vary with the frequency of the auditory stimulus, but so does the location.

**Auditory Pathways** The auditory pathways after sensory transduction show many of the same properties as the visual pathways. The inner hair cells have synapses with the neurons that make up the auditory nerve. The neurons in the auditory nerve show frequency tuning. Each has a preferred or characteristic frequency that corresponds to the location on the basilar membrane of the hair cell from which it receives input but will fire less strongly to a range of frequencies about the preferred one. Neurons can be found with characteristic frequencies for virtually every frequency in the range of hearing. The contour depicting sensitivity of a neuron to different tone frequencies is called a *tuning curve*.

**Figure 11** Schematic of the cochlea uncoiled to show the canals. (From Schiffman, 1996.)

The tuning curves typically are broad, indicating that a neuron is sensitive to a broad range of values, but asymmetric: The sensitivity to frequencies higher than the characteristic frequency is much less than that to frequencies below it. With frequency held constant, there is a dynamic range over which as intensity is increased the neuron's firing rate will increase. This dynamic range is on the order of 25 dB, which is considerably less than the full range of intensities that we can perceive.

The first synapse for the nerve fibers after the ear is the cochlear nucleus, After that point, two separate pathways emerge that seem to have different roles, as in vision. Fibers from the anterior cochlear nucleus go to the superior olive, half to the contralateral side of the brain and half to the ipsilateral side, and then on to the inferior colliculus. This pathway is presumed to be involved in the analysis of spatial information. Fibers from the posterior cochlear nucleus project directly to the contralateral inferior colliculus. This pathway analyzes the frequency of the auditory stimulus. From the inferior colliculus, most of the neurons project to the medial geniculate and then to the primary auditory cortex. Frequency tuning is evident for neurons in all of these regions, with some neurons responding to relatively complex features of stimulation. The auditory cortex has a tonotopic organization, in which cells responsive to similar frequencies are located in close proximity, and contains

neurons tuned to extract complex information. As with vision, the signals from the auditory cortex follow two processing streams (Rauschecker, 2010). The posterior-dorsal stream analyzes *where* a sound is located, whereas the anterior-ventral stream analyzes *what* the sound represents.

### 3.2.2  Basic Auditory Perception

***Loudness and Detection of Sounds***   Loudness for audition is the equivalent of brightness for vision. More intense auditory stimuli produce greater amplitude of movement in the eardrum, which produces higher amplitude movement of the stapes on the oval window, which leads to bigger waves in the fluid of the inner ear and hence higher amplitude movements of the basilar membrane. Thus, loudness is primarily a function of the physical intensity of the stimulus and its effects on the ear, although as with brightness, it is affected by many other factors. The relation between judgments of loudness and intensity follows the power function

$$L = aI^{0.6}$$

where $L$ is loudness, $a$ is a constant, and $I$ is physical intensity.

Just as brightness is affected by the spectral properties of light, loudness is affected by the spectral properties of sound. Figure 12 shows *equal-loudness contours*

**Figure 12**  Equal-loudness contours. Each contour represents the sound pressure level at which a tone of a given frequency sounds as loud as a 1000-Hz tone of a particular intensity. (From Schiffman, 1996.)

for which a 1000-Hz tone was set at a particular intensity level and tones of other frequencies were adjusted to match its loudness. The contours illustrate that humans are relatively insensitive to low-frequency tones below approximately 200 Hz and, to a lesser extent, to high-frequency tones exceeding approximately 6000 Hz. The curves tend to flatten at high intensity levels, particularly in the low-frequency end, indicating that the insensitivity to low-frequency tones is a factor primarily at low intensity levels. This is why most audio amplifiers include a "loudness" switch for enhancing low-frequency sounds artificially when music is played at low intensities. The curves also show the maximal sensitivity to be in the range 3000–4000 Hz, which is critical for speech perception. The two most widely cited sets of equal-loudness contours are those of Fletcher and Munson (1933), obtained when listening through earphones, and of Robinson and Dadson (1956), obtained for free-field listening.

Temporal summation can occur over a brief period of approximately 200 ms, meaning that loudness is a function of the total energy presented for tones of this duration or less. The bandwidth (i.e., the range of the frequencies in a complex tone) is important for determining its loudness. With the intensity held constant, increases in bandwidth have no effect on loudness until a critical bandwidth is reached. Beyond the critical bandwidth, further increases in bandwidth result in increases in loudness.

Extraneous sounds in the environment can mask targeted sounds. This becomes important for situations such as work environments, in which audibility of specific auditory input must be evaluated with respect to the level of background noise. The degree of masking is dependent on the spectral composition of the target and noise stimuli. Masking occurs only from frequencies within the critical bandwidth. Of concern for human factors is that a masking noise will exert a much greater effect on sounds of higher frequency than on sounds of lower frequency. This asymmetry is presumed to arise primarily from the operation of the basilar membrane.

*Pitch Perception* Pitch is the qualitative aspect of sound that is a function primarily of the frequency of a periodic auditory stimulus. The higher the frequency, the higher the pitch. The pitch of a note played on a musical instrument is determined by what is called its *fundamental frequency*, but the note also contains energy at frequencies that are multiples of the fundamental frequency, called *harmonics* or *overtones*. Observers can resolve perceptually the lower harmonics of a complex tone but have more difficulty resolving the higher harmonics (Plomp, 1964). This is because the perceptual separation of the successive harmonics is progressively less as their frequency increases.

Pitch is also influenced by several factors in addition to frequency. A phenomenon of particular interest in human factors is that of the missing fundamental effect. Here, the fundamental frequency can be removed, yet the pitch of a sound remains unaltered. This suggests that pitch is based on the pattern of harmonics and not just the fundamental frequency. This phenomenon

allows a person's voice to be recognizable over the telephone and music to be played over low-fidelity systems without distorting the melody. The pitch of a tone also varies as a function of its loudness. Equal-pitch contours can be constructed much like equal-loudness contours by holding the stimulus frequency constant and varying its amplitude. Such contours show that as stimulus intensity increases, the pitch of a 3000-Hz tone remains relatively constant. However, tones whose frequencies are lower or higher than 3000 Hz show systematic decreases and increases in pitch, respectively, as intensity increases.

Two different theories were proposed in the nineteenth century to explain pitch perception. According to Ernest Rutherford's (1886) *frequency theory*, the critical factor is that the basilar membrane vibrates at the frequency of an auditory stimulus. This in turn gets transduced into neural signals at the same frequency such that the neurons in the auditory nerve respond at the frequency of the stimulus. Thus, according to this view, it is the frequency of firing that is the neural code for pitch. The primary deficiency of frequency theory is that the maximum firing rate of a neuron is restricted to about 1000 spikes/s. Thus, the firing rate of individual neurons cannot match the frequencies over much of the range of human hearing. Wever and Bray (1937) provided evidence that the range of the auditory spectrum over which frequency coding could occur can be increased by neurons that phase lock and then fire in volleys. The basic idea is that an individual neuron fires at the same phase in the cycle of the stimulus but not on every cycle. Because many neurons are responsive to the stimulus, some neurons will fire on every cycle. Thus, across the group of neurons, distinct volleys of firing will be seen that when taken together match the frequency of the stimulus. Phase locking extends the range for which frequency coding can be effective up to 4000–5000 Hz. However, at frequencies beyond this range, phase locking breaks down.

According to Hermann von Helmholtz's (1877) *place theory*, different places on the basilar membrane are affected by different frequencies of auditory stimulation. He based this proposal on his observation that the basilar membrane was tapered from narrow at the base of the cochlea to broad at its apex. This led him to suggest that it was composed of individual fibers, much like piano strings, that would resonate when the frequency of sound to which it was tuned occurred. The neurons that receive their input from a location on the membrane affected by a particular frequency would fire in its presence, whereas the neurons receiving their input from other locations would not. The neural code for frequency thus would correspond to the particular neurons that were being stimulated. However, subsequent physiological evidence showed that the basilar membrane is not composed of individual fibers.

Von Békésy (1960) provided evidence that the basilar membrane operates in a manner consistent with both frequency and place theory. Basically, he demonstrated that waves travel down the basilar membrane from the base to the apex at a frequency corresponding to that of the tone. However, because the width and thickness

of the basilar membrane vary along its length, the magnitude of the *traveling wave* is not constant over the entire membrane. The waves increase in magnitude up to a peak and then decrease abruptly. Most important, the location of the peak displacement varies as a function of frequency. Low frequencies have their maximal displacement at the apex; as frequency increases, the peak shifts systematically toward the oval window. Although most frequencies can be differentiated in terms of the place at which the peak of the traveling wave occurs, tones of less than 500–1000 Hz cannot be. Frequencies in this range produce a broad pattern of displacement, with the peak of the wave at the apex. Consequently, location coding does not seem to be possible for low-frequency tones. Because of the evidence that frequency and location coding both operate but over somewhat different regions of the auditory spectrum, it is now widely accepted that frequencies less than 4000 Hz are coded in terms of frequency and those above 500 Hz in terms of place, meaning that at frequencies within this range both mechanisms are involved.

### 3.3 Vestibular System and Sense of Balance

The vestibular system provides us with our sense of balance. It contributes to the perception of bodily motion and helps in maintaining an upright posture and the position of the eyes when head movements occur (Lackner, 2010). The sense organs for the vestibular system are contained within a part of the inner ear called the *vestibule*, which is a hollow region of bone near the oval window. The vestibular system includes the *otolith organs*, one called the *utricle* and the other the *saccule*, and three semicircular canals (see Figure 10). The otolith organs provide information about the direction of gravity and linear acceleration. The sensory receptors are hair cells lining the organs whose cilia are embedded in a gelatin-like substance that contains otoliths, which are calcium carbonate crystals. Tilting or linear acceleration of the head in any direction causes a shearing action of the otoliths on the cilia in the utricle, and vertical linear acceleration has the same effect in the saccule. The semicircular canals are placed in three perpendicular planes. They also contain hair cells that are stimulated when relative motion between the fluid inside them and the head is created and thus respond primarily to angular acceleration or deceleration in specific directions.

The vestibular ganglion contains the cell bodies of the afferent fibers of the vestibular system. The fibers project to the vestibular nucleus, where they converge with somatosensory, optokinetic, and motor-related input. These are reciprocally connected with the vestibulocerebellar cortex and nuclei in the cerebellum (Green and Angelaki, 2010). Two functions of the vestibular system, one static and one dynamic, can be distinguished. The *static function*, performed primarily by the utricle and saccule, is to monitor the position of the head in space, which is important in the control of posture. The *dynamic function*, performed primarily by the semicircular canals, is to track the rotation of the head in space. This tracking is necessary for reflexive control of what are called *vestibular eye movements*. If you maintain fixation on an object while rotating your head, the position of the eyes in the sockets will change gradually as the head moves. When your nose is pointing directly toward the object, the eyes will be centered in their sockets, but as you turn your head to the right, the eyes will rotate to the left, and vice versa as the head is turned to the right. These smooth, vestibular eye movements are controlled rapidly and automatically by the brain stem in response to sensing of the head rotation by the vestibular system.

Exposure to motions that have angular and linear accelerations substantially different from those normally encountered, as occurs in aircraft, space vehicles, and ships, can produce erroneous perceptions of attitude and angular motion that result in *spatial disorientation* (Benson, 1990). Spatial disorientation accounts for approximately 35% of all general aviation fatalities, with most occurring at night when visual cues are either absent or degraded and vestibular cues must be relied on heavily. The vestibular sense also is key to producing *motion sickness* (Kennedy et al., 2010). The dizziness and nausea associated with motion sickness are generally assumed to arise from a mismatch between the motion cues provided by the vestibular system, and possibly vision, with the expectancies of the central nervous system. The vestibular sense also contributes to the related problem of simulator sickness that arises when the visual cues in a simulator or virtual reality environment do not correspond well with the motion cues that are affecting the vestibular system (Draper et al., 2001).

### 3.4 Somatic Sensory System

The somatic sensory system is composed of four distinct modalities (Gardner et al., 2000). *Touch* is the sensation elicited by mechanical stimulation of the skin; *proprioception* is the sensation elicited by mechanical displacements of the muscles and joints; *pain* is elicited by stimuli of sufficient intensity to damage tissue; and *thermal sensations* are elicited by cool and warm stimuli. The receptors for these senses are the terminals of the peripheral branch of the axons of ganglion cells located in the dorsal root of the spinal cord. The receptors for pain and temperature, called *nociceptors* and *thermoreceptors*, are bare (or free) nerve endings. Three types of nociceptors exist that respond to different types of stimulation. Mechanical nociceptors respond to strong mechanical stimulation, thermal nociceptors respond to extreme heat or cold, and polymodal nociceptors respond to several types of intense stimuli. Distinct thermoreceptors exist for cold and warm stimuli. Those for cold stimuli respond to temperatures between 1 and $20°C$ below skin temperature, whereas those for warm stimuli respond to temperatures up to $13°C$ warmer than skin temperature,

The mechanoreceptors for touch have specialized endings that affect the dynamics of the receptor to stimulation. Some mechanoreceptor types are rapidly adapting and respond at the onset and offset of stimulation, whereas others are slow adapting and respond throughout the time that a touch stimulus is present. Hairy

skin is innervated primarily by hair follicle receptors. Hairless (glabrous) skin receives innervation from two types: Meissner's corpuscles, which are fast adapting, and Merkel's disks, which are slow adapting. Pacinian corpuscles, which are fast adapting, and Ruffini's corpuscles, which are slow adapting, are located in the dermis, subcutaneous tissue that is below both the hairy and glabrous skin.

The nerve fibers for the skin senses have a center-surround organization of the type found for vision. The receptive fields for the Meissner corpuscles and Ruffini disks are smaller than those for the Pacinian and Ruffini corpuscles, suggesting that the former provide information about fine spatial differences and the latter about coarse spatial differences. The density of mechanoreceptors is greatest for those areas of the skin, such as the fingers and lips, for which two-point thresholds (i.e., the amount of difference needed to tell that two points rather than one are being stimulated) are low. Limb proprioception is mediated by three types of receptors: mechanoreceptors located in the joints, muscle spindle receptors in muscles that respond to stretch, and cutaneous mechanoreceptors. The ability to specify limb positions decreases when the contribution of any of these receptors is removed through experimental manipulation.

The afferent fibers enter the spinal cord at the dorsal roots and follow two major pathways, the dorsal-column medial-lemniscal pathway and the anterolateral (or spinothalamic) pathway. The lemniscal pathway conveys information about touch and proprioception. It receives input primarily from fibers with corpuscles and transmits this information quickly. It ascends along the dorsal part of the spinal column, on the ipsilateral side of the body. At the brain stem, most of its fibers cross over to the contralateral side of the brain and project to the medial lemniscus in the thalamus and from there to the anterior parietal cortex. The fibers in the anterolateral pathway ascend along the contralateral side of the spinal column and project to the reticular formation, midbrain, or thalamus and then to the anterior parietal cortex and other cortical regions. This system is primarily responsible for conveying pain and temperature information.

The somatic sensory cortex is organized in a spatiotopic manner, much as is the visual cortex. That is, it is laid out in the form of a homunculus representing the opposite side of the body, with areas of the body for which sensitivity is greater, such as the fingers and lips, having relatively larger areas devoted to them. There are four different, independent spatial maps of this type in the somatic sensory cortex, with each map receiving its inputs primarily from the receptors for one of the four somatic modalities. The modalities are arranged into columns, with any one column receiving input from the same modality. When a specific point on the skin is stimulated, the population of neurons that receive innervation from that location will be activated. Each neuron has a concentric excitatory–inhibitory center-surround receptive field, the size of which varies as a function of the location on the skin. The receptive fields are smaller for regions of the body in which sensitivity

to touch is highest. Some of the cells in the somatic cortex respond to complex features of stimulation, such as movement of an object across the skin.

*Vibrotaction* has proven to be an effective way of transmitting complex information through the tactile sense (Verrillo and Gescheider, 1992). When mechanical vibrations are applied to a region of skin such as the tips of the fingers, the frequency and location of stimulation can be varied. For frequencies below 40 Hz, the size of the contactor area does not influence the absolute threshold for detecting vibration. For higher frequencies, the threshold decreases with increasing size of the contactor, indicating spatial summation of the energy within the stimulated region. Except for very small contactor areas, sensitivity reaches a maximum for vibrations of 200–300 Hz. A similar pattern of less sensitivity for low-frequency vibrations than for high-frequency vibrations is evident in equal sensation magnitude contours (Verrillo et al., 1969), much like the equal-loudness contours for audition. Because of the sensitivity to vibrotactile stimuli, it has been suggested that vibrotactile stimulation provided through the brake pedal of a vehicle may make an effective frontal collision warning system (de Rosario et al., 2010).

With multicontactor devices, which can present complex spatial patterns of stimulation, masking stimuli presented in close temporal proximity to the target stimulus can degrade identification (e.g., Craig, 1982), as in vision and audition. However, with practice, pattern recognition capabilities with these types of devices can become quite good. As a result, they can be used successfully as reading aids for the blind and to a lesser extent as hearing aids for the hearing impaired (Summers, 1992). Hollins et al. (2002) provide evidence that vibrotaction also plays a necessary and sufficient role in the perception of fine tactile textures.

A distinction is commonly made between active and passive touch (Gibson, 1966; Katz, 1989). *Passive touch* refers to situations in which a person does not move her or his hand, and the touch stimulus is applied passively, as in vibrotaction. *Active touch* refers to situations in which a person moves his or her hand intentionally to manipulate and explore an object. According to Gibson, active touch is the most common mode of acquiring tactile information in the real world and involves a unique perceptual system, which he called *haptics*. Pattern recognition with active touch typically is superior to that with passive touch (Appelle, 1991). However, the success of passive vibrotactile displays for the blind indicates that much information can also be conveyed passively. Passive and active touch can combine in a third type of touch, called *intra-active touch*, in which one body part is used to provide active stimulation to another body part, as when using a finger to roll a ball over the thumb (Bolanowski et al., 2004).

## 3.5 Gustation and Olfaction

Smell and taste are central to human perceptual experience. The taste of a good meal and the smell of perfume can be quite pleasurable. On the other hand, the taste of rancid potato chips or the smell of manure or of a paper mill can be quite noxious. In fact, odor

and taste are quite closely related, in that the taste of a substance is highly dependent on the odor it produces. This is evidenced by the changes in taste that occur when a cold reduces olfactory sensitivity. In human factors, both sensory modalities can be used to convey warnings. For example, ethylmercaptan is added to natural gas to warn of gas leaks because humans are quite sensitive to its odor. Also, as mentioned in Section 2.2.2, there is concern with environmental odors and their influence on people's moods and performance.

The sensory receptors for taste are groups of cells called *taste buds*. They line the walls of bumps on the tongue that are called *papillae*, as well as being located in the throat, the roof of the mouth, and inside the cheeks. Each taste bud is composed of several receptor cells in close arrangement. The receptor mechanism is located in projections from the top end of each cell that lie near an opening called a *taste pore*. Sensory transduction occurs when a taste solution comes in contact with the projections. The fibers from the taste receptors project to several nuclei in the brain and then to the insular cortex, located between the temporal and parietal lobes, and the limbic system.

In 1916, Henning proposed a taste tetrahedron in which all tastes were classified in terms of four primary tastes: sweet, sour, salty, and bitter. This categorization scheme has been accepted since then, although not without opposition. A fifth taste, umami, that of monosodium glutamate (MSG) and described as "savoriness," has also been suggested. People can identify this taste when the MSG is placed in water solutions, and they can also identify it in prepared foods after some training (Sinesio et al., 2009).

For smell, molecules in the air that are inhaled affect receptor cells located in the *olfactory epithelium*, a region of the nasal cavity. An *olfactory rod* extends from each receptor and goes to the surface of the epithelium. Near the end of the olfactory rod is a knob from which olfactory cilia project. These cilia are thought to be the receptor elements. Different receptor types apparently have different receptor proteins that bind the odorant molecules to the receptor. The axons from the smell receptors project to the olfactory bulb, located in the front of the brain, via the olfactory nerve. From there, the fibers project to a cluster of neural structures called the *olfactory brain*.

Olfaction shows several functional attributes (Engen, 1991). For one, a novel odor will almost always cause apprehension and anxiety. As a consequence, odors are useful as warnings. However, odors are not very effective at waking someone from sleep, which is illustrated amply by the need for smoke detectors that emit a loud auditory signal, even though the smoke itself has a distinctive odor. There also seems to be a bias to falsely detect the presence of odors and to overestimate the strength when the odor is present. Such a bias ensures that a miss is unlikely to occur when an odor signal is really present. The sense of smell shows considerable plasticity, with associations of odors to events readily learned and habituation occurring to odors of little consequence. Doty (2003) and Rouby

et al. (2002) provide detailed treatment of the perceptual and cognitive aspects of smell and taste.

## 4 HIGHER LEVEL PROPERTIES OF PERCEPTION

### 4.1 Perceptual Organization

The stimulus at the retina consists of patches of light energy that affect the photoreceptors. Yet we do not perceive patches of light. Rather, we perceive a structured world of meaningful objects. The organizational processes that affect perception go unnoticed in everyday life, until we encounter a situation in which we initially misperceive the situation in some way. When we realize this and our perception now is more veridical, we become aware that the organizational processes can be misled.

Perceptual organization is particularly important for the design of any visual display. If a symbol on a street sign is organized incorrectly, it may well go unrecognized. Similarly, if a warning signal is grouped perceptually with other displays, its message may be lost. The investigation of perceptual organization was initiated by a group of German psychologists called *Gestalt psychologists*, whose mantra was, "The whole is more than the sum of the parts." The demonstrations they provided to illustrate this point were sufficiently compelling that the concept is now accepted by all perceptual psychologists.

According to the Gestalt psychologists, the overriding principle of perceptual organization is that of *prägnanz*. The basic idea of this law is that the organizational processes will produce the simplest possible organization allowed by the conditions (Palmer, 2003). The first step in perceiving a figure requires that it be separated from the background. Any display that is viewed will be seen as a figure or figures against a background. The importance of *figure–ground* organization is illustrated clearly in figures with ambiguous figure–ground organizations, as in the well-known Ruben's vase (see Figure 13). Such figures can be organized with either the light region or the dark region seen as the figure. When a region is seen as the figure, the contour appears to be part of it. Also, the region seems to be in front of the background and takes on a distinct form. When the organization changes so that the region is now seen as the ground, its perceived relation with the other region reverses.

Clearly, when designing displays, one wants to construct them such that the figure–ground organization of the observer will correspond with what is intended. Fortunately, research has indicated factors that influence figure–ground organization. Symmetric patterns tend to be seen as the figure over asymmetric ones; a region that is surrounded completely by another tends to be seen as the figure and the surrounding region as the background; convex contours tend to be seen as the figure in preference to concave contours; the smaller of two regions tends to be seen as the figure and the larger as the ground; and a region oriented vertically or
**Figure 13** Ruben's vase, for which two distinct figure–ground organizations are possible. (From Schiffman, 1996.)

**Figure 14** Gestalt organizational principles. (From Proctor and Van Zandt, 2008.)

horizontally will tend to be seen as the figure relative to one that is not so oriented.

In addition to figure–ground segregation being crucial to perception, the way that the figure is organized is important as well (see Figure 14). The most widely recognized *grouping principles* are *proximity*, display elements that are located close together will tend to be grouped together; *similarity*, display elements that are similar in appearance (e.g., orientation or color) will tend to be grouped together; *continuity*, figures will tend to be organized along continuous contours; *closure*, display elements that make up a closed figure will tend to be grouped together; and *common fate*, elements with a common motion will tend to be grouped together. Differences in orientation of stimuli seem to provide a particularly distinctive basis for grouping. As illustrated in Figure 15, when stimuli differ in orientation, those of like orientation are grouped and perceived separately from those of a different orientation. This relation lies behind the customary recommendation that displays for check reading be designed so that the pointers on the dials all have the same orientation when working properly. When something is not right, the pointer on the dial will be at an orientation different from that of the rest of the pointers, and it will "jump out" at the operator.

Two additional grouping principles (see Figure 14) were described by Rock and Palmer (1990). The principle of connectedness is that lines drawn between some elements but not others will cause the connected elements to be grouped perceptually. The principle of common region is that a contour drawn around display elements will cause those elements to be grouped together. Palmer (1992) has demonstrated several important properties of grouping by common region. When multiple, conflicting regions are present, the smaller enclosing

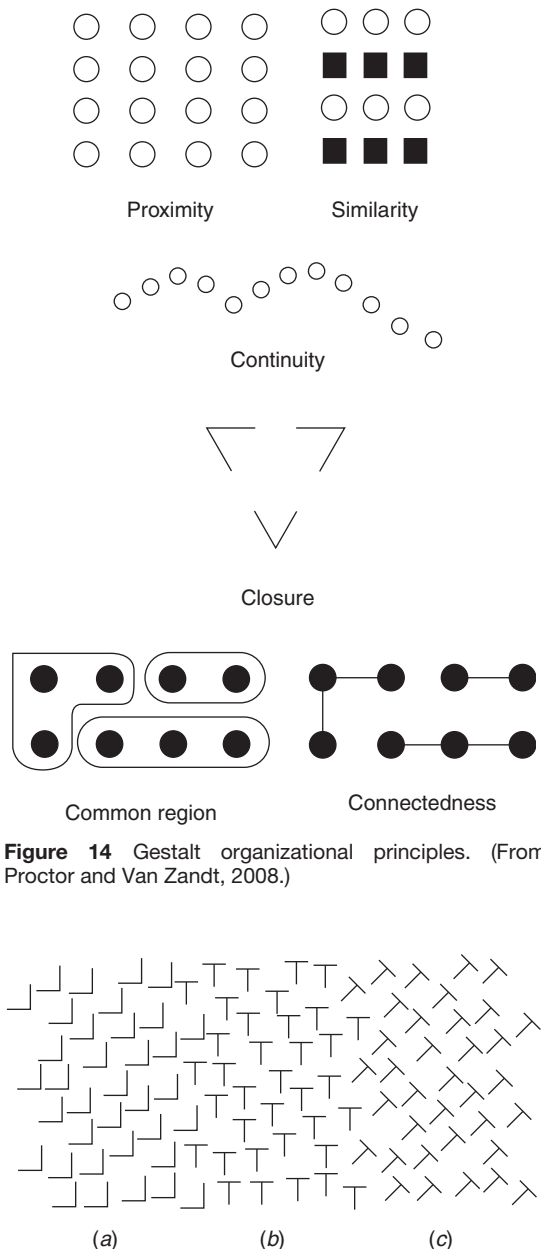

**Figure 15** Tilted-T group appears more distinct from upright T's than do backward-L characters.

region seems to dominate the organization; for nested, consistent regions, the organization appears to be hierarchical. Grouping by common region breaks down when the elements and background region are at different perceived depths, as does grouping by proximity (Rock and Brosgole, 1964), suggesting that such grouping occurs relatively late in processing, after at least some depth perception has occurred.

Although most work on perceptual organization has been conducted with visual stimuli, there are numerous demonstrations where the principles apply as well to auditory stimuli (Julesz and Hirsh, 1972). Grouping by similarity is illustrated in a study by Bregman and Rudnicky (1975) in which listeners had to indicate which of two tones of different frequency occurred first in a sequence. When the two tones were presented in isolation, performance was good. However, when preceded and followed by a single occurrence of a distractor tone of lower frequency, performance was relatively poor. The important finding is that when several occurrences of the distractor tone preceded and followed the critical pair, performance was just as good as when the two tones were presented in isolation. Apparently, the distractor tones were grouped as a distinct auditory stream based on their frequency similarity. Grouping of tones occurs not only with respect to frequency but also on the basis of similarities of their spatial positions, similarities in the fundamental frequencies and harmonics of complex tones, and so on (Bregman, 1990, 1993). Based on findings that the two-tone paradigm often yields instability of streaming under conditions that should be biased toward a particular organization, Denham et al. (2010) concluded that auditory perception is inherently multistable, but rapid switches of attention back to the dominant organization yield the experience of stability.

Another distinction that has received considerable interest over the past 35 years is that between *integral* and *separable* stimulus dimensions (Garner, 1974). The basic idea is that stimuli composed from integral dimensions are perceived as unitary wholes, whereas stimuli composed from separable dimensions are perceived in terms of their distinct dimensions. The operations used to distinguish between integral and separable dimensions are that (1) direct similarity scaling should produce a Euclidean metric for integral dimensions (i.e., the psychological distance between two stimuli should be the square root of the sum of the squares of the differences on each dimension) and a city-block metric for separable dimensions (i.e., the psychological distance should be the sum of the differences on the two dimensions); and (2) in free perceptual classification tasks, stimuli from sets with integral dimensions should be classified together if they are close in terms of the Euclidean metric (i.e., in overall similarity), whereas those from sets with separable dimensions should be classified in the same category if they match on one of the dimensions (i.e., the classifications should be in terms of dimensional structure; Garner, 1974). Perhaps most important for human factors, speed of classification with respect to one dimension is unaffected by its relation to the other dimension if the dimensions are separable but shows strong dependencies if they are integral. For integral dimensions, classifications are slowed when the value of the irrelevant dimension is uncorrelated with the value of the relevant dimension but speeded when the two dimensions are correlated.

Based on these criteria, dimensions such as hue, saturation, and lightness, in any combination, or pitch and loudness have been classified as integral; size and lightness or size and angle are classified as separable

**Figure 16** Configural dimensions. The bracket context helps in discriminating the line whose slope is different from the rest.

(e.g., Shepard, 1991). A third classification, called *configural dimensions* (Pomerantz, 1981), has been proposed for dimensions that maintain their separate codes but have a new relational feature that emerges from their specific configuration. For example, as illustrated in Figure 16, a diagonally oriented line can be combined with the context of two other lines to yield an emergent triangle. Configural dimensions behave much like integral dimensions in speeded classification tasks, although the individual dimensions are still relatively accessible. Potts et al. (1998) presented evidence that the distinction between interacting (integral and configural) and noninteracting (separable) dimensions may be oversimplified. They found that with some instructions and spatial arrangements the dimensions of circle size and tilt of an enclosed line behaved as if they were separable, whereas under others they behaved as if they were integral. Thus, Potts et al. suggest that specific task contexts increase or decrease the salience of dimensional structures and may facilitate or interfere with certain processing strategies.

Wickens and his colleagues have extended the distinction between interactive dimensions (integral and configural) and separable dimensions to display design by advocating what they call the *proximity compatibility principle* (e.g., Wickens and Carswell, 1995). This principle states that if a task requires that information be integrated mentally (i.e., processing proximity is high), that information should be presented in an integral or integrated display (i.e., one with high display proximity). High display proximity can be accomplished by, for example, increasing the spatial proximity of the display elements, integrating the elements so that they appear as a distinct object, or combining them in such a way as to yield a new configural feature. The basic idea is to replace the cognitive computations that the operator must perform to combine the separate pieces of information with a much less mentally demanding pattern recognition process. The proximity compatibility principle also implies that if a task requires that the information be kept distinct mentally (i.e., processing proximity is low), the information should be presented in a display with separable dimensions (i.e., one with low display proximity). However, the cost of high display proximity for tasks that do not require integration of displayed information is typically much less than that associated with low display proximity for tasks that do require information integration.

## 4.2 Spatial Orientation

We live in a three-dimensional world and hence must be able to perceive locations in space relatively accurately

if we are to survive. Many sources of information come into play in the perception of distance and spatial relations (Proffitt and Caudek, 2003), and the consensus view is that the perceptual system constructs the three-dimensional representation using this information as cues.

### 4.2.1  Visual Depth Perception

Vision is a strongly spatial sense and provides us with the most accurate information regarding spatial location. In fact, when visual cues regarding location conflict with those from the other senses, the visual sense typically wins out, a phenomenon called *visual dominance*. There are several areas of human factors in which we need to be concerned about visual depth cues. For example, accurate depth cues are crucial for situations in which navigation in the environment is required; misleading depth cues at a landing strip at an airfield may cause a pilot to land short of the runway. For another, a helmet-mounted display, viewed through a monocle, will eliminate binocular cues and possibly provide information that conflicts with that seen by the other eye. As a final example, it may be desired that a simulator depict three-dimensional relations relatively accurately on a two-dimensional display screen.

One distinction that can be made is between oculomotor cues and visual cues. The *oculomotor cues* are accommodation and vergence angle, both of which we discussed earlier in the chapter. At relatively close distances, vergence and accommodation will vary systematically as a function of the distance of the fixated object from the observer. Therefore, either the signal sent from the brain to control accommodation and vergence angle or feedback from the muscles could provide cues to depth. However, Proffitt and Caudek (2003) conclude that neither oculomotor cue is a particularly effective cue for perceiving absolute depth and both are easily overridden when other depth cues are available.

*Visual cues* can be partitioned into binocular and monocular cues. The binocular cue is *retinal disparity*, which arises from the fact that the two eyes view an object from different locations. An object that is fixated falls on corresponding points of the retinas. This object can be regarded as being located on an imaginary curved plane, called the *horopter*; any other object that is located on this plane will also fall on corresponding points. For objects that are not on the horopter, the images will fall on disparate locations of the retinas. The direction of disparity, uncrossed or crossed (i.e., whether the image from the right eye is located to the right or left of the image from the left eye), is a function of whether the object is in back of or in front of the horopter, respectively, and the magnitude of disparity is a function of how far the object is from the horopter. Thus, retinal disparity provides information with regard to the locations of objects in space with respect to the surface that is being fixated.

The first location in the visual pathway at which neurons are sensitive to disparity differences is the primary visual cortex. However, Parker (2007) emphasizes that "generation of a full, stereoscopic depth percept is a multi-stage process that involves both dorsal and ventral cortical pathways . . . . Both pathways may contribute to perceptual judgements about stereo depth, depending on the task presented to the visual system" (p. 389).

Retinal disparity is a strong cue to depth, as witnessed by the effectiveness of three-dimensional (3D) movies and stereoscopic static pictures, which are created by presenting slightly different images to the two eyes to create disparity cues. Anyone who has seen any of the recent spate of 3D movies realizes how compelling these effects can be. They are sufficiently strong that 3D is now being incorporated into home television and entertainment systems. In addition to enhancing the perception of depth relations in displays of naturalistic scenes, stereoptic displays may be of value in assisting scientists and others in evaluating multidimensional data sets. Wickens et al. (1994) found that a three-dimensional data set could be processed faster and more accurately to answer questions that required integration of the information if the display was stereoptic than if it was not.

The fundamental problem for theories of stereopsis is that of matching. Disparity can be computed only after corresponding features at the two eyes have been identified. When viewing the natural world, each eye receives the information necessary to perceive contours and identify objects, and stereopsis could occur after monocular form recognition. However, one of the more striking findings of the past 40 years is that there do not have to be contours present in the images seen by the individual eyes in order to perceive objects in three dimensions. This phenomenon was discovered by Julesz (1971), who used random-dot stereograms in which a region of dot densities is shifted slightly in one image relative to the other. Although a form cannot be seen if only one of the two images is viewed, when each of the two images is presented to the respective eyes, a three-dimensional form emerges. Random-dot stereograms have been popularized recently through figures that utilize the autostereogram variation of this technique, in which the disparity information is incorporated in a single, two-dimensional display. That stereopsis can occur with random-dot stereograms suggests that matching of the two images can be based on dot densities.

There are many static, or pictorial, monocular cues to depth. These cues are such that people with only one eye and those who lack the ability to detect disparity differences are still able to interact with the world with relatively little loss in accuracy. The monocular cues include retinal size (i.e., larger images appear to be closer) and familiar size (e.g., a small image of a car provides a cue that the car is far away). The cue of interposition refers to an object that appears to block part of the image of another object located in front of it. Although interposition provides information that one object is nearer than another, it does not provide information about how far apart they are. Another cue comes from shading. Because light sources typically project from above, as with the sun, the location of a shadow provides a cue to depth relations. A darker shading at the bottom of a region implies that the region

is elevated, whereas one at the top of a region provides a cue that it is depressed. Aerial perspective refers to blue coloration, which appears for objects that are far away, such as is seen when viewing a mountain at a distance. Finally, the cue of linear perspective occurs when parallel lines receding into the distance, such as train tracks, converge to a point in the image.

Gibson (1950) emphasized the importance of texture gradient, which is a combination of linear perspective and relative size, in depth perception. If one looks at a textured surface such as a brick walkway, the parts of the surface (i.e., the bricks) become smaller and more densely packed in the image as they recede into the distance. The rate of this change is a function of the orientation of the surface in depth with respect to the line of sight. This texture change specifies distance on the surface, and an image of a constant size will be perceived to come from a larger object that is farther away if it occludes a larger part of the texture. Certain color gradients, such as a gradual change from red to gray, provide effective cues to depth as well (Truscianko et al., 1991).

For a stationary observer, there are plenty of cues to depth. However, cues become even richer once the observer is allowed to move. When you maintain fixation on an object and change locations, as when looking out a train window, objects in the background will move in the same direction in the image as you are moving, whereas objects in the foreground will move in the opposite direction. This cue is called *motion parallax*. When you move straight ahead, the optical flow pattern conveys information about how fast your position is changing with respect to objects in the environment. There are also numerous ways in which displays with motion can generate depth perception (Braunstein, 1976).

Of particular concern for human factors is how the various depth cues are integrated. Bruno and Cutting (1988) varied the presence or absence of four cues: relative size, height in the projection plane, interposition, and motion parallax. They found that the four cues combined additively in one direct and two indirect scaling tasks. That is, each cue supported depth perception, and the more cues that were present, the more depth was revealed. Bruno and Cutting interpreted these results as suggesting that a separate module processes each source of depth information. Landy et al. (1995) have developed a detailed model of this general nature, according to which interactions among depth cues occur for the purpose of establishing for each cue a map of absolute depth throughout the scene. The estimate of depth at each location is determined by taking a weighted average of the estimates provided by the individual cues.

Because the size of the retinal image of an object varies as a function of the distance of the object from the observer, perception of size is intimately related to perception of distance. When accurate depth cues are present, good *size constancy* results. That is, the perceived size of the object does not vary as a function of the changes in retinal image size that accompany changes in depth. One implication of this view is

**Figure 17**  Ponzo illusion. The top circle appears larger than the lower circle, due to the linear perspective cue.

that size and shape constancy will break down and illusions appear when depth cues are erroneous. There are numerous illusions of size, such as the Ponzo illusion (see Figure 17), in which one of two stimuli of equal physical size appears larger than another, due at least in part to misleading depth cues. Misperceptions of size and distance also can arise when depth cues are minimal, as when flying at night.

### 4.2.2  Sound Localization

The cues for sound localization on the horizontal dimension involve disparities at the two ears, much as disparities of the images at the two eyes are cues to depth. Two different sources of information, interaural intensity and time differences, have been identified (Yost, 2010). Both of these cues vary systematically with respect to the position of the sound relative to the listener. At the front and back of the listener, the intensity of the sound and the time at which it reaches the ears will be equal. As the position of the sound along the azimuth (i.e., relative to the listener's head) is moved progressively toward one side or the other, the sound will become increasingly louder at the ear closest to it relative to the ear on the opposite side, and it also will reach the ipsilateral ear first. The interaural intensity differences are due primarily to a sound shadow created by the head. Because the head produces no shadow for frequencies less than 1000 Hz, the intensity cue is most effective for relatively high frequency tones. In contrast, interaural time differences are most effective for low-frequency sounds. Localization accuracy is poorest for tones between 1200 and 2000 Hz, because neither the intensity nor time cue is very effective in this intermediate-frequency range (Yost, 2010).

Both the interaural intensity and time difference cues are ambiguous because the same values can be produced by stimuli in more than one location. To locate sounds in the vertical plane and to distinguish whether the sound

is in front of or behind the listener, spectral alterations in the sound wave caused by the outer ears, head, and body (collectively called a head-related transfer function) must be relied on. Because these cues vary mainly for frequencies above 6000 Hz (Yost, 2010), front–back and vertical-location confusions of brief sounds will often occur. Confusions are relatively rare in the natural world because head movements and reflections of sound make the cues less ambiguous than they are in the typical localization experiment (e.g., Guski, 1990; Makous and Middlebrooks. 1990). As with vision, misleading cues can cause erroneous localization of sounds. Caelli and Porter (1980) illustrated this point by having listeners in a car judge the direction from which a siren occurred. Localization accuracy was particularly poor when all but one window were rolled up, which would alter the normal relation between direction and the cues.

## 4.3 Eye Movements and Motion Perception

Because details can be perceived well only at the fovea, the location on which the fovea is fixated must be able to be changed regularly and rapidly if we are to maintain an accurate perceptual representation of the environment and to see the details of new stimuli that appear in the peripheral visual field. Such changes in fixation can be brought about by displacement of the body, movements of the head, eye movements, or a combination of the three. Each eye has attached to it a set of extraocular muscle pairs: medial and lateral rectus, superior and inferior rectus, and superior and inferior obliques. Each pair controls a different axis of rotation, with the two members of the pairs acting antagonistically. Fixation is maintained when all of the muscles are active to similar extents. However, even in this case there is a continuous tremor of the eye as well as slow drifts that are corrected with compensatory micromovements, causing small changes in position of the image on the retina. Because the visual system is insensitive to images that are stabilized on the retina, such as the shadows cast by the blood vessels that support the retinal neurons, this tremor prevents images from fading when fixation is maintained on an object for a period of time.

Two broad categories of eye movements are of deepest concern. *Saccadic eye movements* involve a rapid shift in fixation from one point to another. Typically, up to three saccadic movements will be made each second (Kowler and Coolewijn, 2010). Saccadic movements can be initiated automatically by the abrupt onset of a stimulus in the peripheral visual field or voluntarily. The latency of initiation typically is on the order of 200 ms, and the duration of movement less than 100 ms. One of the more interesting phenomena associated with these eye movements is that of saccadic suppression, which is reduced sensitivity to visual stimulation during the time that the eye is moving. Saccadic suppression does not seem to be due to the movement of the retinal image being too rapid to allow perception or to masking of the image by the stationary images that precede and follow the eye movement. Rather, it seems to have a neurological basis. The loss of sensitivity is much less for high-spatial-frequency

gratings of light and dark lines than for low-spatial-frequency gratings and is absent for colored edges (Burr et al., 1994). Because lesioning studies suggest that the low spatial frequencies are conveyed primarily by the magnocellular pathway, this pathway is probably the locus of saccadic suppression.

*Smooth pursuit movements* are those made when a moving stimulus is tracked by the eyes. Such movements require that the direction of motion of the target be decoded by the system in the brain responsible for eye movements. This information must be integrated with cognitive expectancies and then translated into signals that are sent to the appropriate members of the muscle pairs of both eyes, causing them to relax and contract in unison and the eyes to move to maintain fixation on the target. Pursuit is relatively accurate for relatively slow moving targets, with increasingly greater error occurring as movement speed increases.

Eye movement records provide precise information about where a person is looking at any time. Such records have been used to obtain evidence about strategies for determining where successive saccades are directed when scanning a visual scene and about the extraction of information from the display (see Abernethy, 1988, for a review). Because direction of gaze can be recorded online by appropriate eye-tracking systems, eye gaze computer interface controls have considerable potential applications for persons with physical disabilities and for high-workload tasks (e.g., Goldberg and Schryver, 1995). It is tempting to equate direction of fixation with direction of attention, and in many cases that may be appropriate. However, there is considerable evidence that attention can be directed to different locations in space while fixation is held constant (e.g., Sanders and Houtmans, 1985), indicating that direction of fixation and direction of attention are not always one and the same.

Movements of our eyes, head, and body produce changes in position of images on the retina, as does motion of an object in the environment. How we distinguish between motion of objects in the world and our own motion has been an issue of concern for many years (Crapse and Sommer, 2008). We have already seen that many neurons in the visual cortex are sensitive to motion across the retina. However, detecting changes in position on the retina is not sufficient for motion perception, because those changes could be brought about by our own motion, motion of an object, or a combination of the two. Typically, it has been assumed that the position of the eyes is monitored by the brain, and any changes that can be attributed to eye movements are taken into account. According to inflow theory, first suggested by Sherrington (1906), it is the feedback from the muscles controlling the eyes that is monitored. According to outflow theory, first proposed by Helmholtz (1909), it is the command to the eyes to move (referred to as efference copy or corollary discharge) that is monitored. Evidence, such as that the scene appears to move when an observer who has been paralyzed tries to move her or his eyes (which do not actually move; Stevens et al., 1976; Matin et al., 1982), has tended to support the outflow theory. Crapse and Sommer (2008) present evidence that

corollary discharge is important for many aspects of perception when a person (or other organism) is moving through the world because it allows predictions of consequences of one's own movements. In their words, "CD (corollary discharge) contributes to sensorimotor harmony as primates interact with the world" (p. 552).

Sensitivity to motion is affected by many factors. For one, motion can be detected at a slower speed if a comparison, stationary object is also visible. When a reference object is present, changes of as little as $0.03°$ per second can be perceived (Palmer, 1986). However, this gain in sensitivity for detecting relative motion is at the potential cost of attributing the motion to the wrong object. For example, it is common for movement of a large region that surrounds a smaller object to be attributed to the object, a phenomenon that is called *induced motion* (Mack, 1986). The possibility for misattribution of motion is a concern for any situation in which one object is moving relative to another.

Induced motion is one example of a phenomenon in which motion of an object is perceived in the absence of motion of its image on the retina. The phenomenon of apparent, or stroboscopic, motion is probably the most important of these. This phenomenon of continuous perceived motion occurs when discrete changes in position of stimulation on the retina take place at appropriate temporal and spatial separations. It appears to be attributable to two processes, a short-range process and a long-range process (Petersik, 1989). The short-range process is presumed to reflect relatively low-level directionally sensitive neurons that respond to small spatial changes that occur with short interstimulus intervals. The long-range process is presumed to reflect higher level processes and to respond to stimuli at relatively large retinal separations presented at interstimulus intervals as long as 500 ms. Apparent motion is responsible not only for the motion produced in flashing signs but also for motion pictures and television, in which a series of discrete images is presented.

## 4.4 Pattern Recognition

The organizational principles and depth cues determine form perception, that is, what shapes and objects will be perceived. However, for the information in a display to be conveyed accurately, the objects must be recognized. If there are words, they must be read correctly; if there is a pictograph, the pictograph must be interpreted accurately. In other words, good use of the organizational principles and depth cues by a designer does not ensure that the intended message will be conveyed to the observer.

Concern with the way in which stimuli are recognized and identified is the domain of pattern recognition. Much research on pattern recognition has been conducted with verbal stimuli. The initial step in pattern recognition is typically presumed to be feature analysis. If visual, alphanumeric characters are presented, they are assumed to be analyzed in terms of features such as a vertical line segment, a horizontal line segment, and so on. Such an assumption is generally consistent

with the evidence that neurons in the primary visual cortex respond to specific features of stimulation. Evidence indicates that detection of features provides the basis for letter recognition (Pelli et al., 2006). Confusion matrices obtained when letters are misidentified indicate that an incorrect identification is most likely to involve a letter with considerable feature overlap with the one that was actually displayed (e.g., Townsend, 1971). Detailed evaluations of the features show that line terminations (e.g., the lower termination of *C* vs. *G*) and horizontal lines are most important for letter identification (Fiset et al., 2009).

Letters are composed of features, but they in turn are components of the letter patterns that form syllables and words (see Figure 18). The role played by letter-level information in visual word recognition has been the subject of considerable debate. Numerous findings have suggested that in at least some cases letter-level information is not available prior to word recognition. For example, Healy and colleagues have found that when people perform a letter detection task while reading a prose passage, the target letter is missed more often when it occurs in a very high frequency word such as *the* than when it appears in lower frequency words (e.g., Healy, 1994; Proctor and Healy, 1995). Their results have shown that this "missing-letter" effect is not just due to skipping over the words while reading. To explain these and other results, Greenberg et al. (2004) proposed a guidance-organization model of reading, which has the following properties: Unitization processes facilitate identification of function words

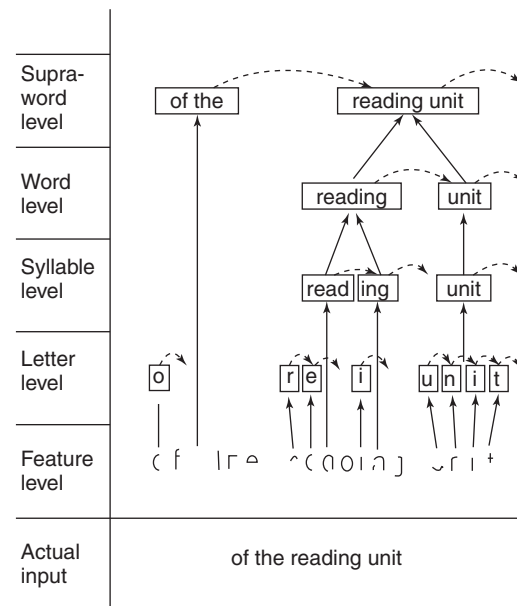

**Figure 18** Levels of representation in reading a short passage of text. Operation of the unitization hypothesis is illustrated by the bypassing of levels that occurs for "of the." (From Healy, 1994.)

that operate as cues for the structural organization of the sentence; this organization then directs attention to the content words, allowing semantic analysis and integration of meaning. In contrast to the unitization hypothesis, Pelli et al. (2003, 2006) have found that a word in isolation cannot be identified unless its letters are separately identifiable and the difficulty in identification of even common words can be predicted from the difficulties in identifying the individual letters. This has led them to conclude that people identify words as letter combinations and, even more broadly, that "everything seen is a pattern of features" (Pelli et al., 2003, p. 752).

The primary emphasis in the accounts just described is on bottom-up processing from the sensory input to recognition of the pattern, but pattern recognition is also influenced by top-down, nonvisual information of several types (Massaro and Cohen, 1994). These include orthographic constraints on the spelling patterns, regularities in the mapping between spelling and spoken sounds, syntactic constraints regarding which parts of speech are permissible, semantic constraints based on coherent meaning, and pragmatic constraints derived from the assumption that the writer is trying to communicate effectively. Interactive activation models, in which lower level sources of information are modified by higher levels, have been popular (e.g., McClelland and Rumelhart, 1981). However, Massaro and colleagues (e.g., Massaro and Cohen, 1994) have been successful in accounting for a range of reading phenomena with a model, which they call the *fuzzy logical model* of perception, in which the multiple sources of information are assumed to be processed independently, rather than interactively, and then integrated.

Reading can be viewed as a prototypical pattern recognition task. The implications of the analysis of reading are that multiple sources of information, both bottom up and top down, are exploited. For accurate pattern recognition, the possible alternatives need to be physically distinct and consistent with expectancies created by the context. More complex than reading, applied tasks such as identifying unwanted activity from computer log files involve pattern recognition, and the difficulty of these tasks can be minimized by taking pattern recognition accounts when displaying the information that goes into the log files.

## 5 SUMMARY

In this chapter we have reviewed much of what is known about sensation and perception. Any such review must necessarily exclude certain topics and be limited in the treatment given to the topics that are covered. Mather (2011) provides an accessible overview of sensation and perception that assumes no prior background, and excellent introductory texts that provide more thorough coverage include Schiffman (2001), Goldstein (2010), Sekuler and Blake (2006), and Wolfe et al. (2009). More advanced treatments of most areas are included in Volume 1 of *Stevens' Handbook of Experimental Psychology* (Pashler and Yantis, 2002) and Volume 1

of *Handbook of Perception and Human Performance* (Boff et al., 1986). *Engineering Data Compendium: Human Perception and Performance* (Boff and Lincoln, 1988) is an excellent, although now somewhat dated, resource for information pertinent to many human engineering concerns. Also, throughout the text we have provided references to texts and review articles devoted to specific topics. These and related sources should be consulted to get an in-depth understanding of the relevant issues pertaining to any particular application involving perception.

Virtually all concerns in human factors and ergonomics involve perceptual issues to at least some extent. Whether dealing with instructions for a consumer product, control rooms for chemical processing or nuclear power plants, interfaces for computer software, guidance of vehicles, office design, and so on, information of some type must be conveyed to the user or operator. To the extent that the characteristics of the sensory systems and the principles of perception are accommodated in the design of displays and the environments in which the human must work, the transmission of information to the human will be fast and accurate and the possibility for injury low. To the extent that they are not accommodated, the opportunity for error and the potential for damage are increased.

# CHAPTER 4

# SELECTION AND CONTROL OF ACTION

**Robert W. Proctor**
**Purdue University**
**West Lafayette, Indiana**

**Kim-Phuong L. Vu**
**California State University–Long Beach**
**Long Beach, California**

*Psychology's search for quantitative laws that describe human behavior is long-standing, dating back to the 1850s. A few notable successes have been achieved, including Fitts's law (1954) and the Hick–Hyman law (Hick, 1952; Hyman, 1953).*

Delaney et al. (1998)

## 1  INTRODUCTION

Research on selection and control of action has a long history, dating to at least the middle of the nineteenth century. Modern-day research in this area has developed contemporaneously with that on human factors and ergonomics (Proctor and Vu, 2010a). Influential works in both areas appeared in the period following World War II, and in many instances, people who played important roles in the development of human factors and ergonomics also made significant contributions to our understanding of selection and control of action. Two such contributions are those alluded to in the opening quote from Delaney et al. (1998), the Hick–Hyman law and Fitts's law, involving selection and control of action, respectively, which are among the few well-established quantitative laws of behavior.

Paul M. Fitts, for whom Fitts's law is named, was perhaps the most widely known of those who made significant contributions to the field of human factors and ergonomics and to basic research on human performance (Pew, 1994). He headed the Psychology Branch of the U.S. Army Airforce Aeromedical Laboratory at its founding in 1945 and is honored by a teaching award in his name given annually by the Human Factors and Ergonomics Society. Although Fitts's primary goal was the design of military aircraft and other machines to accommodate the human operator, he fully appreciated that this goal could only be accomplished against a background of knowledge of basic principles of human performance established under controlled laboratory conditions. Consequently, Fitts made many lasting empirical and theoretical contributions to knowledge concerning selection and control of action, including the quantitative law that bears his name and the principle of stimulus–response (SR) compatibility, both of which are discussed in this chapter.

Since the groundbreaking work of Fitts and others in the 1950s, much research has been conducted on selection and control of action under the headings of human performance, motor learning and control, and motor behavior, among others. Indeed, the relation between perception and action is a very active area of research in psychology and associated fields [see, e.g., the special issue of *Psychological Research* devoted to cognitive control of action (Nattkemper and Ziessler, 2004)]. In the present chapter we review some of the major findings, principles, and theories concerning selection and control of action that are relevant to designing for human use.

## 2 SELECTION OF ACTION

### 2.1 Methods

Selection of action is most often studied in choice–reaction tasks, in which a set of stimulus alternatives is mapped to a set of responses. On each trial, one or more stimuli appear and a response is to be made based on task instructions. Simple responses such as keypresses are typically used because the intent is to study the central decisions involved in selecting actions, not the motoric processes involved in executing the actions. In a choice–reaction study, response time (RT) is characteristically recorded as the primary dependent measure and error rate as a secondary measure. Among the methods used to interpret the RT data are the additive factors method and related ones that allow examination of the selective influence of variables on various processes (Sternberg, 1998). Analyses based on these methods have suggested that the primary variables affecting the duration of action selection, or response selection, processes include SR uncertainty, SR compatibility, response precuing, and sequential dependencies (Sanders, 1998). Analyses of measures in addition to mean RT and percentage of error, including RT distributions, specific types of errors that are made, and psychophysiological/neuroimaging indicators of brain functions, can also be used to obtain information about the nature of action selection.

One well-established principle of performance in choice–reaction tasks, as well as of any tasks for which speeded responses are required, is that speed can be traded for accuracy (Pachella, 1974). The speed–accuracy trade-off function (see Figure 1) can be captured by sequential sampling models of response selection, according to which information accumulates over time after stimulus onset in a later decision stage until a decision is reached (Busemeyer and Diederich, 2010). One class of such models, race models, assume that there is a separate decision unit, or counter, for each response, with the response that is ultimately selected being the one for the counter that "wins the race" and reaches threshold first (e.g., Van Zandt et al., 2000). One point of sequential sampling models is that action selection is a function of both the quality of the stimulus information, which affects the rate at which the information accumulates, and the level of the response thresholds, which is affected by instructions and other factors. Speed–accuracy trade-off methods in which subjects are induced to adopt different speed–accuracy criteria in different trial blocks, or in which biases toward one response category or another are introduced, can be used to examine details of the choice process (e.g., Band et al., 2003).

Many situations outside the laboratory require performance of multiple tasks, either in succession or concurrently. Choice RT methods can be used not only to examine action selection for single-task performance but also for conditions in which two or more task sets must be maintained, and the person is required to switch between the various tasks periodically or to perform the tasks concurrently. Because considerable research on action selection has been conducted using both single

**Figure 1** Speed–accuracy trade-off. Depending on instructions, payoffs, and other factors, when a person must choose a response to a stimulus, he or she can vary the combination of response speed and accuracy between the extremes of very fast with low accuracy or very slow with high accuracy.

and multiple tasks, we cover single- and multiple-task performance separately.

### 2.2 Action Selection in Single-Task Performance

#### 2.2.1 Uncertainty and Number of Alternatives: Hick–Hyman Law

Hick (1952) and Hyman (1953), following up on much earlier work by Merkel (1885; described in Woodworth, 1938), conducted studies showing a systematic increase in choice RT as the number of SR alternatives increased. Both Hick and Hyman were interested in whether effects of SR uncertainty could be explained in terms of information theory, which Shannon (1948) had recently developed in the field of communication engineering. Information theory provides a metric for information transmission in bits (binary digits), with the number of bits conveyed by an event being a function of uncertainty. The average number of bits for a set of $N$ equally likely stimuli is $\log_2 N$. Because uncertainty also varies as a function of the probabilities with which individual stimuli occur, the average amount of information for stimuli that occur with unequal probability will be less than $\log_2 N$. More generally, the average amount of information ($H$) conveyed by a stimulus for a set of size $N$ is

$$H = -\sum_{i=1}^{N} p_i \log_2 p_i$$

where $p_i$ is the probability of alternative $i$. Across trials, all of the information in the stimulus set is transmitted through the responses if no errors are made. However, when errors are made, the amount of transmitted information ($H_T$) will be less than the average information in the stimulus set.

The stimuli in Hick's (1952) study were 10 lamps arranged in an irregular circle, to which subjects responded by pressing one of the 10 keys, on which the fingers from each hand were placed. Hick served as his
**Figure 2** Hick–Hyman law: Reaction time increases as a function of the amount of information transmitted.

own subject in two experiments (and a third control experiment). In experiment 1, Hick performed blocks of trials with set sizes ranging from 2 to 10 in ascending and descending order, maintaining a high level of accuracy. In experiment 2 he used only the set size of 10 but adopted various speed–accuracy criteria in different trial blocks. For both experiments, RT increased as a logarithmic function of the average amount of information transmitted. Hyman (1953) also manipulated the probabilities of occurrence of the alternative stimuli and sequential dependencies. In both cases, RT increased as a logarithmic function of the average amount of information conveyed by a stimulus, as predicted by information theory.

This relation between RT and the stimulus information that is transmitted in the responses is the Hick–Hyman law (see Figure 2), sometimes called Hick's law, mentioned in the opening quote of the chapter. According to it,

$$RT = a + bH_T$$

where $a$ is basic processing time and $b$ is the amount that RT increases with increases in the amount of information transmitted ($H_T$; $\log_2 N$ for equally likely SR pairs with no errors).

The Hick–Hyman function is obtained in a variety of tasks, although the slope of the function is influenced by several factors (Teichner and Krebs, 1974). The slope is typically shallower for highly compatible SR pairings than for less compatible ones (see later), and it decreases as the amount of practice at a task increases. Thus, the cost associated with high event uncertainty can be reduced by using highly compatible display–control arrangements or giving the operators training on the task. In fact, an essentially zero slope for the Hick–Hyman function, or even a decrease in RTs for larger set sizes, can be obtained with vibrotactile

stimulation of fingers requiring corresponding press responses (ten Hoopen et al., 1982), saccadic eye movements to targets (Marino and Munoz, 2009), and visually guided, aimed hand movements (Wright et al., 2007).

Usher et al. (2002) provided evidence that the Hick–Hyman law may result from subjects trying to maintain a constant accuracy for all set sizes. Usher et al. evaluated race models for which, as mentioned earlier, the response selection process is characterized as involving a separate stochastic accumulator for each SR alternative. Upon stimulus presentation, activation relevant to each alternative builds up dynamically within the respective accumulators, and when the activation in one accumulator reaches a threshold, that response is selected. Response selection is faster with lower than with higher thresholds because a threshold is reached sooner after stimulus presentation. However, this benefit in response speed is obtained at the cost of accuracy because the threshold for an incorrect alternative is more likely to be reached due to the noisy activation process.

With two SR alternatives there are two accumulators, with four alternatives there are four accumulators, and so on. Each additional accumulator provides an extra chance for an incorrect response to be selected. Consequently, if the error rate is to be held approximately constant as the size of the SR set increases, the response thresholds must be adjusted upward. Usher et al. (2002) showed that if the increase in the threshold as $N$ increases is logarithmic, the probability of an incorrect response remains approximately constant. This logarithmic increase in criterion results in a logarithmic increase in RT. Based on their model fits, Usher et al. concluded that the major determinant of the Hick–Hyman law is the increase in likelihood of erroneously reaching a response threshold as the number of SR alternatives increases, coupled with subjects attempting to keep the error rate from increasing under conditions with more alternatives.

### 2.2.2 Stimulus–Response Compatibility

**Spatial Compatibility** SR compatibility refers to the fact that some arrangements of stimuli and responses, or mappings of individual stimuli to responses, are more natural than others, leading to faster and more accurate responding (see Proctor and Vu, 2006, for a review). SR compatibility effects were demonstrated by Fitts and colleagues in two classic studies conducted in the 1950s. Specifically, Fitts and Seeger (1953) had subjects perform eight-choice tasks in which subjects moved a stylus (or a combination of two styluses) to a location in response to a stimulus. Subjects performed with each of nine combinations of three display configurations and three control configurations (see Figure 3), using the most compatible mapping of the stimulus and response elements for each combination. The primary finding was that responses were fastest and most accurate when the display and control configurations corresponded spatially than when they did not. Fitts and Deininger (1954) examined different mappings of the stimulus and response elements. In the case of circular display and control arrangements (see Figure 3a), performance was much worse with a random mapping of the eight
**Figure 3** Three configurations of stimulus sets and response sets used by Fitts and Seeger (1953). Displays are shown in black boxes, with the stimulus lights shown as circles. Response panels are in gray, with the directions in which one or two styluses could be moved shown by arrows. As an example, an upper right stimulus location was indicated by the upper right light for stimulus set (*a*), the upper and right lights for stimulus set (*b*), and the right light of the left pair and upper light of the right pair for stimulus set (*c*). The upper right response was a movement of a stylus to the upper right response location for response sets (*a*) and (*b*), directly for response set (*a*) and indirectly through the right or upper position for response set (*b*), or of two styluses for response set (*c*), one to the right and the other up.

stimulus locations to the eight response locations than with a spatially compatible mapping in which each stimulus was mapped to its spatially corresponding response. This finding demonstrated the basic spatial compatibility effect that has been the subject of many subsequent studies. Almost equally important, performance was much better with a mirror opposite mapping of stimuli to responses than with the random mapping. This finding implies that action selection benefits from being able to apply the same rule regardless of which stimulus occurs.

Spatial compatibility effects also occur when there are only two alternative stimulus positions, left and right, and two responses, left and right keypresses or movements of a joystick or finger, and regardless of whether the stimuli are lights or tones. Moreover, spatial correspondence not only benefits performance when stimulus location is relevant to the task but also when it is irrelevant. If a person is told to press a right key to the onset of a high pitch tone and a left key to onset of a low pitch tone, the responses are faster when the high pitch tone is in a right location (e.g., the right ear of a headphone) than when it is in a left location, and vice versa for the low pitch tone (Simon, 1990). This effect, which is found for visual stimuli as well, is known as the *Simon effect* after its discoverer, J. R. Simon. The Simon effect and its variants have attracted considerable research interest in the past 15 years because they allow examination of many fundamental issues concerning the relation between perception and action (Proctor, 2011).

**Accounts of SR Compatibility** Most accounts of SR compatibility effects attribute them to two factors. One factor is direct, or automatic, activation of the corresponding response. The other is intentional translation of the stimulus into the desired response according to the instructions that have been provided for the task. The Simon effect is attributed entirely to the automatic

activation factor, with intentional translation not considered to be involved because stimulus location is irrelevant to the task. The basic idea is that, because the response set has a spatial property, the corresponding response code is activated automatically by the stimulus at its onset, producing a tendency to select that response regardless of whether it is correct. Evidence suggests that this activation may dissipate across time, through either passive decay or active inhibition, because the Simon effect often decreases as RT becomes longer (Hommel, 1993b; De Jong et al., 1994).

In many situations, stimuli can be coded as left or right with respect to multiple frames of reference, as, for example, when there is a row of eight possible stimulus positions, four in the left hemispace and four in the right, with each of those divided into left and right pairs and left and right elements within the pairs. In such circumstances, stimulus position is coded relative to all frames of reference, with the magnitude of the Simon effect reflecting the sum of the weighted correspondence effects for each position code (e.g., Lamberts et al., 1992). Errors can result if an inappropriate reference frame is weighted more heavily than one that is relevant to the response, as appears to have been the case in the 1989 crash of a British Midland Airways Boeing 737-400 aircraft in which the operating right engine was shut down instead of the nonoperating left engine (Learmount and Norris, 1990). Confusion arose about which engine to shut down because the primary instruments for both engines were grouped in a left panel and the secondary instruments for both engines in a right panel, for which the global left and right panels were not mapped compatibly to the left and right engines (and controls).

SR compatibility proper is also presumed by many researchers to be determined in part by automatic activation of the corresponding response. As for the Simon

effect, the activated response is correct when the mapping is compatible and incorrect when the mapping is incompatible. The most influential dual-route model, that of Kornblum et al. (1990), assumes that this automatic activation occurs regardless of the SR mapping, a strong form of automaticity. However, certain results question this assumption with regard to compatibility effects (e.g., Read and Proctor, 2009), and more recent treatments of automaticity in general suggest that goal independence is not a defining feature (e.g., Moors and De Houwer, 2006). The intentional translation route is also presumed to play an important role in SR compatibility effects, with translation being fastest when a "corresponding" rule can be applied, intermediate when some other rule is applicable (e.g., respond at the opposite position), and slowest when there is no simple rule and the specific response assigned to a stimulus must be retrieved from memory.

**Dimensional Overlap** Although spatial location is an important factor influencing performance, it is by no means the only type of compatibility effect. Kornblum et al. (1990) introduced the term *dimensional overlap* to describe stimulus and response sets that are perceptually or conceptually similar. Left and right stimulus locations overlap with left and right response locations both perceptually and conceptually, and responding is fastest with the SR mapping that maintains spatial correspondence (left stimulus to left response and right stimulus to right response) than with the mapping that does not. The words "left" and "right" mapped to keypress responses also produce a compatibility effect because of the conceptual correspondence between the words and the response dimension, but the effect is typically smaller than that for physical locations due to the absence of perceptual overlap (e.g., Proctor et al., 2002).

SR compatibility and Simon effects have been obtained for a number of different stimulus types with location or direction information, for example, direction of stimulus motion (Galashan et al., 2008) and the direction of gaze of a face stimulus (Ansorge, 2003). They have also been obtained for typing letters on a keyboard, as a function of the positions in which the letters appear on a computer screen relative to the locations of the keys with which they are typed (Logan, 2003), elements in movement sequences (Inhoff et al., 1984), and clockwise versus counterclockwise rotations of a wheel (Wang et al., 2007). Properties such as the durations of stimuli and responses (short and long; Kunde and Stöcker, 2002), positive or negative affective valence of a stimulus in relation to that of a response (Duscherer et al., 2008), and pitch of a tone with that of the vowels in syllable sequences (Rosenbaum et al., 1987) also yield compatibility effects. The point is that compatibility effects are likely to occur for any situation in which the relevant or irrelevant stimulus dimension has perceptual or conceptual overlap with the response dimension.

**Influence of Action and Task Goals** It is important to understand that SR compatibility effects are determined largely by action goals and not the physical responses. This is illustrated by a study conducted by Hommel (1993a) in which subjects made a left or right keypress to a high or low pitch tone, which could occur in the left or right ear. The closure of the response key produced an action effect of turning on a light on the side opposite that on which the response was made. When instructed to turn on the left light to one tone pitch and the right light to the other, a Simon effect was obtained for which responses were faster when the tone location corresponded with the light location than when it did not, even though this condition was noncorresponding with respect to the key that was pressed. Similarly, when holding a wheel at the bottom, for which the direction of hand movements is incongruent with that of wheel movement, some subjects code the responses as left or right with respect to direction of hand movement and others with respect to direction of wheel movement, and these tendencies can be influenced to some extent by instructions that stress one response coding or the other and by controlled visual events (Guiard, 1983; Wang et al., 2007).

Compatibility effects can occur for situations in which there is no spatial correspondence relation between stimuli and responses. One such example is when stimulus and response arrays are orthogonal to each other, one being oriented vertically and the other horizontally (e.g., Proctor and Cho, 2006). Action selection when there is no spatial correspondence has been studied extensively in the literature on display–control population stereotypes, in which the main measure of interest is which action a person will choose when operating a control to achieve a desired outcome. Many studies have examined conditions in which the display is linear and the control is a rotary knob. Their results have yielded several principles relating direction of control motion to display movement (Proctor and Vu, 2010b), including:

- *Clockwise to Right/Up*. Turn the control clockwise to move the controlled element of the display to the right on a horizontal display or up on a vertical display.
- *Clockwise to Increase*. Turn the control clockwise to increase the value of the controlled element of the display.
- *Warrick's*. The controlled element of the display will move in the same direction as the side of the control nearest to the display. This principle is only applicable when the control is to the left or right of a vertical display or below or above a horizontal display.
- *Scale Side*. The controlled element of the display will move in the same direction as that of the side of the control corresponding to the side of the scale markings on the display.

Performance is most consistent when all stereotypes predict the same response to achieve an action goal. When the stereotypes are in conflict (e.g., the clockwise-to-right principle specifies clockwise rotation, whereas Warrick's principle specifies counterclockwise rotation), choices are less consistent across individuals and group differences from experience become more evident. For example, Hoffmann (1997) reported that psychology

students abide more by the clockwise-to-right principle, whereas engineering students tend to adhere to Warrick's principle.

### 2.2.3 Sequential Effects

Because many human–machine interactions involve a succession of responses, it is also important to understand how action selection is influenced by immediately preceding events, which can be evaluated by examining the sequential effects that occur in choice–reaction tasks. The most common sequential effect is that the response to a stimulus is faster when the stimulus and response are the same as those on the preceding trial than when they are not (Bertelson, 1961). This repetition benefit increases in size as the number of SR alternatives becomes larger and is greater for incompatible SR mappings than for compatible ones (Soetens, 1998). Repetition effects have been attributed to two processes, residual activation from the preceding trial when the current trial is identical to it and intentional preparation for what is expected on the next trial (Soetens, 1998). The former contributes to response selection primarily when the interval between a response and onset of the next stimulus is short, whereas the latter contributes primarily when the interval is long.

Although sequential effects with respect to the immediately preceding trial have been most widely studied, higher order repetition effects, which involve the sequence of the preceding two or three stimuli, also occur (Soetens, 1998). For two-choice tasks, at short response–stimulus intervals, where automatic activation predominates, a string of multiple repetitions is beneficial regardless of whether or not the present trial is a repetition of the immediately preceding one. In contrast, at long response–stimulus intervals, where expectancy is important, a prior string of repetition trials is beneficial if the current trial is also a repetition, and a prior string of alternation trials is beneficial if the current trial is an alternation.

When stimuli contain irrelevant stimulus information, as in the Stroop color-naming task in which the task is to name the ink color in which a conflicting color word is printed, RT is typically longer if the relevant stimulus value on a trial (e.g., the color red) is the same as that of the irrelevant information on the previous trial (e.g., the word *red*). This effect is called *negative priming* (Fox, 1995), with reference to the fact that the "priming" from the preceding trial slows RT compared to a neutral trial, for which there is no repetition of the relevant or irrelevant information from that trial. Negative priming was attributed initially to inhibition of the response tendency to the irrelevant information on the previous trial, which then carried over to the current trial. However, the situation is more complex than originally thought, and several other factors may account in whole or in part for negative priming. One such factor is that of episodic retrieval from memory (Neill and Valdes, 1992), according to which stimulus presentation initiates retrieval of the most recent episode involving the stimulus; if the relevant stimulus information was irrelevant on the previous trial, it includes an "ignore" tag, which slows responding. Another factor is that of feature mismatch

(Park and Kanwisher, 1994), according to which symbol identities are bound to objects and locations, and any change in the bindings from the preceding trial will produce negative priming. These accounts are difficult to discriminate because they make similar predictions in many situations (Christie and Klein, 2008).

Similar to negative priming, in which the irrelevant information from the previous trial interferes with processing the relevant feature on the current trial, several studies have also shown that in the Simon task noncorresponding information from the previous trial can alter how the present trial is processed. That is, the Simon effect has been shown to be evident when the preceding trial was one for which the SR locations corresponded and were absent when it was one for which they did not (e.g., Stürmer et al., 2002). A suppression/release hypothesis has been proposed to account for this pattern of results (e.g., Stürmer et al., 2002). According to this hypothesis, the Simon effect is absent following a noncorresponding trial because the direct response selection route is suppressed since automatic activation of the response code corresponding to the stimulus location would lead to the wrong response alternative. This suppression is released, though, following a corresponding trial, which results in the stimulus activating the corresponding response and thus producing a Simon effect.

However, Hommel et al. (2004) noted that the analysis on which the suppression/release hypothesis is based collapses across mapping and location repetitions and nonrepetitions. According to Hommel's (1998b) event file hypothesis, the stimulus features on a trial and the response made to them are integrated into an *event file*. When both stimulus features are repeated on the next trial, the response with which they were integrated on the previous trial is reactivated, and responding is facilitated. When both stimulus features change, neither feature was associated with the previous response, and the change in stimulus features signals a change in the response. Response selection is more difficult on trials for which one stimulus feature repeats and the other changes because one stimulus feature produces reactivation of the previous response and the other signals a change in response.

Hommel et al. (2004) and Notebaert et al. (2001) provided evidence that the pattern of repetition effects in the Simon task can be attributed to feature integration processes of the type specified by the event file hypothesis rather than to suppression/release of the automatic route. That is, responses were faster when the relevant stimulus feature and irrelevant stimulus location both repeated or both changed than when only one stimulus feature repeated. Whether the suppression/release feature integration mechanism accounts for the largest part of the sequential effects is still a matter of debate [cf. Chen and Melara (2009) and Iani et al. (2009)].

### 2.2.4 Preparation and Advance Information

When a stimulus to which a response is required occurs unexpectedly, the response to it will typically be slower than when it is expected. General preparation is studied in choice–reaction tasks by presenting a neutral warning signal at various intervals prior to onset of the imperative

stimulus. A common finding is that RT first decreases as the warning interval increases and then goes up as the warning interval is increased further, but the error rate first increases and then decreases. Bertelson (1967) demonstrated this relation in a study in which he varied the onset between an auditory warning click and a left or right visual stimulus to which a compatible keypress response was to be made. RT decreased by 20 ms for warning intervals of 0–150 ms and increased slightly as the interval increased to 300 ms, but the error rate increased from approximately 7% at the shortest intervals to about 10% at 100- and 150-ms intervals and decreased slightly at the longer intervals. Posner et al. (1973) obtained similar results for a two-choice task in which SR compatibility was manipulated, and compatibility did not interact with the warning interval. These results suggest that the warning tone alters alertness, or readiness to respond, but does not affect the rate at which the information accumulates in the response selection system.

People can also use informative cues to prepare for subsets of stimuli and responses. Leonard (1958) performed a task in which six stimulus lights were assigned compatibly to six response keys operated by the index, middle, and ring fingers of each hand. Of most concern was a condition in which either the three left or three right lights came on, precuing that subset as possible on that trial. RT decreased as precuing interval increased, being similar to that of a three-choice task when the precuing interval was 500 ms. Similar results have been obtained using four-choice tasks in which a benefit for precuing the two left or two right locations occurs within the first 500 ms of precue onset (Miller, 1982; Reeve and Proctor, 1984). However, when pairs of alternate locations are precued, a longer period of time is required to attain the maximal benefit of the precue. Reeve and Proctor (1984) showed that the benefit for precuing the two left or two right responses is also obtained when the hands are overlapped such that the index and middle fingers from the two hands are alternated, indicating that it reflects faster translation of the precued stimulus locations into possible response locations. Proctor and Reeve (1986) attributed this pattern of differential precuing benefits to the left–right distinction being salient for both stimulus and response sets, and Adam et al. (2003) proposed a grouping model that expands on this theme.

### 2.2.5  Acquisition and Transfer of Action–Selection Skill

Response selection efficiency improves with practice or training on a task. This improvement has been attributed to better pattern recognition or chunking of stimuli and responses (Newell and Rosenbloom, 1981), strengthening of associations between stimuli and responses (e.g., Anderson, 1982), and shifting from an algorithmic mode of processing to one based on retrieval of prior instances (Logan, 1988). The general idea behind all of these accounts is that practice results in performance becoming increasingly automatized. For virtually any task, the absolute benefit of a given amount of additional practice is a decreasing function of the amount of prior practice. Newell and Rosenbloom (1981) showed

that the reduction in RT with practice using the mean data from groups of subjects in a variety of tasks is characterized well by a power function:

$$RT = A + BN^{-\beta}$$

where $A$ is the asymptotic RT, $B$ the performance time on the first trial, $N$ the number of practice trials, and $\beta$ the learning rate.

Although the power function for practice has been regarded as a law to which any theory or model of skill acquisition must conform (e.g., Logan, 1988), evidence indicates that it does not provide the best fit for the practice functions of individual subjects. Heathcote et al. (2000) demonstrated that exponential functions of the following form provided better fits than power functions for individual data sets:

$$RT = A + Be^{-\alpha N}$$

where $\alpha$ is the rate parameter. In relatively complex cognitive tasks such as mental arithmetic, individual subject data often show one or more abrupt changes (e.g., Haider and Frensch, 2002; Rickard, 2004), suggesting shifts in strategy. Delaney et al. (1998) showed that in such cases the individual improvement in solution time is fit better by separate power functions for each specific strategy than by a single power function for the entire task.

As noted earlier, practice reduces the slope of the Hick–Hyman function (e.g., Hyman, 1953), indicating that the cost associated with increased SR uncertainty can be offset by allowing more practice. Seibel (1963) showed that after practice with more than 75,000 trials of all combinations of 10 lights mapped directly to 10 keys, RT for a task with 1023 alternatives was only about 25 ms slower than that for a task with 31 alternatives. Practice also benefits performance more for tasks with an incompatible SR mapping than for ones with a compatible mapping (e.g., Fitts and Seeger, 1953). However, as a general rule, performance with an incompatible mapping does not reach the same level as that with a compatible mapping for the same amount of practice (e.g., Fitts and Seeger, 1953; Dutta and Proctor, 1992).

Some evidence suggests that the improvements that occur with practice in spatial choice tasks involve primarily the mappings of the stimuli to spatial response codes and not to the specific motor effectors. Proctor and Dutta (1993) had subjects perform two-choice spatial tasks for 10 blocks of 42 trials each. In alternating trial blocks, subjects performed with their hands uncrossed or crossed such that the right hand operated the left key and the left hand the right key. There was no cost associated with alternating the hand placements for the compatible or incompatible mapping when the mapping of stimulus locations to response locations remained constant across the two hand placements. However, when the mapping of stimulus locations to response locations was switched between blocks so that the hand used to respond to a stimulus remained constant across the two hand placements, there was a substantial cost for

participants who alternated hand placements compared to those who did not, indicating the importance of maintaining a constant location mapping.

Although spatial SR compatibility effects are not eliminated by practice, transfer studies show that changes in processing that occur as one task is practiced can affect performance of a subsequent, different task. Proctor and Lu (1999) had subjects perform with an incompatible spatial mapping of left stimulus to right response and right stimulus to left response for 900 trials. When the subjects then performed a Simon task, for which stimulus location was irrelevant, the Simon effect was reversed: RT was shorter when stimulus location did not correspond with that of the response than when it did. Later studies by Tagliabue et al. (2000) and Vu et al. (2003) showed that as few as 72 practice trials with an incompatible spatial mapping eliminate the Simon effect in the transfer session and that this transfer effect remains present even a week after practice. Thus, a limited amount of practice produces new spatial SR associations that continue to affect performance at least a week later.

The transfer of a spatially incompatible mapping to the Simon task is not an automatic consequence of having executed the spatially incompatible response during practice. Vu (2011) had subjects perform 72 practice trials of a two-choice task for which stimuli occurred in a left or right location and stimulus color was nominally relevant. However, the correct response was always to the side that did not correspond to the stimulus location (i.e., if a left response was to be made to the color red, the red stimulus always occurred in the right location). Thus, the relation between stimulus and response locations was identical to that for a task with an incompatible spatial mapping; if subjects became aware of this spatially noncorresponding relation, they could base response selection on an "opposite" spatial rule instead of on stimulus color. Approximately half of the subjects indicated in a postexperiment interview that they were aware that the noncorresponding response was always correct, whereas half showed no awareness of this relation. Those subjects who were aware of the relation showed a stronger transfer effect to the Simon task than did those who showed no awareness. Related to this finding, Miles and Proctor (2010) showed that imposing an attentional load during practice with an incompatible spatial mapping eliminates transfer of this mapping to the Simon task, indicating that attention is required for the learning to occur.

## 2.3  Action Selection in Multiple-Task Performance

In many activities and jobs, people must engage in multiple tasks concurrently. This is true for an operator of a vehicle, a pilot of an aircraft, a university professor, and a secretary, among others. When more than one task set must be maintained, there is a cost in performance for all tasks even when the person devotes all of his or her attention to only one task at that time. This cost of concurrence that occurs with multiple-task performance has been of considerable interest in human factors and ergonomics. As a result, much research has been devoted to understanding and improving multiple-task performance.

### 2.3.1  Task Switching and Mixing Costs

Since the mid-1990s, there has been considerable interest in task switching (see Kiesel et al., 2010, for a review). In task-switching studies, two distinct tasks are typically performed, one at a time, with the tasks presented either in a fixed sequence (e.g., two trials of one task followed by two trials of the other task) or randomly with the current task indicated by a cue or instruction. The interval between successive trials or between the cue and the imperative stimulus can be varied to allow different amounts of time to prepare for the forthcoming task. Four phenomena are commonly obtained in such situations (Monsell, 2003):

1. *Mixing Cost.* Responses are slower overall compared to when the same task is performed on all trials. This cost represents the "global" demands required to maintain two task sets in working memory and resolve which task is to be performed on the current trial.

2. *Switch Cost.* Responses are slower on trials for which the task switches from the previous trial than for those on which it repeats. This cost reflects the "local" demands associated with switching from the previously performed task to the new task for the current trial.

3. *Preparation Benefit.* The switch cost is reduced if the next task is known, due to either following a predetermined sequence or to being cued, as long as adequate time for preparation is allowed.

4. *Residual Cost.* Although reduced in magnitude, the switch cost is not eliminated, even with adequate time for preparation.

The switch cost is typically attributed to the time needed to change the task set. The fact that the switch cost can be reduced but not eliminated by preparation is often interpreted as evidence for at least two components to the switch cost. One component involves an intentional task set reconfiguration process, and the other reflects exogenous, stimulus-driven processes, of which several have been suggested as possibilities. Rogers and Monsell (1995) proposed that this second component is a part of task set reconfiguration that cannot be accomplished until it is initiated by stimulus components related to the task. Allport et al. (1994) attributed this second component to task set inertia, with the idea that inhibition of the inappropriate task set on the previous trial carries over to the next trial, much as in negative priming. Finally, because the requirement to perform a task a few minutes later can slow performance of the current task, Waszak et al. (2003) proposed that associative retrieval of the task sets associated with the current stimulus is involved in the second component. Monsell (2003) describes the situation as follows: "Most authors now acknowledge a plurality of causes, while continuing to argue over the exact blend" (p. 137).

One important finding in the task-switching literature is that the costs associated with mixing an easy task with

a more difficult one are often larger for the easier task. For example, for Stroop stimuli, in which a color word is printed in an incongruent ink color, the costs are larger for the easy task of naming the word and ignoring the ink color than for the difficult task of naming the ink color and ignoring the word (Allport et al., 1994). Similarly, when compatible and incompatible spatial mappings are mixed within a trial block, responding is not only slowed overall, but the benefit for the compatible mapping is often eliminated (Vu and Proctor, 2008). One way to think of the reduction of the compatibility effect with mixed mappings is that the "automatic" tendency to make the corresponding response must be suppressed because it often leads to the incorrect response. An example of a task environment where operators must maintain both compatible and incompatible spatial mappings is that of driving a coal mine shuttle car, where one mapping is in effect when entering the mine and the other mapping when exiting the mine. Zupanc et al. (2007) found that in a simulated shuttle car driving task, drivers were slower at responding to critical stimuli and made more directional errors when they had to alternate between mappings, as is the case in real mines where forward and reversed maneuvers are necessary, compared to when all trials were performed with a single mapping.

Many of the results for the elimination of the SR compatibility effect with mixing are consistent with a dual-route model of the general type described earlier. According to such an account, response selection can be based on direct activation of the corresponding response when all trials are compatible, but the slower indirect route must be used when compatible trials are mixed with either incompatible trials or trials for which another stimulus dimension is relevant. The most important point for application of the compatibility principle is that the benefit for a task with a compatible mapping may not be realized when that task is mixed with other less compatible tasks.

### 2.3.2 Psychological Refractory Period Effect

Much research on multiple-task performance has focused on what is called the *psychological refractory period* (PRP) *effect* [see Pashler and Johnston (1998) and Lien and Proctor (2002) for reviews]. This phenomenon

refers to slowing of RT for the second of two tasks that are performed in rapid succession. Peripheral sensory and motor processes can contribute to decrements in dual-task performance. For example, if you are looking at the display for a compact disk changer in your car, you cannot respond to visual events that occur outside, and if you are holding a cellular phone in one hand, you cannot use that hand to respond to other events. However, research on the PRP effect has indicated that the central processes involved in action selection seem to be the locus of a major limitation in performance.

In the typical PRP study, the subject is required to perform two speeded tasks. Task 1 may be to respond to a high or low pitch tone by saying "high" or "low" out loud, and task 2 may be to respond to the location of a visual stimulus by making a left or right key press. The stimulus onset asynchrony (SOA, the interval between onsets of the task 1 stimulus, S1, and the task 2 stimulus, S2) is typically varied, either randomly within a block of trials or between blocks. The characteristic PRP effect is that RT is slowed, often considerably, for task 2 when the SOA is short (e.g., 50 ms) compared to when it is long (e.g., 800 ms).

The most widely accepted account of the PRP effect is what has been called the *central bottleneck model* (e.g., Welford, 1952; Pashler and Johnston, 1998). This model assumes that selection of the response for task 2 (R2) cannot begin until response selection for task 1 (R1) is completed (see Figure 4). The central bottleneck model has several testable implications that have tended to be confirmed by the data. First, increasing the duration of response selection for task 2 should not influence the magnitude of the PRP effect because response selection processes occur after the bottleneck. This result has been obtained in several studies in which manipulations such as SR compatibility for task 2 have been found to have additive effects with SOA, that is, to affect task 2 RT similarly at all SOAs (e.g., Pashler and Johnston, 1989; McCann and Johnston, 1992). Second, increasing the duration of stimulus identification processes for task 2 by, for example, degrading S2 should reduce the PRP effect because this increase can be absorbed into the "slack" at short SOAs after which identification of S2 is completed but response selection for the task cannot begin. This predicted underadditive

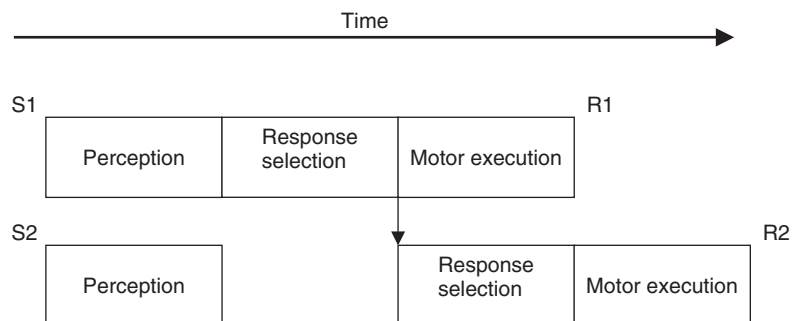

**Figure 4** Central bottleneck model. Response selection for task 2 cannot begin until that for task 1 is completed. S1 and S2 are the stimuli for tasks 1 and 2, respectively, and R1 and R2 are the responses.

interaction has been obtained in several studies (e.g., Pashler and Johnston, 1989).

The central bottleneck influences performance in tasks other than typical choice–reaction tasks. Pashler et al. (2008) found that when the second task required spontaneously choosing an action (whether to accept a card denoting a gamble), response latencies were longer at short SOAs, and this PRP effect was additive with the effects of several decision-related variables. Likewise, Levy et al. (2006) showed that in simulated driving vehicle braking was subject to dual-task slowing. Thus, evidence suggests that the bottleneck imposes a limitation on multitasking performance in real-world environments.

Numerous issues concerning the central response selection bottleneck have been investigated in recent years. One issue is whether all processes associated with action selection are subject to the bottleneck or only a subset. Consistent with the latter view, several studies have shown crosstalk correspondence effects such that the responses for both tasks 1 and 2 are faster when they correspond than when they do not (e.g., Hommel, 1998a; Lien et al., 2005), which suggests that activation of response codes occurs prior to the response selection bottleneck. A second issue is whether the bottleneck is better conceived as being of limited capacity than all-or-none. Navon and Miller (2002) and Tombu and Jolicœur (2003) have argued that the evidence is most consistent with a central-capacity sharing model, in which attentional capacity can be allocated in different amounts to response selection for the two tasks. One finding that the capacity-sharing account can explain that is difficult for the all-or-none bottleneck model is that RT for task 1, as well as that for task 2, sometimes increases at short SOAs.

Another issue is whether there is a structural bottleneck at all, or whether the bottleneck reflects a strategy adopted to perform the dual tasks as instructed. Meyer and Kieras (1997) developed a computational model, implemented within their EPIC (executive-process interactive control) architecture, which consists of perceptual, cognitive, and motor components, that does not include a limit on central-processing capacity. The specific model developed for the PRP effect, called the strategic response deferment model, includes an analysis of the processes involved in the performance of each individual task and of the executive control processes that coordinate the joint performance of the two tasks. Attention begins at the perceptual level, orienting focus (i.e., moving the eyes) on sensory input. Limits in the systems are attributed to the sensory and motor effectors, but not to the central processes. Central limitations arise from individuals' strategies for satisfying task demands (e.g., making sure that the responses for the two tasks are made in the instructed order). Specifically, according to the model, the PRP effect occurs when people adopt a conservative strategy of responding with high accuracy at the expense of speed. EPIC computational models can be developed for multitasking in real-world circumstances such as human–computer interaction and military aircraft operation as well as for the PRP effect.

The view that the bottleneck is strategic implies that it should be possible to bypass its limitations. Greenwald and Shulman (1973) provided evidence suggesting that this is the case when two tasks are "ideomotor" compatible: that is, the feedback from the response is similar to the stimulus. Their ideomotor-compatible tasks were moving a joystick to a positioned left- or right-pointing arrow (task 1) and saying the name of an auditorily presented letter (task 2). Greenwald and Shulman's experiment 2 showed no PRP effect when both tasks were ideomotor compatible, although an effect was apparent when only one task was. However, other experiments in which the two tasks were ideomotor compatible, including Greenwald and Shulman's experiment 1, have consistently shown small PRP effects (e.g., Lien et al., 2002). Regardless of whether such tasks bypass the bottleneck, dual-task interference is much smaller with two ideomotor-compatible tasks than for most other pairs of tasks.

Under certain conditions, the PRP effect can be virtually eliminated with considerable practice, a finding that some authors have interpreted as evidence against a central bottleneck (e.g., Schumacher et al., 2001). However, this elimination is accomplished primarily through the reduction of RT for task 1, which leaves open the possibility that the bottleneck is "latent" and not affecting performance (Ruthruff et al., 2003). That is, because the speed of performing task 1 improves with practice, even at short SOAs, task 1 response selection can be completed prior to the time at which response selection for task 2 is ready to begin. For practical purposes, though, the messages to take from the PRP research is that it is difficult to select different actions concurrently, but many factors can reduce the magnitude of the cost associated with trying to do so.

## 3 MOTOR CONTROL AND LEARNING

### 3.1 Methods

Whereas action selection focuses primarily on choice between action goals, motor control is concerned mainly with the execution of movements to carry out the desired actions. Tasks used to study motor control typically require movement of one or more limbs, execution of sequences of events, or control of a cursor following a target that is to be tracked. For example, a person may be asked to make an aimed movement from a start key to a target location under various conditions, and measures such as movement time and accuracy can be recorded. Some issues relevant to human factors include the nature of movement representation, the role of sensory feedback in movement execution, the way in which motor actions are sequenced, and the acquisition of perceptual–motor skills.

### 3.2 Control of Action

Motor control is achieved in two different ways, open loop and closed loop. *Open-loop control* is based on an internal model, called a *motor plan* or *motor program*, which provides a set of movement commands. Two pieces of evidence for motor plans include the

fact that deafferented monkeys, which cannot receive sensation from the deafferented limb, can still make movements including walking and climbing (e.g., Taub and Berman, 1968) and the time to initiate a movement increases as the number of elements to be performed increases (e.g., Henry and Rogers, 1960; Monsell, 1986). *Closed-loop control*, in contrast, relies on sensory feedback, comparing the feedback to a desired state and making the necessary corrections when a difference is detected. The advantages and disadvantages of open- and closed-loop control are the opposite of each other. A movement under open-loop control can be executed quickly, without a delay to process feedback, but at a cost of limited accuracy. In contrast, closed-loop control is slower but more accurate. Not surprisingly, both types of control are often combined, with open-loop control used to approximate a desired action and closed-loop control serving to reduce the deviation of the actual state from the intended state as the action is executed.

### 3.2.1 Fitts's Law

As indicated in the quote with which the chapter began, Fitts's law, which specifies the time to make aimed movements to a target location (Fitts, 1954), is one of the most widely established quantitative relations in behavioral research. As originally formulated by Fitts, the law is

$$\text{Movement time} = a + b \, \log_2(2D/W)$$

where $a$ and $b$ are constants, $D$ is the distance to the target, and $W$ is the target width (see Figure 5). Two important points of Fitts's law are that (1) movement time increases as movement distance increases and (2) movement time decreases as target width increases. It is a speed–accuracy relation in the sense that movement time must be longer when more precise movements are required. Fitts's law provides an accurate description of movement time in many situations, although alternative formulations can provide better fits for certain specific situations. The speed–accuracy relation captured by Fitts's law is a consequence of both open- and closed-loop components. Meyer et al. (1988) provided the most complete account of the relation, a stochastic optimized-submovement model. This model assumes that aimed movements consist of a primary submovement and an optional secondary submovement. Fitts's law arises as a consequence of (1) programming each movement to minimize average movement time while maintaining a high frequency of "hitting" the target and (2) making the secondary, corrective submovement when the index of difficulty is high.

Fitts's law is of considerable value in human factors because it is quite robust and is applicable to many tasks of concern to human factors professionals. The relation holds not only for tasks that require movement of a finger to a target location (e.g., when using an ATM machine) but also for tasks such as placing washers on pegs and inserting pins into holes (Fitts, 1954), using tweezers under a microscope (Langolf and Hancock, 1975), and making aimed movements underwater (Kerr, 1973). Variants of Fitts's law can also be used to model

**Figure 5** Fitts's law: Movement time increases as a function of the index of difficulty [$\log_2(2D/W)$].

limb and head movements with extended probes such as screwdrivers and helmet-mounted interfaces (Baird et al., 2002). The slope of the Fitts's law function has been used to evaluate the efficiency of various ways for moving a computer cursor to a target position. For example, Card et al. (1978) showed that a computer mouse produced smaller slopes than text keys, step keys (arrows), and a joystick for the task of positioning a cursor on a desired area of text and pressing a button or key.

Size and distance are only two of many constraints that influence movement time (Heuer and Massen, in press). Movement time will be longer, for example, if the target must be grasped instead of just touched. Moreover, for objects that must be grasped, movement time depends on properties of the object, being longer to one that has to be grasped cautiously (e.g., a knife) than one that does not.

### 3.2.2 Motor Preparation and Advance Specification of Movement Properties

Movement of a limb is preceded by preparatory processes at various levels of the motor system. For a simple voluntary movement such as a keypress, a negative potential in the electroencephalogram (EEG) begins as much as 1 s before the movement itself, with this potential being stronger over the contralatateral cerebral hemisphere (which controls the finger) 100–200 ms before responding. This asymmetry, called the *lateralized readiness potential*, provides an index of being prepared to respond with a limb on one or the other side of the body (Masaki et al., 2004). In reaction tasks, this preparation may involve what is sometimes called a *response set*, or a readiness to respond, that is, response activation just below the threshold for initiating the response. However, motor preparation depends on the response that is to be performed. As noted, simple RT increases as the number of components of which the to-be-executed movement is composed increases.

Also, motor preparation is sensitive to the end state of an action. For example, when executing an action that requires grasping a bar with a pointer and placing it in a specified target position, the bar will be grasped in a manner that minimizes the awkwardness, or maximizes the comfort, of the final position in which the arm will end up (Rosenbaum et al., 1990).

Advance specification of movement parameters has been studied using a choice–RT procedure in which subjects must choose between aimed-movement responses that differ in, for example, arm (left or right), direction (toward or away), and extent (near or far). One or more parameters are precued prior to presentation of the stimulus to which the person is to respond, the idea being that RT will decrease if those parameters can be specified in advance (Rosenbaum, 1983). The results of such studies have generally supported the view that movement features can be specified in variable order; that is, there is a benefit of precuing any parameter in isolation or in combination with another. Thus, the results support those described in the section on action selection, which indicated that people can take advantage of virtually any advance information that reduces the possible stimulus and response events. A disadvantage of using the movement precuing technique to infer characteristics of parameter specification is that the particular patterns of results may be determined more by SR compatibility than by the motoric preparation process itself (e.g., Goodman and Kelso, 1980; Dornier and Reeve, 1992).

### 3.2.3   Visual Feedback

Another issue in the control of movements is the role of visual feedback. In a classic study, Woodworth (1899) had people repeatedly draw lines of a specified length on a roll of paper moving through a vertical slot in a tabletop. The rate of movement in drawing the lines was set by a metronome that beat from 20 to 200 times each minute, with one complete movement cycle to be made for each beat. Subjects performed the task with their eyes open or closed. At rates of 180 per minute or greater, movement accuracy was equivalent for the two conditions, indicating that visual feedback had no effect on performance. However, at rates of 140 per minute or less, performance was better with the eyes open. Consequently, Woodworth concluded that the minimum time required to process visual feedback was 450 ms.

Subsequent studies have reduced this estimate substantially. Keele and Posner (1968) had people perform a discrete movement of a stylus to a target that, in separate pacing conditions, was to be approximately 150, 250, 350, or 450 ms in duration. The lights turned off at the initiation of the movement on half of the trials, without foreknowledge of the performer. Movement accuracy was better with the lights turned on than off in all but the fastest pacing condition, leading Keele and Posner to conclude that the minimum duration for processing visual feedback is between 190 and 260 ms. Moreover, when people know in advance whether visual feedback will be present, results indicate that feedback can be used for movements with durations of only slightly longer than 100 ms (Zelaznik et al., 1983).

It might be thought that the role of visual feedback would decrease as a movement task is practiced, but evidence indicates that vision remains important. For example, Proteau and Cournoyer (1992) had people perform 150 trials of a task of moving a stylus to a target with either full vision, vision of both the stylus and the target, or vision of the target only. Performance during these practice trials was best with full vision and worst with vision of the target only. However, when the visual information was eliminated in a subsequent transfer block, performance was worst for those people who had practiced with full vision and worst for those who had practiced with vision of only the target. What appears to happen is that participants rely on the visual feedback for accurate performance without developing an adequate internal model of the task. Heuer and Hegele (2008) found similar results to those of Proteau and Cournoyer for a task requiring performance with a novel visuomotor gain when continuous visual feedback was provided. But when only terminal visual feedback about the final positions of the movements was provided, visuomotor adaptation to the practice conditions occurred. Thus, the kind of feedback used during practice will influence what the performer learns.

### 3.3   Coordination of Effectors

To perform many tasks well, it is necessary to coordinate the effectors. For example, when operating a manual transmission, the movements of the foot on the gas pedal must be coordinated with the shifting of gears controlled by the arm and hand. This example illustrates that one factor determining the coordination pattern is the constraints imposed by the task that is to be performed. These coordination patterns are flexible within the structural constraints imposed by the action system.

For tasks involving bimanual movements, there is a strong tendency toward mirror symmetry; that is, it is generally easy to perform symmetric movements of the arms, as in drawing two circles simultaneously with each hand. Moreover, intended asymmetric movement patterns will tend more toward symmetry in duration and timing than they should. This symmetry tendency has been studied extensively for tasks involving bimanual oscillations of the index fingers: It is easier to maintain the instructed oscillatory pattern if told to make symmetrical movements of the fingers inward and outward together than if told to make parallel movements leftward and rightward together (see Figures 6a,b). The symmetry tendency in bimanual oscillatory movements and for other bimanual tasks has traditionally been attributed to coactivation of homologous muscles (e.g., Kelso, 1984).

However, Mechsner et al. (2001) presented evidence that the bias is toward spatial symmetry and not motor symmetry. To dissociate motor symmetry from spatial symmetry, Mechsner et al. had subjects perform with the palm up for one hand and the palm down for the other (see Figures 6c,d). A tendency toward coactivation of homologous muscles would predict that, in this case, the bias should be toward parallel oscillation, whereas a tendency toward spatial symmetry should still show the bias toward symmetrical oscillation. The latter result
**Figure 6** (*a*) Symmetric and (*b*) asymmetric patterns of finger movements for which symmetric movements are typically easier. Parts (*c*) and (*d*) show conditions examined by Mechsner et al. (2001), in which spatial symmetry and muscle homology are dissociated.

was in fact obtained, with the bias toward symmetrical oscillation being just as strong when one palm faced up and the other down as when both hands were palm down or both palm up. Mechsner et al. and Mechsner and Knoblich (2004) obtained similar results for tasks in which two fingers of each hand are periodically tapped together by comparing congruous conditions for which the fingers from the two hands were the same (e.g., index and middle fingers of each hand or middle and ring fingers of each hand) and incongruous conditions for which they were different (index and middle finger for one hand and middle and ring finger for the other). Mechsner and Knoblich concluded that "homology of active fingers, muscular portions, and thus motor commands plays virtually no role in defining preferred coordination patterns, in particular the symmetry tendency" (p. 502) and that the symmetry advantage "originates at a more abstract level, in connection with planning processes involving perceptual anticipation" (p. 502). Evidence from behavioral and neuroscientific investigations has supported this conclusion that a major source of constraint in bimanual control is a consequence of the manner in which the action goals are represented (Oliveira and Ivry, 2008).

### 3.4 Sequencing and Timing of Action

How sequences of actions are planned and executed is one of the central problems of concern in the area of motor control (Rosenbaum, 2010). Most discussions of this problem originate with Lashley's (1951) well-known book chapter in which he presented evidence against an associative chaining account of movement sequences, according to which the feedback from each movement in the sequence provides the stimulus for the next movement. Instead, Lashley argued that the sequences are controlled centrally by motor plans.

Considerable evidence is consistent with the idea that these motor plans are structured hierarchically.

For example, Povel and Collard (1982) had subjects perform sequences of six taps with the four fingers on a hand (excluding the thumb). A sequence was practiced until it could be performed from memory, and then trials were conducted for which the sequence was to be executed as rapidly as possible. The sequences differed in terms of the nature and extent of their structure. For example, the patterns 1−2−3−2−3−4 and 2−3−4−1−2−3, where the numbers 1, 2, 3, and 4 designate the index, middle, ring, and little fingers, respectively, can each be coded as two separate ordered subsets. Povel and Collard found that the pattern of latencies between each successive tap was predicted well by a model that assumed the memory representation for the sequence was coded in a hierarchical decision tree (see Figure 7), with the movement elements represented at the lowest level, which was then interpreted by a decoding process that traversed the decision tree from left to right. Interresponse latencies were predicted well by the number of links that had to be traversed in the tree between successive responses. For example, for the sequences shown above, the longest latencies were between the start signal and the first tap and between the third and fourth taps, both of which required two levels of the tree to be traversed.

Although many results in tasks requiring execution of sequential actions are in agreement with predictions of hierarchical models, it should be noted that it is not so simple to rule out serial association models. Context-sensitive association models, which allow elements farther back than just the immediately preceding one to affect performance, can generate many of the same result patterns as hierarchical models (e.g., Wickelgren, 1969).

Beginning with a study by Nissen and Bullemer (1987), numerous experiments have been conducted on incidental learning of trial sequences in choice–reaction tasks. Nissen and Bullemer had subjects perform a four-choice RT task in which the stimulus on a trial appeared in one of four horizontal locations, and the response was the corresponding location of one of

**Figure 7** Hierarchical representation of the movement sequence 1−2−3−2−3−4. T1 represents the operation *transpose to an adjacent finger*. The tree traversal model predicts longer latencies for the first and fourth elements in the movement sequence, as Povel and Collard (1982) found.

four buttons also arranged in a row, made with the middle and index fingers of the left and right hands. Subjects received eight blocks of 100 trials for which the stimuli were presented in random order or in a sequence that repeated every 10 trials. There was a slight decrease in RT of about 20 ms across blocks with the random order but a much larger one of about 150 ms for the repeating sequence. Nissen and Bullemer presented evidence that they interpreted as indicating that such sequence learning can occur without awareness, but this remains a contentious issue (see, e.g., Fu et al, 2010; Rünger and Frensch, 2010).

Of most interest to present concerns is the nature of the representation that is being learned in sequential tasks. Most studies have found little evidence for perceptual learning of the stimulus sequence (e.g., Willingham et al., 2000), although Gheysen et al. (2009) did find perceptual learning for a task that required attending to the stimulus sequence and maintaining information in working memory. Their study also showed evidence of there being a nonperceptual component to the sequence learning, as have most other studies. In general, results have indicated that this learning is not effector specific, because it can transfer to a different set of effectors (e.g., Cohen et al., 1990). Willingham et al. (2000) concluded that the sequence learning occurs in a part of the motor system involving response locations but not specific effectors or muscle groups. They showed that subjects who practiced the task using a keyboard with one arrangement of response keys during a training phase showed no benefit from the repeating stimulus sequence when subsequently transferred to a keyboard with a different arrangement of response keys. In another experiment, Willingham et al. also showed that subjects who switched from performing the task with the hands crossed in practice to performing with them uncrossed in a transfer session, such that the hand operating each key was switched, showed no cost relative to subjects who used the uncrossed hand placement throughout. Willingham et al. rejected an explanation in terms of SR associations because Willingham (1999) found excellent transfer as long as the response sequence remained the same in both the practice and transfer sessions even when the stimulus set was changed from digits to spatial locations or the mapping of spatial stimuli to responses was changed. Note that Willingham et al.'s conclusions are similar to those reached by Mechsner and Knoblich (2004) for bimanual coordination in that much of the motor control and learning occur at a level of spatial response relations rather than the muscles used to execute the actions.

Whereas in some situations the speed with which a sequence of actions is executed is important, in others the timing of the actions is crucial. One influential model of response timing is that of Wing and Kristofferson (1973), who developed it to explain the timing of successive, discrete tapping responses. According to this model, two processes control the timing of the responses. One is an internal clock that generates trigger pulses that can be used to time the delay (by the number of pulses) and initiate motor responses. The other is a delay process between when a trigger pulse initiates a response and when the movement is actually executed. The interval between successive pulses is assumed to be an independent random variable, as is the interval between a trigger pulse and the response that it initiates. One key prediction of the model is that the variance of the interval between responses should increase as the delay between the responses increases, due to the variability of the internal clock. Another prediction is that adjacent interresponse intervals should be negatively correlated, due to the variability of the delay process. These predictions have tended to be confirmed, and Wing and Kristofferson's model has generally been successful for timing of discrete responses such as tapping. However, evidence has suggested that, for more continuous motor acts such as drawing circles at a certain rate with the dominant hand, the timing is an emergent property of the movement rather than the consequence of a central timer (e.g., Ivry et al., 2002; Studenka and Zelaznik, 2008).

## 3.5 Motor Learning and Acquisition of Skill

Performance of virtually any perceptual–motor skill improves substantially with practice, as with the sequence learning described in the previous section, becoming faster, more accurate, and more fluid. Considerable research has been devoted to understanding the ways in which training and augmented feedback (knowledge of results or performance) should be scheduled to optimize the acquisition of motor skill. Some of this research is described in the following sections.

### 3.5.1 Practice Schedules

A long-standing issue in the study of motor skill has been whether better learning results from a distributed practice schedule, in which there is a break or rest period between performance attempts, or a massed practice schedule, for which there is not. Although distributed practice often leads to better performance during acquisition of a motor skill, it does not necessarily result in better learning and retention. Lee and Genovese (1988) conducted a meta-analysis of the literature on the distribution of practice and concluded that distributed practice does result in more learning for motor tasks that require continuous movements, such as cycling. Donovan and Radosevich (1999) reached a similar conclusion from a larger scale meta-analysis, with their findings indicating that distributed practice is more beneficial for simple tasks than for complex ones.

For discrete tasks, however, massed practice may even be beneficial to learning. Carron (1969) found better retention for massed than distributed practice when the task required the three discrete steps of picking up a dowel out of a hole, flipping the ends of the dowel, and putting the dowel back into the hole. Lee and Genovese (1989) directly compared discrete and continuous versions of a task in which the interval between when a stylus was lifted from one plate and moved to another was to be 500 ms. A single movement was made for the discrete version of the task, whereas 20 movements back and forth were performed in succession for the continuous version. Massed practice produced better retention than distributed practice did for the

discrete task, but distributed practice produced better retention for the continuous task.

The conclusions of Lee and Genovese (1988, 1989) and Donovan and Radosevich (1999) hold for distribution of practice within a session. For performance across practice sessions, evidence suggests that shorter practice sessions spread over more days are more effective than longer sessions spread over fewer days. For example, Baddeley and Longman (1978) gave postal trainees 60 h of practice learning to operate mail-sorting machines. The trainees who received this practice in 1-h/day sessions over 12 weeks learned the task much better than those who received the practice in 2-h sessions twice daily over three weeks. One factor contributing to the smaller benefit in learning with the longer, more massed sessions is that the sessions may get tiresome, causing people's attention to wander.

Another issue is whether different tasks or task variations should be practiced individually, in distinct practice blocks, or mixed together within a practice block. Retention and transfer of motor tasks have been shown typically to be better when the tasks are practiced in random order than in distinct blocks, even though performance during the practice session is typically better under blocked conditions. This finding, called the *contextual interference effect*, was first demonstrated by Shea and Morgan (1979). They had subjects knock down three of six barriers in a specified order as quickly as possible when a stimulus light occurred. During the acquisition phase, each subject performed three different versions of the task, which differed with respect to the barriers that were to be knocked down and their order. For half of the subjects, the three barrier conditions were practiced in distinct trial blocks, whereas for the other half, the barrier conditions were practiced in a random order. Although performance during acquisition was consistently faster for the blocked group than for the random group, performance on retention tests conducted 10 min or 10 days later was faster for the random group.

The contextual interference effect has been replicated in numerous studies and tasks (see, e.g., Magill and Hall, 1990; Wright et al., 2005). Shea and Morgan (1979) originally explained the contextual interference effect as follows: Because performance during practice is more difficult for the random group than for the blocked group, the random group is forced to use multiple processing strategies, leading to more elaborate long-term memory representations and better retention. Lee and Magill (1985) proposed instead that the benefit of random practice arises from subjects often forgetting how the task to be performed on the current trial was done previously, requiring that an action plan be reconstructed. This reconstruction process results in a more highly developed memory trace. Although these accounts differ slightly in their details, they make the similar point that random practice schedules lead to better long-term retention because they require deeper or more elaborate processing of the movements. Evidence suggests that this processing is reflected in greater activation of the motor cortex (Lin et al., 2009).

Because real-world perceptual–motor skills may be quite complex, another issue that arises is whether it is beneficial for learning to practice parts of a task in isolation before performing the whole, integrated task. Three types of part-task practice can be distinguished (Wightman and Lintern, 1985): *Segmentation* involves decomposing a task into successive subtasks, which are performed in isolation or in groups and then recombined; *fractionation* involves separate performance of subtasks that typically are performed simultaneously and then recombining them; *simplification* involves practicing a reduced version of a task that is easier to perform (such as using training wheels on a bicycle) before performing the complete version. Part-task training is often beneficial, and the results can be striking, as illustrated by Frederiksen and White's (1989) study, involving performance of a video game called Space Fortress that entailed learning and coordinating many perceptual–motor and cognitive components. In that study, subjects who received part-task training on the key task components performed about 25% better over the last five of eight whole-game transfer blocks than did subjects who received whole-game practice (see Figure 8), and this difference showed no sign of diminishing.

Although part-task training is beneficial for complex tasks that require learning complex rules and relations and coordinating the components, it is less beneficial for motor skills composed of several elements, such as a tennis serve, where practicing one element in isolation shows at most small transfer to the complete task (e.g., Lersten, 1968). Evidence suggests, though, that part-task practice with the first half of a movement sequence prior to practice of the whole sequence causes participants to code the two halves as separate parts, resulting in better performance than that of a whole-task group when required to perform just the second half in a transfer test (Park et al., 2004).

### 3.5.2 Provision of Feedback

Intrinsic feedback arises from movement, and this sensory information is a natural consequence of action. For example, as described previously, several types of visual and proprioceptive feedback are typically associated with moving a limb from a beginning location to a target location. Of more concern for motor learning, though, is extrinsic, or augmented, feedback, which is information that is not inherent to performing a task itself. Two types of extrinsic feedback are typically distinguished, *knowledge of results*, which is information about the outcome of the action, and *knowledge of performance*, which is feedback concerning how the action was executed.

Knowledge of results (KR) is particularly important for motor learning when the intrinsic feedback for the task itself does not provide an indication of whether the goal was achieved. For example, in learning to throw darts at a target, the extrinsic KR is not of extreme importance because intrinsic visual feedback provides information about the amount of error in the throws. However, even in this case, KR may provide motivation to the performer and reinforcement of their actions, and knowledge of performance (e.g., whether the throwing motion was appropriate) may also be beneficial. If the task is one of learning to throw darts in the dark, KR
**Figure 8** Mean score of Frederiksen and White's (1989) subjects on eight game blocks of Space Fortress in the transfer session after receiving part- or whole-task training in a prior session.

increases in importance because there is no longer visual feedback to provide information about the accuracy of the throws. Many issues concerning KR have been investigated, including the precision of the information conveyed and the schedule by which it is conveyed.

Feedback can be given with varying precision. For example, when performing a task that requires contact with a target at a specified time window, say, 490–500 ms after movement initiation, the person may be told whether or not the movement was completed within the time window (qualitative KR) or how many milliseconds shorter or longer the movement was than allowed by the window (quantitative KR). Qualitative feedback can be effective, particularly at early stages of practice when the errors are often large, but people tend to learn better when KR is quantitative than when it is just qualitative (Magill and Wood, 1986; Reeve et al., 1990).

Although it may seem that it is best to provide feedback on every trial, research has indicated to the contrary. For example, Winstein and Schmidt (1990) had people learn to produce a lever movement pattern consisting of four segments in 800 ms. Some subjects received KR after every trial during acquisition, whereas others received KR on only half of the trials. The two groups performed similarly during acquisition, but those subjects who received feedback after every trial did substantially worse than the other group on a delayed retention test. Similar results have been obtained for a more naturalistic golf-putting task (Ishikura, 2008). Summary KR, for which feedback about a subset of trials is not presented until the subset is completed, has also been found to be successful (Lavery, 1962; Schmidt et al., 1989). Schmidt et al. had people learn a timed lever movement task similar to that used by Winstein and Schmidt (1990), providing summary KR after 1, 5, 10,

or 15 trials. A delayed retention test showed that learning was best when summary KR was provided every 15 trials and worst when KR was provided every trial. The apparent reason why it is best not to provide feedback on every performance attempt is that the person comes to depend on it. Thus, much like blocked practice of the same task, providing feedback on every trial does not force the person to engage in the more effortful information processing that is necessary to produce enduring memory traces needed for long-term performance.

## 4 SUMMARY AND CONCLUSIONS

Human–machine interactions involve a succession of reciprocal actions taken by the human and the machine. For performance of the human component to be optimal, it is necessary not only to consider how the machine should display information regarding its states and activities to the human, but also to take into account the processes by which the human selects and executes actions in the sequence of the interaction. Selection and control of action have been studied since the earliest days of research on human performance, and research in these areas continues to produce significant empirical and theoretical advances, several of which have been summarized in this chapter. Because the purpose of the chapter is to provide readers with an overview of the topic of selection and control of action, readers are encouraged to refer to more detailed information on topics of interest in chapters by Rosenbaum (2002), Heuer and Massen (in press), and Proctor and Vu (in press); and books by Rosenbaum (2010), Proctor and Dutta (1995), Sanders (1998), and Schmidt and Lee (1999); and other sources.

This chapter showed that the relations between choice uncertainty and response time, captured by the

Hick–Hyman law, movement difficulty and movement time, conveyed by Fitts's law, and amount of practice and performance time, depicted by the power law of practice, follow quantitative laws that can be applied to specific research and design issues in human factors and ergonomics. In addition, many qualitative principles are apparent from research that is directly applicable to human factors:

- The relative speed and accuracy of responding in a situation depends in part on the setting of response thresholds, or how much noisy evidence needs to be sampled before deciding which alternative action to select.
- Sequential sampling models can capture the relations between speed and accuracy of performance in various task conditions.
- Response time increases as the number of alternatives increases, but the cost of additional alternatives is reduced when compatibility is high or the performer is highly practiced.
- Spatially compatible relations and mappings typically yield better performance than spatially incompatible ones.
- Compatibility effects are not restricted to spatial relations but occur for stimulus and response sets that have perceptual or conceptual similarity of any type.
- Compatibility effects occur when an irrelevant dimension of the stimulus set shares similarity with the relevant response dimension.
- For many situations in which compatible mappings are mixed with less compatible ones, the benefit of compatibility is eliminated.
- When actions are not performed in isolation, the context of preceding events can affect performance significantly.
- Advance information can be used to prepare subsets of responses.
- Improvements in response selection efficiency with practice that occur in a variety of tasks involve primarily spatial locations of the actions and their relation to the stimuli, not the effectors used to accomplish the actions.
- Small amounts of experience with novel relations may influence performance after a long delay, even when those relations are no longer relevant to the task.
- Costs that are associated with mixing and switching tasks can be only partly overcome by advance preparation.
- It is difficult to select an action for more than one task at a time, although the costs in doing so can be reduced by using highly compatible tasks and with practice.
- Many constraints influence movement time, and the particular way in which an action will be carried out needs to be accommodated when designing for humans.

- Feedback of various types is important for motor control and acquisition of perceptual–motor skills.
- The tendency toward symmetry in preferred bimanual coordination patterns is primarily one of spatial symmetry, not of homologous muscles.
- Practice and feedback schedules that produce the best performance of perceptual–motor skills during the acquisition phase often do not promote learning and retention of the skills.
- Part-task training can be an effective means of teaching someone how to perform complex tasks.

Beyond these general laws and principles, research has yielded many details concerning the factors that are critical to performance in specific situations. Moreover, models of various types, some qualitative and some quantitative, have been developed for various domains of phenomena that provide relatively accurate descriptions and predictions of how performance will be affected by numerous variables. The laws, principles, and model characteristics can be incorporated into cognitive architectures such as EPIC (Meyer and Kieras, 1997) and ACT-R (Anderson et al., 2004; Byrne, 2001), along with other facts, to develop computational models that enable quantitative predictions to be derived for complex tasks of the type encountered in much of human factors and ergonomics.

## 1 INTRODUCTION

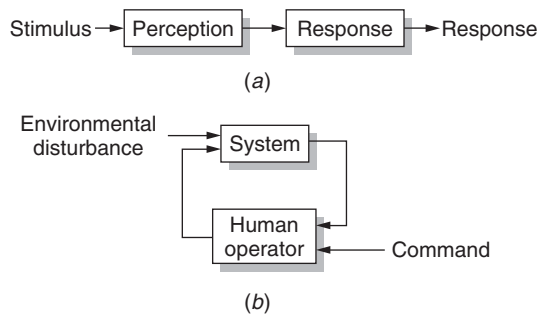
Information processing lies at the heart of human performance. In a plethora of situations in which humans interact with systems, the operator must perceive information, transform that information into different forms, take actions on the basis of the perceived and transformed information, and process the feedback from that action, assessing its effect on the environment. These characteristics apply whether information processing is defined in terms of the classic open-loop information-processing model that derives from much of psychological research (Figure 1*a*) or the closed-loop model of Figure 1*b*, which has its roots within both control engineering (e.g., Pew and Baron, 1978; McRuer, 1980; Jagacinski and Flach, 2003) and more recent conceptualizing in ecological psychology (Flach et al., 1995; Hancock et al., 1995). In either case, *transformations* must be made on the information as it flows through the human operator. These transformations take time


**Figure 1** Two representations of information processing: (*a*) traditional open-loop representation from cognitive psychology; (*b*) closed-loop system, following the tradition of engineering feedback models.

and may be the source of error. Understanding their nature, their time demands, and the kinds of errors that result from their operation is critical to predicting and modeling human–system interaction.

In this chapter we describe characteristics of the different important *stages* of information processing, from perception of the environment to acting on that environment. We try to do so in a way that is neither too specific to any particular system nor so generic that the relevance of the information-processing model to system design is not evident. We begin by contrasting three ways in which information processing has been treated in applied psychology, and then we describe processes and transformations related to *attention, perception, memory* and *cognition, action selection*, and *multiple-task performance*.

## 2 THREE APPROACHES TO INFORMATION PROCESSING

The classic information-processing approach to describing human performance owes much to the seminal work of Broadbent (1958, 1972), Neisser (1967), Sternberg (1969), Posner (1978), and others in the decades of the 1950s, 1960s, and 1970s, who applied the metaphor of the digital computer to human behavior. In particular, as characterized by the representation in Figure 1*a*, information was conceived as passing through a finite number of discrete stages. These stages were identifiable, not only by experimental manipulations, but also by converging evidence from brain physiology. For example, it makes sense to distinguish a perceptual stage from one involving the selection and execution of action, because of the morphological distinctions between perceptual and motor cortex.

There is also a human factors rationale for the stage distinction made by information-processing psychology. This is because different task or environmental factors appear to influence processing differentially at the different stages, a distinction that has certain design implications. For example, the *aging process* appears to affect the selection and execution of actions more than

the speed of perceptual encoding (Strayer et al., 1987). Immersed displays may improve perceptual–motor interaction, even as they inhibit the allocation of attention (Olmos et al., 2000), and different sources of workload may have different influences on the different stages (Wickens and Hollands 2000). Decision-making biases can be characterized by whether they influence perception, diagnosis, or action selection (Wallsten, 1980; Wickens and Hollands, 2000), and the different stages may also be responsible for the commission of qualitatively different kinds of errors (Reason, 1990; see Chapter 27). The support that automation provides to the human operator can also be well represented within the information-processing stage taxonomy (Parasuraman et al., 2000, 2008). Within the stage approach, there is no need to assume that processing starts at stage 1. For example, if one has an intention to act, processing can start with the response.

In contrast to the stage approach, the *ecological approach* to describing human performance provides much greater emphasis on the integrated flow of information through the human rather than on the distinct, analyzable stage sequence (Gibson, 1979; Flach et al., 1995; Hancock et al., 1995). The ecological approach also emphasizes the human's integrated interaction with the *environment* to a greater extent than does the stage approach, which can sometimes characterize information processing in a more context-free manner. Accordingly, the ecological approach focuses very heavily on modeling the perceptual characteristics of the environment to which the user is "tuned" and responds in order to meet the goals of a particular task. Action and perception are closely linked, since to act is to change what is perceived, and to perceive is to change the basis of action in a manner consistent with the closed-loop representation shown in Figure 1*b*.

As a consequence of these properties, the ecological approach is most directly relevant to describing human behavior in interaction with the natural environment (e.g., walking or driving through natural spaces or manipulating objects directly). However, as a direct outgrowth, this approach is also quite relevant to the design of controls and displays that mimic characteristics of the natural environment—the concept of *direct-manipulation interfaces* (Hutchins et al., 1985). As a further outgrowth, the ecological approach is relevant to the design of interfaces that mimic characteristics of how users *think* about a physical process, even if the process itself is not visible in a way that can be represented directly. In this regard, the ecological approach has been used as a basis for designing effective displays of energy conversion processes such as those found in a nuclear reactor (Vicente and Rasmussen, 1992; Moray et al., 1994; Vicente et al., 1995; Burns, 2000; Vicente, 2002; Burns et al., 2004).

Because of its emphasis on interaction with the natural (and thereby familiar) environment, the ecological approach is closely related to other approaches to performance modeling that emphasize people working with domains and systems about which they are experts. This feature characterizes, for example, the study of *naturalistic decision making* (Zsambock and Klein, 1997;

Kahneman and Klein, 2009; see Chapter 3), which is often set up in contrast to the representation of decision making within an information-processing framework (Wickens and Hollands, 2000).

Both the stage-based approach and the ecological approach have a great deal to offer to human factors, and the position we take in this chapter is that aspects of each can and should be selected, as they are more appropriate for analysis of the operator in a particular system. For example, the ecological approach is highly appropriate for modeling vehicle control, but less so for describing processes in reading, understanding complex instructions under stress, or dealing with highly symbolic logical systems (e.g., the logic of computers, information retrieval systems, or decision tree analysis; see Chapter 8). Finally, both approaches can be fused harmoniously, as when, for example, the important constraints of the natural environment are analyzed carefully to understand the information available for perception and the control actions allowable for action execution in driving, but the more context-free limits of information processing can be used to understand how performance might break down from a high load that is imposed on memory or dual-task performance requirements in a car.

A final approach, that of *cognitive engineering*, or *cognitive ergonomics* (Rasmussen et al., 1995; Vicente, 1999, 2002; Bizants and Roth, 2007; Jenkins et al., 2009), is somewhat of a hybrid of the two described above. The emphasis of cognitive engineering is, on the one hand, based on a very careful understanding of the environment and task constraints within which an operator works, a characteristic of the ecological approach. On the other hand, as suggested by the prominence of the word *cognitive*, the approach places great emphasis on modeling and understanding the knowledge structures that expert operators have of the domains in which they must work and, indeed,

the knowledge structures of computer agents in the system. Thus, whereas the ecological approach tends to be more specifically applied to human interaction with physical systems and environments (particularly those that obey the constraints of Newtonian physics), cognitive engineering is relevant to the design of almost any system about which the human operator can acquire knowledge, including the very symbolic computer systems, which have no physical analogy.

Whether human performance is approached from an information-processing, ecological, or cognitive engineering point of view, we assert here that, in almost any task, a certain number of mental processes involved in selecting, interpreting, retaining, or responding to information may be implemented, and it is understanding the vulnerabilities of these processes and capitalizing, where possible, on their strengths which can provide an important key to effective human factors of system design.

In this chapter we adopt as a framework the information-processing model depicted in Figure 2 (Wickens and Hollands, 2000). Here stimuli or events are *sensed and attended* (Section 3) and that information received by our sensory system is *perceived*, that is, provided with some meaningful interpretation based on memory of past experience (Section 4). That which is perceived may be responded to directly, through a process of action selection (decision of what act to take) and execution (Section 6). Alternatively, it may be stored temporarily in working memory, a system that may also be involved in thinking about or transforming information that was not sensed and perceived but was generated internally (e.g., mental images, rules, Section 5). Working memory is of limited capacity and heavily demanding of attention in its operation but is closely related to our large-capacity long-term memory, a system that stores vast amounts of information about the world, including both facts and procedures, and

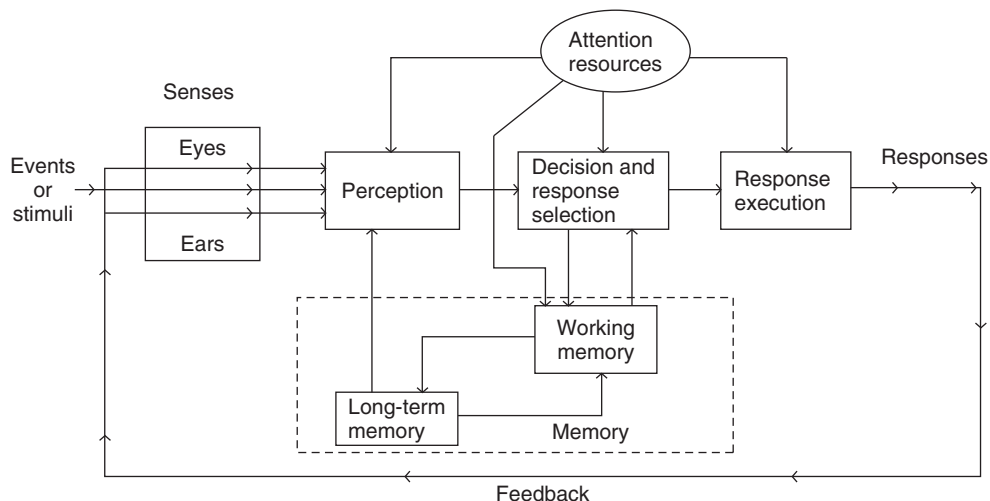

**Figure 2**  Model of human information processing. (Adapted from Wickens, 1992.)

retains that information without attention but not always fully available for retrieval.

As noted in the figure and highlighted in the ecological approach, actions generally produce feedback which is then sensed to complete the closed-loop cycle. In addition, human attention, a limited resource, plays two critical roles in the information-processing sequence (Wickens, 2007; Wickens and McCarley, 2008). As a selective agent, it chooses and constrains this information that will be perceived (Section 3). As a task management agent, it constrains what tasks (or mental operations) can be performed concurrently (Section 7).

## 3   SELECTING INFORMATION

Since Broadbent's (1958) classic book, it has been both conventional and important to model human information processing as, in part, a filtering process. This filtering is assumed to be carried out by the mechanisms of *human attention* (Kahneman, 1973; Parasuraman et al., 1984; Damos, 1991; Pashler, 1998; Johnson and Proctor, 2004). Attention, in turn, may be conceptualized as having three *modes*: Selective attention chooses what to process in the environment, focused attention characterizes the efforts to sustain processing of those elements while avoiding distraction from others, and *divided attention* characterizes the ability to process more than one attribute or element of the environment at a given time.

We discuss below the human factors implications of the selective and focused attention modes and their relevance to visual search and discuss those of divided attention in more detail in Sections 4.6 and 7.

### 3.1   Selective Attention

In complex environments, selective attention may be described in terms of how it is influenced by the combined force of four factors: salience, effort, expectancy, and value (Wickens et al., 2003). These influences can often be revealed by eye movements when visual selective attention is assessed by visual scanning; obviously, however, eye movements cannot reflect the selectivity between vision and the other sensory modalities, such as auditory or tactile (Sarter, 2007).

1. *Salient features* of the environment will attract, or "capture," attention. Thus, auditory sounds tend to be more attention grabbing than visual events, leading to the choice of sounds to be used in alarms (Stanton, 1994; see also Chapterx 24). Within a visual display, the onset of a stimulus (e.g., increase in brightness from zero, or the appearance of an object where one was not present previously) tends to be the most salient or attention-attracting property (Yantis, 1993; Egeth and Yantis, 1997); other features, such as uniqueness, can also attract attention, but these are typically less powerful than onsets. The prominent role of onsets as attention-capturing devices can explain the value of repeated onsets ("flashing") as a visual alert. Salient events

are sometimes described as those that govern *bottom-up* or stimulus-driven allocation of attention, to be contrasted with knowledge-driven or *top-down* features of selective attention, which we describe next in the context of expectations.

2. *Expectancy* refers to knowledge regarding the probable time and location of information availability. For example, frequently changing areas are scanned more often than slowly changing areas (Senders, 1980). Thus, drivers will keep their eyes on the road more continuously when the car is traveling fast on a curvy road than when traveling slowly on a straight one. The former has a higher "bandwidth." Also, expectancy defines the role of cueing in guiding attention. For example, an auditory warning may direct attention toward the display indicator that the warning is monitoring, because the operator will now expect to see an abnormal reading on that display.

3. *Value* is a third factor. High-frequency changes are not, however, sufficient to direct attention. The driver will not look out the side window despite the fact that there is a lot of perceptual "action" there, because information in the side window is generally not relevant to highway safety. It has already passed. Thus, selective attention is also driven by the *value* of information received at different locations. This describes the importance of knowing that information in carrying out useful tasks, or the costs of failing to note important information. It is valuable for the driver to look forward, because of the cost of failing to see a roadway hazard or of changing direction toward the side of the road. Thus, the effect of expectancy (bandwidth or frequency) on the allocation of selective attention is modulated by the value, as if the probability of attending somewhere, $p(A)$, is equal to the *expected value* of information sources to be seen at that location (Moray, 1986; Wickens et al., 2003; Wickens et al., 2008). Indeed, Moray (1986) and Wickens et al. (2003) find that well-trained, highly skilled operators scan the environment very much as if their attention is driven primarily and nearly exclusively by the multiplicative function of expectancy and value. Thus, we may think of the well-trained operator as developing scanning *habits* that internalize the expectancy and value of sources in the environment, defining an appropriately calibrated *mental model* (Bellenkes et al., 1997).

4. The final factor that may sometimes influence attention allocation is a negative one, and this factor, unique to eye movements, is the *effort* required to move attention around the environment. Small attention movements, such as scanning from one word to the next in a line of text or a quick glance at the speedometer in a car, require little effort. However, larger movements, such as shifting the eyes *and* head to check the side-view mirrors in a car, or coupling these

with rotation of the trunk to check the "blind spot" before changing lanes, requires considerably more information access effort (Ballard et al, 1995; Wickens, 1993). Indeed, the role of the information access effort also generalizes to the effort costs of using the fingers to manipulate a keyboard and access printed material that might otherwise be accessed by a simple scan to a dedicated display (Gray and Fu, 2001). The effort to shift attention to more remote locations may have a minimal effect on the well-rested operator with a well-trained mental model who knows precisely the expectancy and value of information sources (Wickens et al., 2003). However, the combination of fatigue (depleting effort) and a less well calibrated mental model can seriously inhibit accessing information at effortful locations, even when such information may be particularly valuable.

Collectively, the forces of salience, effort, expectancy, and value on attention can be represented by a visual attention model called SEEV, in which $P(A) = S - EF + EX \times V$ (Wickens et al., 2003, 2008, 2009a; Horrey et al., 2006). Good design should try to reduce these four components to two by making valuable information sources salient (correlating salience and value) and by minimizing the effort required to access valuable *and* frequently used (expected) sources. For example, head-up displays (HUDs) in aircraft and automobiles are designed to minimize the information access effort of selecting the view outside and the information contained in important instruments (Fadden et al., 2001; Wickens et al., 2004). Reduced information access effort can also be achieved through effective layout of display instruments (Wickens et al., 1997).

While SEEV may predict what **is** attended, and salience highlights the roll of bottom-up attention capture, a large body of research has also recently focused on *attentional blindness,* particularly *change blindness,* highlighting the events in the world that are not noticed, even when they may be valuable (Simons and Levin, 1997 Rensink, 2002; Wickens et al., 2009a).

It seems that the human's attention system is not well designed to notice unexpected events, particularly when they appear in peripheral vision, under conditions of high workload. Naturally if these events are not salient as well (e.g., the offset of a stimulus, or a change in a word, say from "off" to "on"), then noticing will degrade still further. While in many circumstances such events may be noticed a majority of the time, when the events are safety critical (as in the above, "on" designating the activation of power) and relatively rare (referred to as "black swans"; Taleb, 2007; Wickens et al., 2009a), human miss rates as low as 10–20% can illuminate the safety concerns of change blindness (Wickens, 2009).

## 3.2   Focused Attention

While selective attention dictates where attention should travel, the goal of focused attention is to maintain processing of the desired source and avoid the distracting influence of potentially competing sources. The primary sources of breakdowns in focused attention are certain physical properties of the visual environment (clutter) or the auditory environment (noise), which will nearly guarantee some processing of those environments, whether or not such processing is desired. Thus, any visual information source within about $1°$ of visual angle of a desired attentional focus will disrupt processing of the latter to some extent (Broadbent, 1982). Any sound within a certain range of frequency and intensity of an attended sound will have a similar disruptive effect on auditory focused attention (Banbury et al., 2001; see Chapter 3). However, even beyond these minimum limits of visual space and auditory frequency, information sources can be disruptive of focused attention if they are salient.

## 3.3   Discrimination and Confusability

A key to design that can address issues of both selective and focused attention is concern for *discrimination* between information sources. Making sources discriminable by space, color, intensity, frequency, or other physical differences has two benefits. First, it will allow the display viewer to *parse* the world into its meaningful components on the basis of these physical features, thereby allowing selective attention to operate more efficiently (Treisman, 1986; Yeh and Wickens, 2001; Wickens et al., 2004). For example, an air traffic controller who views on her display all of the aircraft within a given altitude range depicted in the same color can easily select all of those aircraft for attention to ascertain which ones might be on conflicting flight paths. Parsing via a discrimination will be effective as long as all elements that are rendered physically similar (and therefore are parsed together) share in common some characteristic that is relevant for the user's *task* (as in the example above, all aircraft at the same altitude represent potential conflicts).

Second, when elements are made more discriminable by some physical feature, it is considerably easier for the operator to *focus* attention on one and ignore distraction from another, even if the two are close together in space (or are similar in other characteristics). Here, again, in our air traffic control example, it will be easier for the controller to focus attention on the converging tracks of two commonly colored aircraft if other aircraft are colored differently than if all are depicted in the same hue.

Naturally, the converse of difference-based discriminability is similarity- (or identity-) based confusion between information sources, a property that has many negative implications for design. For example, industrial designers may strive for consistency or uniformity in the style of a particular product interface by making all touchpad controls the same shape or size. Such stylistic uniformity, however, may result in higher rates of errors from users activating the wrong control because it looks so similar to the control intended.

## 3.4   Visual Search

Discrimination joins with selective and focused attention when the operator is engaged in *visual search*, looking for something in a cluttered environment (Wickens and

McCarley, 2008). The task may characterize looking for a sign by the roadway (Holohan et al., 1978), conflicting aircraft in an air traffic control display (Remington et al., 2000), a weapon in an X-rayed luggage image (McCarley et al., 2004), a feature on a map (Yeh and Wickens, 2001), or an item on a computer menu (Fisher et al., 1989). *Visual search models* are designed to predict the time required to find a target. Such time predictions can be very important for both safety (e.g., if the eyes need to be diverted from vehicle control while searching) and productivity (e.g., if jobs require repeated searches, as in quality control inspection or menu use).

The simplest model of visual search, based on a *serial self-terminating search* (Neisser et al., 1964), assumes that a *search space* is filled with items most of which are *nontargets* or *distracters*. The mean time to find a target is modeled to be RT = $NT/2$, where $N$ is the number of items in the space, $T$ is the time to examine each item and determine that it is *not* a target before moving on to the next, and division by 2 reflects the fact that on average the target will be reached after half of the space is searched, but sometimes earlier and sometimes later. Hence, the variance in search time will also grow with $N$. Importantly, in many displays, we can think of $N$ as a very functional measure of *clutter* (Yeh and Wickens, 2001).

The elegant and simple prediction of the serial self-terminating search model often provides a reasonable accounting for data (Yeh and Wickens 2001; Remington et al., 2000) but is also thwarted (but search performance is improved) by three factors that characterize search in many real-world search tasks: bottom-up parallel processing, top-down processing, and target familiarity. The first two can be accommodated by the concept of a *guided search model* (Wolfe, 2007; Wolfe and Horowitz, 2004). Regarding parallel processing, as noted in Section 3.1, certain features (e.g., uniqueness, flashing) will capture attention because they can be preattentively processed or processed in parallel (rather than in series) with all other elements in the search field. Hence, if the target is known to contain such features, it will be found rapidly, and search time will be unaffected by the number of nontarget items in the search field. This is because all nontarget items can be discriminated automatically (as discussed in Section 1) and thereby eliminated from imposing any search costs (Yeh and Wickens, 2001; L. D. Wickens, Alexander et al., 2004). For example, in a police car dispatcher display, all cars currently available for dispatching can be highlighted, and the dispatcher's search for the vehicle closest to a trouble spot can proceed more rapidly. Stated in other terms, search is "guided" to the subset of items containing the single feature which indicates that they are relevant. If there is more than a single such item, the search may be serial between those items that remain. *Highlighting* (Fisher et al., 1989; L. D. Wickens, Alexander et al., 2004; Remington et al., 2000) is a technique that capitalizes on this guided search.

Regarding top-down processing, search may also be guided by the operator's knowledge of *where* the target is most likely to be found. Location expectancy, acquired with practice and expertise, will create search strategies that scan the most likely locations first, to the extent that such predictability exists in the searched environments. For example, tumors may be more likely to appear in some parts of an organ than others, and skilled radiologists capitalize on this in examining an X ray in a way that novices do not (Kundel and Nodine, 1978). However, such a strategy may not be available to help the scanner of luggage X rays for weapons, because such weapons may be hidden anywhere in the luggage rather than in a predicable location (McCarley et al., 2004).

A second influence of top-down processing on search is the expectancy of whether a target will be present or not, the "target prevalence rate." Wolfe et al. (2005) observe that a low expectancy for targets will lead searchers to terminate their search prematurely, even though the target may still be present in the cluttered search field.

A third factor that can speed visual search, target familiarity is, like guided search, related to experience and learning and, like parallel search, related to salient features. Here we find that repeated exposures to the same consistent target can speed the search for that target and, in particular, reduce the likelihood that the target may be looked at (fixated) but not actually detected (McCarley et al., 2004). With sufficient repetition looking for the same target (or target possessing the same set of features), the expert tunes his or her sensitivity to discriminate target from nontarget features, and with extensive practice, the target may actually "pop out" of the nontargets, as if its discriminating features are processed preattentively (Schneider and Shiffrin, 1977). Further, even if a target does not become sufficiently salient to pop out when viewed in the visual periphery, repeated exposure can help ensure that it will be detected and recognized once the operator has fixated on it (McCarley et al., 2004).

The information processing involved in visual search culminates in a target detection decision, which sometimes may be every bit as important as the search operations that preceded it. In the following section we examine this detection process in its own right.

## 4 PERCEPTION AND DATA INTERPRETATION

### 4.1 Detection as Decision Making

At the top of many display design checklists is a reminder that critical targets must be detectable in the environment for which they are intended (e.g., Travis, 1991; Sanders and McCormick, 1993). Assuring such detectability might seem to be a simple matter of knowing enough about the limits of the operator's sensory systems to choose appropriate levels of physical stimulation, for example, appropriate wavelengths of light, frequencies of sound, or concentrations of odorants. Human sensitivity to the presence and variation of different physical dimensions is reviewed in Chapter 3, and these data must be considered limiting factors in the design of displays. Yet the detectability of any critical signal is also a function of the operator's goals, knowledge, and expectations. As noted in our discussion of

**Table 1  Joint Contingent Events Used in Signal Detection Theory Analysis**

| Operator's Decision (Response Criterion) | State of the World | |
|---|---|---|
| | Signal | No Signal (Noise) |
| Signal | Hit | False alarm |
| No signal | Miss | Correct rejection |

visual search, there are plenty of opportunities for targets that are clearly above threshold to be missed when the operator is hurried and the display is cluttered. As we noted in our discussion of change blindness above, the magnitude of the superthreshold changes in a scene that can be missed is often surprising (Rensink, 2002).

The interpretive and vulnerable nature of even the simplest signal detection task becomes most apparent when we consider that missing a target is not the only possible detection error; we may also make *false alarms*, responding as if a signal is present when it is not (see Table 1). *Signal detection theory* (SDT) provides a valuable conceptual and computational framework for describing the processes that can lead to both types of errors (Green and Swets, 1989; Wickens, 2002; MacMillan and Creelman, 2005). In SDT, signals are never assumed to occur against a "clean" background of zero stimulation. Instead, all signals occur against a background of fluctuating *noise*. The noise arises from both internal (e.g., baseline neuronal activity) and external sources. The observer's detection task is thus, in reality, a *decision* task: Is the level of stimulation experienced at any moment the results of high levels of noise or does it represent the presence of a signal? Because noise is always present and is always fluctuating in intensity, detection errors are inevitable.

To deal with the uncertainty inherent in detection, SDT asserts that operators choose a level of sensory excitation to serve as a *response criterion*. If excitation exceeds this criterion, they will respond as if a signal is present. Operators who raise their response criteria, making them more conservative, will also increase the likelihood of missing targets. Lowering their criteria, however, will decrease the number of misses at the expense of increased false alarms. Signal detection theory provides a way to describe the criterion set by a particular operator performing a particular detection task and of determining the optimality of the selected criterion in the face of task characteristics such as signal probabilities and the relative repercussions (i.e., practical outcomes) of making the two types of errors.

Signal detection theory formally demonstrates that as signal probability increases, response criteria should be lowered in order to minimize overall error rates. People performing laboratory detection tasks tend to adjust their response criteria in the direction prescribed by SDT; however, they do *not* tend to adjust them far enough (Green and Swets, 1989). Probability-related shifts in response criteria also seem to occur in a wide variety of operational settings. For example, Lusted (1976) found that physicians' criteria for detecting particular medical conditions were influenced by the base rate of the abnormality (probability of signal). Similarly, industrial inspectors adjusted their criteria for fault detection based on estimated defect rates (Drury and Addison, 1973), although they fail to adjust their criteria enough when defect rates fall below 5% (Harris and Chaney, 1969). Many errors in the judicial process may also be linked to the biasing effects of implicit and potentially unreliable clues about signal probability. Saks et al. (2003) argue that such probability estimates influence the performance of forensic scientists asked to detect critical matches in evidence such as fingerprints, bite marks, and bomb residues. Research has also demonstrated an effective intervention for operators with overly low response criteria: Inserting "false signals" into some inspection tasks can increase perceived signal probability and, as a result, shift response criteria downward (Baker, 1961; Wilkinson, 1964).

A second factor that should influence the setting of the response criterion, according to SDT, is the relative costs associated with misses and false alarms and the relative benefits of correct responses. As an extreme example, if there were dire consequences associated with a miss and absolutely no costs for false alarms, the operator should adopt the lowest criterion possible and simply respond as if the signal is there at *every* opportunity. Usually, however, circumstances are not so simple. For example, a missed (or delayed) air space conflict by the air traffic controller or a missed tumor by the radiologist may have enormous costs, possibly in terms of human lives. However, actions taken because of false alarms, such as evasive flight maneuvers or unnecessary surgery, also have costs. The operator should adjust his or her response criterion downward to the degree that misses are more costly than false alarms and upward to the extent that avoiding false alarms is more important.

An important use of SDT in human factors research is often to diagnose the source of unsatisfactory detection performance. Has the operator failed to appropriately calibrate his or her response criterion to actual signal probabilities and response outcomes? Or, are limitations in the sensitivity of the operator's own (internal) signal-processing systems at fault? Depending on the answers to these questions, interventions can be devised to enhance detection performance. In the case of sensory limitations, engineering innovations may be required to enhance the fundamental signal-to-noise ratio, or greater target exposure may be necessary to enhance the operator's sensory tuning to critical target features (Gold et al., 1999). For example, attempts to increase the performance of airport luggage screeners have led to the development of a threat image projection (TIP) system for on-the-job training (Schwaninger and Wales, 2009). The system intermittently projects "false threat" images onto actual X-ray images, giving screeners greater exposure to potential targets (increasing overall sensitivity) and increasing their estimates of signal probability as well (thus, keeping their response criteria relatively low).

The job of the baggage screener exemplifies a combination of demands that can prove particularly challenging to operators—detection of low-probability signals

over lengthy monitoring periods. Such *vigilance tasks*, and the predictable *vigilance decrements* in detection performance that occur as the watch progresses, have been the target of extensive research over much of the last century (Warm, 1984). In reviewing this literature, Warm et al. (2008) have argued that vigilance tasks are a part of many modern jobs and are both more mentally demanding and stressful than is often realized. As a way of dealing with such demands and the relatively poor detection performance that often results, designers often develop alarms and alerts to assist or sometimes replace the operator (Stanton, 1994). Yet considerable evidence suggests that such automation does not eliminate the detection problem. Automated alerts must also confront challenging issues of distinguishing signals from highly similar noise (e.g., friend and foe on a military image display), and such alert systems can be counted on to create errors. Thus, the alarm designer, rather than the human monitor, is now the agent responsible for adjusting the response criterion of the alarm, to trade off misses versus false alarms, and designers are often tempted to make this adjustment in such a way that signals are never missed by their systems. (Consider the possible litigation if a fire alarm fails to go off.) However, when the human and automation are considered as a total system, the resulting increase in automation false alarms can have serious consequences (Sorkin and Woods, 1985; Dixon et al., 2007). These consequences arise because a high false-alarm rate can lead to serious issues of *automation mistrust*, in which people may ignore the alarms altogether (Sorkin, 1989) and experience the "cry wolf" phenomenon (Breznitz, 1983).

The analysis of diagnostic systems also reveals that the problems of high false-alarm rates will be further amplified to the extent that the signals to be detected themselves occur rarely—the "low-base-rate problem," as is often the case with alarm systems (Parasuraman et al., 1997), so that a large majority of the alarms that do sound will be false alarms. Answers to these problems lie in part in making available to human perception the raw data of the signal domain that is the basis of the alarm (Wickens et al, 2009b); and this appears to mitigate or even eliminate the cry-wolf effect. There is some evidence that *likelihood alarms* that can signal their own degrees of certainty in graded form (rather than a two-state on–off logic) will assist (Sorkin and Woods, 1985; St. Johns and Manes, 2002). Finally, it is reasonable to assume that training operators as to the nature of the mandatory miss/false-alarm trade-off, and the inevitable high false-alarm rate when there are low-base-rate events, should mitigate problems of distrust to some degree.

## 4.2   Expectancy, Context, and Identification

We have seen that our knowledge and expectations about the world help determine the efficiency of both our visual search and signal detection performance. Based on our past experience, attention can be directed to locations where targets are more likely to occur and response criteria can be adjusted according to the perceived likelihood or value of signals. We now consider how our ability to identify enormous numbers of objects from a variety of vantage points, often under less than optimal conditions, is also dependent on prior knowledge. Much research in object perception has been devoted to determining how the co-occurrence of particular stimulus attributes helps define individual objects (e.g., Biederman, 1987). However, research in cognitive psychology and computer vision has also provided compelling demonstrations of how our knowledge of statistical dependencies across entire scenes and events helps us make "educated guesses" about the likely identity of constituent objects (Oliva and Torralba, 2010).

Many studies, ranging from those using simple, artificial stimuli to those using complex, naturalistic scenes, have demonstrated that objects and attributes are recognized more quickly when they are embedded in consistent contexts (i.e., those in which the targets are naturally and frequently found) rather than when presented alone or in inconsistent contexts. Words are more efficiently identified when embedded in meaningful sentences rather than alone (e.g., Tulving et al., 1964). Individual letters are recognized more efficiently when embedded in words rather than when presented alone or as part of nonwords (Reicher, 1969). Caricature facial features require less physical detail for recognition when they are embedded in a face (Palmer, 1975). Photographs of naturalistic scenes also seem to enhance the identification of objects typically found there (Biederman et al., 1981). Even relatively subtle (but meaningful) object relations can influence identification; for example, an image of a glass is identified more rapidly when presented with an image of a pitcher that has its spout oriented toward the glass rather than away from it (Green and Hummel, 2006).

Explanations for context effects generally assume that added items in the stimulus array will increase the odds that the operator will recognize at least some portion of it. Even if the portion immediately recognized is not the target object, the recognition is still useful because it reduces the likelihood that some stimuli will be encountered while increasing the likelihood of others. In this way, the total set of possible objects, words, or letters from which the observer must choose becomes smaller and more manageable [see Massaro (1979) and McClelland and Rumelhart (1981) for formal models].

It is important to note that not all research on context effects focuses on our use of knowledge about contingencies among and within perceptual objects. Some researchers are more interested in identifying global *scene statistics* that might constrain the processing (and enhance the efficiency) of our interpretation of local scene elements (e.g., Ariely, 2001). These global properties may not be as subjectively accessible as the objects that form the scene, but they may provide an efficient means to reduce perceptual load. These statistics may include the mean size and variance of a set of objects, the center of mass, and textural properties (Oliva and Torralba, 2010). Evidence is accumulating that we do, in fact, extract global scene statistics such as mean object size, even of nonattended display elements (e.g., Chong and Treisman, 2005).

Taken together, these findings suggest that the old design maxim that "less is more" may well be wrong when the goal is to support the operator's identification of task-critical information. Unlike performance in visual search tasks, where additional nontarget stimuli or events usually cause declines in performance, identification tasks often benefit from the presence of additional stimuli, as long as those stimuli are normally encountered in spatial or temporal proximity to the target. In fact, operator expectancies can be used to offset degraded stimulus conditions such as poor print reproductions, faulty lighting, brief stimulus exposures, presentation to peripheral vision, or even the momentary diversion of attention. Therefore, the redundant use of red, an octagonal shape, and the letters S–T–O–P enhances the identification of a stop sign, as does its expected location to the driver's right immediately before an intersection. A "less is more" stop sign that only used the letter S as a distinguishing feature would not be advised!

In addition to the design implications of providing a *consistent* context for critical information, context effects also warn of the dangers of contextual *inconsistency*. The detection of such inconsistencies by safety professionals may be particularly useful for identifying environmental hazards. For example, a sidewalk interrupted by isolated steps may be a dangerous spot for a fall if not surrounded by changes in scene texture that typically indicate abrupt changes in landscape elevation [see Cohen (2003) for further examples of expectancy effects in trips and falls]. The availability of normative scene statistics may one day contribute to the identification of such hazards and is consistent with the ecological approach to human information processing.

## 4.3 Judgments of Two-Dimensional Position and Extent

Both detection and identification are categorical judgments. Sometimes, however, we may be more interested in determining specific qualitative properties of a stimulus such as its location and the magnitude of its various properties (e.g., length, volume, orientation). These judgments are critical for manual control and locomotion (see Section 6) as well as for the interpretation of maps, graphs, and dynamic analog indicators. In this section we focus mainly on spatial judgments of static formats before turning to their dynamic counterparts.

It is well known that the spatial judgments required to read even the most everyday graphs are prone to systematic distortions, knowledge of which can sometimes be used to manipulate a graph's message [e.g., Penrose (2008) evaluates the prevalence of such distortions in corporate annual reports]. Some examples include:

1. Our overestimation of values represented in bar graphs, especially with shorter bars and those farthest from the y axis (Graham, 1937)

2. The perceptual flattening of line graphs with respect to the y axis, resulting in larger underestimations of the represented data as the reader follows the line from its origin (Poulton, 1985)

3. Cyclic patterns of bias in estimations of part–whole relationships (e.g., reading pie charts) that are dependent on the number of available reference points on the graphs (Hollands and Dyre, 2000)

4. Distance distortions between cursor locations and target/icon locations induced by the shape of the cursor (overestimations and overshooting occur when the cursor is an arrow pointed toward the target; Phillips et al., 2003)

These distortions in distance and size may be special cases of geometric illusions such as those reviewed by Gillam (1980) and Gregory (1980). Poulton (1985), for example, has ascribed the perceptual flattening of lines in graphs to the Poggendorf illusion (Figure 3a). Phillips et al. (2003) refer to the Muller–Lyer illusion (Figure 3b) when describing the overestimations of distances between cursor and target. A variety of information-processing mechanisms have been proposed for such illusions, including misallocation of attention, and our tendency to misapply depth cues to wo-dimensional (2D) images. Whatever the cause, design modifications can reduce the impact of these illusions. Poulton (1985), for example, found that simply adding a redundant y axis to the right side of his graphs effectively reduced point-reading errors. Lowlighted horizontal gridlines can have the same beneficial effect. Kosslyn (2006) describes more ways to minimize the likelihood of these graphical illusions as well as ways to reduce graphical miscommunication more generally.

Although there are many salient examples of the use of perceptual illusions to misrepresent data in graphical displays, the presence of illusions is not always harmful. Some designers have even used illusions of size to increase traffic safety. Shinar et al. (1980) painted a pattern similar to that used to induce the Wundt illusion (see Figure 3c) on a roadway leading to a dangerous obscured curve. After the roadway was painted, drivers tended to reduce their speed before encountering the curve, presumably because the pattern made the road seem narrower.

The most systematic work on the size and nature of errors in the perception of graphical displays has focused

(a)          (b)          (c)

**Figure 3** Three perceptual illusions, influencing the perception of location and spatial extent: (a) Poggendorf illusion, in which two diagonal line segments that are actually collinear do not appear so; (b) Muller–Lyer illusion, in which the distances between the horizontal line segment and the tips of the two arrowheads appear to be different, even though they are not; (c) Wundt illusion, in which two parallel vertical lines appear to curve inward.
1. Linear extent with common baseline

2. Linear extent without baseline

3. Comparison of line length, along a single axis

4. Comparison of angle (pie graphs)

5. Comparison of area

6. Comparison of volume

7. Comparison of hue     Green     Blue

**Figure 4** Graphical dimensions for making comparative judgments. (From Wickens, 1992; used by Cleveland and McGill, 1985.)

on how precisely we can make comparisons *between* data values. Cleveland and McGill (1984; Cleveland, 1985) developed a list of the physical dimensions that are commonly used to represent data in graphs and maps. These dimensions were ordered, as shown in Figure 4, in terms of the accuracy with which they could be used to make relative-magnitude judgments (e.g., "What percentage is point *A* of point *B*?"). Using this list as a guide, designers are advised, for example, to avoid using variation in volume or area to represent data. Thus, pictograms should usually be avoided in favor of bar charts or point displays. Similar lists have also been proposed for other sensory modalities. For example, Wall and Brewster (2003) have suggested that haptic graphs should use friction to represent data values rather than stiffness or the spatial period of sinusoidal textures.

Although a sensible first step in designing displays, lists of this type do not ensure the eventual efficacy of graphs. The Cleveland–McGill list of preferred graphical dimensions, for example, predicts performance in graph-reading tasks less well when users move from making simple comparisons to performing more integrative tasks such as describing trends (Carswell, 1992). Furthermore, each step down the Cleveland–McGill list is not equally detrimental to performance. Position, length, and angle judgments are associated with small differences from one another, but all three are used much more accurately than either area or volume. As we will see next, the misperception of volume and other spatial

stimulus dimensions may reflect ambiguities in our perception of three-dimensional (3D) form and distance.

Additional comprehensive coverage of information-processing factors and biases in graph interpretation can be found in Kosslyn (2006), Gillan et al. (1998), and Wickens and Hollands (2000).

### 4.4 Judgments of Distance and Size in Three-Dimensional Space

Judgments of extent and position, discussed in the preceding section, are also made in 3D space, a space that can be either true space (e.g., judging whether there is adequate room to pass a car on a two-lane road) or a display-synthesized 3D space (e.g., comparing the volume of cubes in Figure 5). When making judgments in either real or synthesized virtual spaces, human perception depends on a host of cues to provide information about the absolute or relative distance from the viewer (Cutting and Vishton, 1995). Many of these depth cues are called *pictorial cues* because they can be used to generate the impression of depth in 2D pictures such as Figure 6. Here the convergence of the edges of the roadway at the horizon, the *linear perspective*, suggests that the roadway is receding. The decreasing grain of the texture of the cornfield moving

**Figure 5** Role of size constancy in depth perception in creating illusions: (*a*) distorted overestimation of the size of the more distant bar graphs; (*b*) Ponzo illusion, illustrating the greater perceived length of the more distant bar.

**Figure 6** Perceptual cues for depth perception. (From Wickens, 1992.)

from the bottom to the top of the figure, the *textural gradient*, also informs us that the surface is receding, as well as revealing the slant angle of the surface and the vantage point of the viewer above the landscape. Three additional pictorial cues allow us to judge which building is closer. The building closer to the top of the image is signaled to be farther away (*height in the plane*), as is the building that captures the smaller retinal image (*relative size*); the building that obscures the contours of the other is seen to be closer (*interposition or occlusion*).

In addition to the pictorial cues, which are part of the image itself, there are five cues that result from characteristics of the viewer. *Motion parallax* results whenever the viewer moves, with nearer objects producing greater relative motion across the visual field than distant objects. *Binocular disparity* refers to the difference in viewpoint of the two eyes, a difference that diminishes exponentially as objects are farther from the viewer. *Stereopsis*, the use of binocular disparity to perceive depth, can occur in 3D displays when slightly different images are presented to the two eyes (Patterson, 1997). Some depth information is also obtained from *accommodation* and *binocular convergence*. These cues result from the natural adjustments of the eyes needed to focus on specific objects at different distances. Accommodation is the response of the lens required to bring very close objects into focus, and convergence is the "cross-eyed" viewing of the two eyes, also necessary to bring the image of closer objects into focus on the back of both retinas.

In viewing real 3D scenes, most of these depth cues operate redundantly and fairly automatically to give us very precise information about the relative distance of objects in the visual scene and adequate information about the absolute distance (particularly of nearby objects). Such distance judgments are also a necessary component of judgments of 3D shape and form. A host of research studies on depth perception reveal that the depth cues respond in a generally additive fashion to convey a sense of distance (see Wickens et al., 1989). Thus, as the viewer looks at a 3D display, the more depth cues that are available to the viewer, the more perceived separation there is between objects in depth (i.e., along the $Z$ axis in 3D space).

Although all depth cues contribute to the sense of distance, there is evidence that three of those cues (i.e., motion parallax, binocular disparity, and interposition) are the most powerful and will dominate other cues when they are placed in opposition (e.g., Braunstein et al., 1986; Wickens et al., 1989, 2000). Hence, in designing a 3D display to synthesize the 3D spatial world, it is a good idea to try to incorporate at least one, if not two, of these dominant cues.

In constructing a 3D perceptual representation from a displayed or real 3D image, people may often be guided by knowledge-driven expectancies when interpreting the bottom-up distance cues. For example, the use of relative size as an effective cue depends on the viewer's assumption about the *true size* of the objects to be compared. If the assumptions are inaccurate, the use of relative size to judge distance can lead to illusions,

sometimes dangerous ones. For example, Eberts and MacMillan (1985) concluded that the high rate of rear-end collisions suffered by small cars resulted from drivers' misuse of relative size. The trailing driver, seeing the smaller-than-expected retinal image of the small car, perceives the car to be of normal size and farther away. The perception of greater distance between cars, in turn, may lead to dangerously delayed braking.

Recent research indicates that reliance on other pictorial depth cues may lead to equally poor distance estimations on the part of drivers. Buchner et al. (2006) found that cars with higher backlights are at an increased risk of being perceived as more distant than they actually are. This illusion may be due to the misapplication of the depth cue that associates height in the picture plane with increased distance. Naturally, such illusions, based on inappropriate application of knowledge and expectancies, are more likely to occur when there are fewer depth cues available. This is why pilots are particularly susceptible to illusions of depth and distance (Previc and Ercoline, 2004), since many of the judgments they must make are removed from the natural coordinate framework of Earth's surface and must sometimes be made in the degraded conditions of haze or night.

Besides the problems of impoverished cues, a second problem with 3D displays is *line-of-sight ambiguity*. This is illustrated in Figure 7, which depicts a viewer looking into a volume containing three objects, A, B, and C, as we see the views from the side (top view). The view of these objects on the screen is shown below. Here we see that when the viewer makes judgments of position along the viewing axis into the 3D world, a given distance in the world is represented by a smaller visual angle than when judgments are made parallel to the display surface, a phenomenon known as *compression* (Stelzer and Wickens, 2006). In Figure 7 judgment of the distance $AB$ along the $Z$ axis is compressed, whereas the judgment of the distance $AC_1$ along the $X$ axis is not. As a consequence of this reduced resolution along the viewing axis, it is harder to tell exactly how distant things are. This distance ambiguity, in turn, has repercussions for the ability to make precise spatial comparisons between objects in the plane orthogonal to the line of sight. Returning to Figure 5*a*, note how difficult it is to tell if the difference in height between the two distant bars is the same or different from the closer ones.

To make matters worse, it is often difficult in 3D displays to resolve the extent to which an object displaced to a new location is receding in depth or is moved to a higher location at the same depth, a further form of ambiguity. For example, the various movements of point $C$ in Figure 7 to points $C_1$, $C_2$, and $C_3$ would all appear nearly equivalent to the viewer of the 3D display with few depth cues, since they all would occupy the same position along the line of sight into the display; the relative contribution of altitude to distance change would be difficult to resolve.

Of course, as we have noted, some of this ambiguity can be resolved in display viewing if the designer incorporates progressively more depth cues. Yet in many
**Figure 7** Ambiguity in 3D displays. The actual distance of objects A, B, and C from the observer is shown from the side, in the top view. The screen viewed by the observer is shown below. From the 3D screen view it may be ambiguous whether A or B is closer. Movement from $C$ to $C_1$, $C_2$ and $C_3$ may all look identical.

circumstances it may be cumbersome or computer intensive to incorporate the most powerful cues of stereo and relative motion realistically; furthermore, there are certain tasks, such as those involved in air traffic control, precise robotic control, and some forms of minimally invasive surgery, in which the requirement for very precise spatial judgments with no ambiguity on any axis is so strong that a set of 2D displays, from orthogonal viewing axes, may provide the best option, even if they present a less natural or realistic view of the world (Wickens, 2000, 2003a).

Concerns for 3D ambiguity notwithstanding, the power of computers to create stereo and motion parallax rapidly and effectively continues to grow, thereby supporting the design of *virtual environments* that capture the natural 3D properties of the world. Such environments have many uses, as discussed in Chapter 40, and their creation must again make effective use of an understanding of the human's natural perception of depth cues. Further discussion of the benefits of different kinds of 3D displays for active navigation is provided in Section 5.4.2.

### 4.5 Motion Perception and Dynamic Displays

Although many of the displays discussed above are static, many other analog displays are frequently or continuously updated. Such displays have long been a part of air and ground transportation, process control, and manufacturing systems, and our ability to process motion cues is a requirement for our interaction with objects in both natural and virtual worlds. However, as with the perception of depth and 3D shape, the visual perception of motion can fall prey to a variety of illusions and ambiguities (Blake and Sekuler, 2006). Sometimes these perceptual distortions predispose operators to accidents, for example, the alarming tendency of drivers to cross railroads when trains are drawing dangerously close. Leibowitz (1985) has argued that this behavior may, in part, be due to a size-contingent distortion of speed. Specifically, we tend to see small objects as approaching faster than large ones, perhaps causing drivers to underestimate the speed at which trains, a large object by most vehicular standards, are approaching. Fortunately, errors of motion perception can sometimes be corrected by intentionally employing some of these same illusions, as we will see below. And most of us would agree that at least one motion illusion is of particular value as it is at the very core of many forms of communication and entertainment, that is, media that involve "moving" pictures.

*Apparent motion* is our ability to perceive seamless motion of displayed objects from a series of still images—as long as the individual images are presented within certain spatial–temporal bounds. Given over a century of experience with apparent motion, many of the parameters that affect this illusion are well known among animators and videographers as well as scientists (Hochberg, 1998). For example, an object is seen as moving smoothly from one location to another when presented in two successive pictures that are separated by approximately 20 m and when the displacement of the image is no more than approximately 15° of arc. Under these circumstances, the movement of an object usually appears to take the shortest path between its positions in the two frames. Although this process is mediated by relatively early, bottom-up processing, there is evidence that when intervals between images are long enough, apparent motion appears to be influenced by top-down factors such as the plausibility of the movement (e.g., a person's hand will be seen going over rather than through her head when the two successive images used to create apparent motion show a hand first on one side and then on the other side of her head; Shiffrar and Freyd, 1990).

Of importance to a variety of simulation and gaming applications is another motion illusion—*vection*, or the perception of self-motion by a stationary operator. The illusion of self-motion can be induced by visual displays that imitate the regularities in the pattern of flow of textures across the visual field as we change speed and trajectories in the natural world (Hettinger, 2002), thus taking advantage of some of the types of scene statistics we introduced when discussing context effects on recognition. In addition to their use to create perceptions of self-motion in virtual environments, relevant scene properties can be manipulated in the real world to alter operators' perceptions of self-motion in ways that can enhance safety. In order to encourage

drivers to slow down when approaching a roadwork site, for example, researchers have found that placing a series of cones by the roadway can be helpful, especially when the spacing between the cones systematically decreases, giving drivers the illusory impression that they are accelerating (Allpress and Leland, 2010; also see Denton, 1980).

Further sources of uncertainty in motion judgments are *framework effects.* As a general rule, the visual perception of motion is greatly influenced by the framework within which it occurs. A very sparse display with few fixed reference elements, for example, can make it appear that a small, slowly moving display element is actually stationary. At the opposite end of the spectrum are situations where the target object is too big to be fully seen through the viewing framework. If there is uncertainty about the overall shape of the target object, the target may appear to move in a direction other than its true course. DeLucia et al. (2006) demonstrate the potential importance of this *aperture effect* during minimally invasive surgeries, where the view through the endoscope reveals only a very limited part of the surgical field, and the shape and location of various anatomical landmarks may be distorted by disease. The surgeon may make incorrect judgments about the location of the endoscope inside the patient because of an incorrect perception of its direction of movement based on the apparent flow of organs under the endoscope. This aperture effect can be reduced by using rectangular rather than round viewing windows, but its existence is one reason designers are pursuing the development of augmented displays that generate a computer model of the entire surgical field surrounding the immediate, detailed view from the endoscope (e.g., Wang et al., 2009).

Even when the motion of target objects in dynamic displays can be accurately perceived, operators may still have difficulty linking the motion or changes they perceive to the appropriate actions they should take. Thus, moving displays need to consider the compatibility of their changing elements with the mental models of their users (Gentner and Stevens, 1983; Norman, 1988). In the remainder of this section, we describe two general principles that can help designers match the elements of dynamic displays to users' expectations. The first of these is clearly applicable to both static and dynamic displays, although it may be more important in situations where users must quickly react to changing information. The second principle, however, deals with the meaning of motion itself in the context of the user's goals.

*Code congruence* requires that designers take into consideration users' expectations about the codes (i.e., stimulus dimensions) that should represent critical information. If a display is being designed to represent temperature, for example, then the use of a vertically moving bar might be an appropriate code because of mental models associated with mercury-based thermometers that often show temperatures "rising" and "falling." If we do choose this code, we must also be careful to map the values of the to-be-represented variable (temperature) to the display code in a way that conforms to users' experience. Thus, an increase in bar height should indicate hotter rather than colder temperatures.

In the preceding example, temperature is associated with vertical position through experience with thermometers rather than because there is anything inherently spatial about temperature. Many other variables, however, *are* spatial to begin with. In these cases, code congruence is maintained simply by using rescaled versions of the original spatial dimensions, making sure to orient the spatial model in a manner consistent with the typical viewpoint of the user. Thus, the temperature of different rooms in a building could be represented by superimposing our individual temperature displays on an actual plan view, elevation, or 3D view of the building. When the spatial metaphor is direct, as in this case, the display fulfills Roscoe's (1968) *principle of pictorial realism*.

Finally, in dynamic displays, the designer must be concerned with whether motion represented in a display is compatible with the movement expected by the operator. These expectations in turn are often driven by the *frame of reference* of display motion. As an example, a common design decision in systems involving robotics control is whether the camera generating a display of the moving robotics arm or vehicle should be mounted to the moving element itself (viewing the target to be reached) or to an external frame viewing the moving element. The difference between these two views is that when a control moves the element to the right, in the first case the display of the world slews to the left, whereas in the second case, the world is stable and the rightward control depicts rightward motion on the display. These two frames of reference are referred to respectively as (1) inside-out, moving world, or "ego referenced," and (2) outside-in, moving object, or world referenced.

There is some evidence that the second frame is better and more compatible (Johnson and Roscoe, 1972) in that it corresponds to what we naturally see when we view our hand as well as to the ecological perspective that the world is stable and objects move within it. However, it is also acknowledged that in many complex systems both views are needed, often the outside-in view for global positioning and the inside-out view for fine vernier control. What is most vital is to understand that it is possible for an operator to confuse the two if both are offered (simultaneously or sequentially). An operator viewing an inside-out view moves the control to the right with the intention of moving the object to the right; he or she suddenly sees a left movement on the display, perceives (incorrectly) it to be a control error, and quickly reverses the movement, now inadvertently creating such an error. This problem can be amplified if views are often switched between different modes.

## 4.6 Perceptual Organization, Display Organization, and Proximity Compatibility

Our discussion of motion highlighted how the *relationship* among displayed elements, in both time and space, can produce psychologically important effects such as apparent motion from still images. In this section, we look at how the relationship among component elements of multielement displays, such as those found

in emergency management information systems, scientific visualizations, and process control workstations, can influence the effectiveness of these display systems, sometimes in dramatic ways.

The challenge for the designer of multielement displays is to determine how best to organize the various displays so that the natural laws of *perceptual organization* (e.g., Pomerantz and Kubovy, 1986; Hochberg, 1998) may support rather than hinder the user's acquisition of information. That is, we must take into account the laws by which our perceptual systems parse raw sensory data into potential targets for attention (e.g., perceptual parts, objects, and configurations). As noted in Section 3, multielement displays have the potential to create a variety of problems for the viewer, including increases in search time, increased information access effort, similarity-based confusion, and challenges to focused attention. Such concerns are becoming even more critical with the rapid evolution of expansive, high-definition displays (e.g., "data walls") to represent information for multiple concurrent tasks and users (Yost and North, 2006).

Many of the principles of display organization can be accounted for by the *proximity compatibility principle* (*PCP*) (Carswell and Wickens, 1987, 1996; Barnett and Wickens, 1988; Wickens and Andre, 1990; see Wickens and Carswell, 1995, for review). This is a broad-ranging principle with two parts: (1) when two (or more) elements of a display must be integrated (e.g., compared, multiplied, subtracted) in the service of a single task—a feature we describe as "close (or high) mental proximity"—they should be placed in close physical proximity on the display. However, (2) when one element must be processed by itself, without distraction from others (distant or low mental proximity requiring focused attention), its processing is

best served when its display is more distant from its neighbors (low physical proximity). Hence there is a sort of "compatibility" between proximity in the mind and proximity on the display. Of course, what this means is that no single display layout serves all tasks, for what may be best for integration tasks ("how does my speed compare with a maximum speed allowable?") may not serve focused attention ("what is my current speed?").

The previous broad overview of the PCP is complicated by the fact that there are at least two kinds of "mental integration" (simple comparison and arithmetic combination, such as computing and amount from the product of rate and time) and a large number of ways of creating or manipulating "display proximity," as illustrated in Figure 8. The most obvious source of physical proximity is simple distance, as illustrated by rows (a) and (b) of the figure. Moving things closer together can minimize visual scanning; in a cluttered display, it can also minimize visual search for the two items to be compared, as attention must move from one to the other to compare them. From an information-processing perspective, the problem is often that information from one display must be held in vulnerable working memory as the other is sought. At a minimum, this dual-task requirement may produce a delay— a decay in the representation of the first item until the second is found. More severely, it may produce concurrent task interference (see Section 7) as an effort-consuming search must be carried out while information from the first display is rehearsed.

To cite extreme examples of low physical proximity, consider the challenge of comparing a picture on one page of a textbook to the text describing that picture on the back side of the same page. Would it not be better if text and picture were side by side so that repeated page flipping would not be needed? Instructional designers

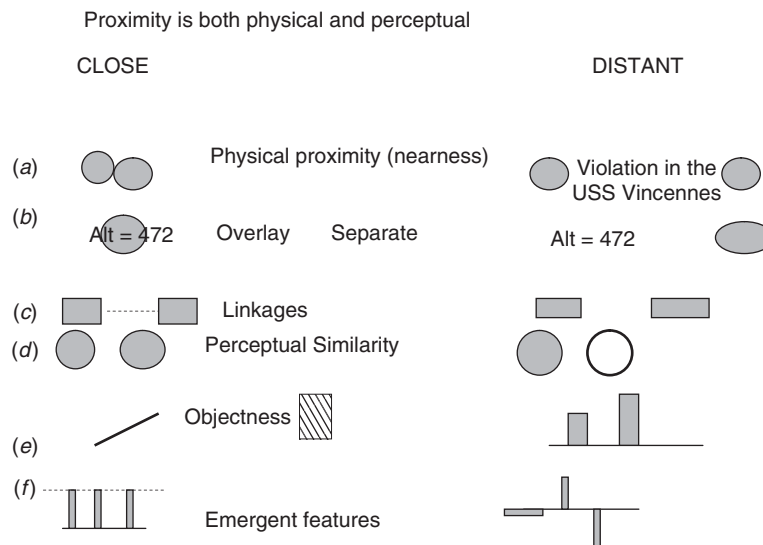

**Figure 8** Six examples of close (left side) vs. distant (right side) display proximity between information sources influencing different perceptual mechanisms

need to consider the role of cognitive load of information integration in preparing their material (Paas et al, 2003). Or consider the problem of comparing a box legend on a graph labeling the multiple graph lines with the graph itself. It would be better if each graph line had its own label attached to it (Huestegge et al, in press) In this sense, display proximity can not only be conceptualized as physical distance affecting visual scanning but also includes the manual (and sometimes cognitive) effort required to "move" attention from one source to the other.

Row (b) of Figure 8 also illustrates the occasional downside of close physical proximity for focused attention. On the right, the oval indicator and the digital altitude reading are separated. It is easy to focus on one and ignore the other. On the left, they are overlaid. The very close physical proximity can create clutter, making it hard to focus on one and ignore the other. Such overlay is often created when viewing the world beyond through a head-mounted display (C. D. Wickens et al., 2004); such clutter of close proximity also may be created by overlaying computer windows (Mori and Hayashi, 1995). Of course, the reader may ask, "Can't we get the best of both worlds by placing the two indicators adjacent, and not overlapping?" and the answer here is "yes." Adjacency will greatly reduce the costs of integration, but if there is at least $1°$ of visual angle separating an item from its neighbors, this will pretty well minimize the costs to focusing attention.

Naturally, there are some circumstances in which displays simply cannot be moved to create adjacency or close proximity. In a cluttered demographic map, for example, two cities may be located at different places whose demographics (portrayed in icons, or text boxes) cannot be "relocated." As shown in row (c), linkages can achieve such physical proximity or "connectedness" (Jolicoeur and Ingleton, 1991). Indeed, in the simple line graphs, the lines connecting the data points are not essential to understanding the trends. But those lines, linking points belonging to the same condition, greatly assist graph interpretation. (As we will see below, the lines have another benefit for integration by creating emergent features.) Thus, if rendered appropriately, often in lower intensity, linkages can increase benefits to integration without imposing costs on focused attention.

When displays cannot be moved, an alternative to linkages, as shown in row (d), is to exploit perceptual similarity; for example, two items to be compared may be highlighted in the same color (as this *word* and the word in the paragraph below; L. D. Wickens, Alexander, et al., 2004) or may both be flashed or "jittered" in synchrony. This technique can be quite advantageous for an air traffic controller (ATC) who needs to consider the trajectories of two planes on the same altitude and converging but still far apart. On an ATC display cluttered with many other aircraft symbols, a highlighting tool (Remington et al., 2000) that can illuminate each in a common color can greatly reduce the demands of such a comparison.

In row (e) is depicted a conceptually different way of creating display proximity. Here a single object (in this case a line connecting two points on a line graph) is created to foster integration, whereas the more separated display shown on the right contains two objects (two bar graphs, or even three, if the baseline is considered). Basic research in attention describes how processing of all attributes of a single object can take place more or less in parallel, whereas processing two objects requires serial processing (and less efficiency; Treisman et al., 1983; Duncan, 1984; Scholl, 2007). In the graph shown in (e), not only is the single line more perceptually efficient to process, but also the slope of the line provides a direct indicator of the strength of the effect or trend, an indication that is easier to extract than by comparing the height of the two bars in the more separated display on the right (Carswell and Wickens, 1996; Hollands and Spence, 1992). We refer to this slope as one example of an *emergent feature* of the object display, a concept elaborated below.

There are of course many other ways of creating an object than just "connecting the dots." Shown just to the right of the word "objectness" in row (e) is a rectangle. This object has four features, its height, width, color, and texture, all conveyed within the confines of a single object. It would require four bar graphs (four objects) to convey all that information in separate displays. And object displays, if carefully configured, can be shown to greatly improve the facility of information integration (Barnett and Wickens, 1988). As a simple example, consider a demographic map. If each city were represented by four bar graphs, when several cities are closely packed together, the display would appear extremely cluttered, in contrast to the case where each is represented by a single rectangle.

Finally, row (f) of the figure illustrates a concept of display proximity that can also facilitate integration. Emergent features of the multiple elements of a display are created when the display is "configured" in such a way that a feature emerges from the combination of the elements (Buttigieg and Sanderson, 1991; Pomerantz and Pristach, 1989). In the close-proximity version on the left, the bar graphs are all aligned to the same baseline. Hence the emergent feature of "colinearity" is created when all bars are the same height (e.g., all of three engines of a machine are operating at the same power setting). In this configuration, it is quite easy to perform the mental integration task: "Is the power equally distributed?" Any break from this equality will be rapidly and easily perceived. In contrast, the configuration on the right will make the precise integration judgment of equality very challenging.

Referring back to row (e), we can see how, for example, the simple connections of endpoints to form a single object as in the line graph creates an emergent feature (line slope) that directly serves the integration task (how strong is the trend from left to right?). Also, creating an object like a rectangle display creates an emergent feature from its height and width: its area (the product of height and width) as well as its shape (tall skinny, short fat), which can often carry important information (Barnett and Wickens, 1988). But it is important to realize that not all dimensions of an object will configure in some geometric or spatial pattern: For example, color and height do not form an emergent

feature (Carswell and Wickens, 1996). And of course, as row (f) illustrates, emergent features can readily be formed in the absence of the object display.

Regardless of whether emergent features are part of an object display or result from the configuration of separate objects, they can have potent effects on performance. We must caution that these effects are not always positive. Emergent features are *only* useful if they directly represent integrated variables or system states of importance to the operator. If they are irrelevant or, worse, cause patterns that cue responses inconsistent with those that are appropriate for safe and efficient system operation, the user may be better off with separable formats. Using the terms of Section 3, emergent features are salient and capture focused attention, whether wanted or not. *Representation aiding* is a display design approach in the cognitive engineering tradition (Section 2) that provides guidance on how to optimize the design of displays, including the use of emergent features (Vicente and Rasmussen, 1992; Smith et al., 2006). The focus of this approach is directly on understanding the physical constraints of dynamic systems and matching these to the geometric properties of configural formats in a way that is perceptually salient and meaningful to the operator. An example is shown in Figure 9.

Our discussion above has focused most heavily on the way in which close proximity supports information integration. But while we have identified separation (lower proximity) as a tool to support focused attention on a single element, lower proximity has a second benefit. That is, the close proximity and particularly

the "binding" in an object display represent a designer-imposed solution to encourage the user to integrate particular subsets of information sources. However, such binding or grouping is not a "free lunch" for the viewer. If the viewer's task is not appropriately characterized by the designer, or if the task demands change, the viewer may need to "unbind" one or more elements from the perceptual group to use in a new way. The extra effort and reduced performance efficiency that occur in this situation may be considered a "parsing cost." This is what we experience when a graph's designer has not organized individual data points in a way that allows us to make the comparisons that are of most interest to us, instead forcing us to compare points across different perceptual groups (e.g., points on different lines or bars in different data series).

Clearly, the specific way in which a designer uses proximity tools in any display will make some integration tasks easy while imposing parsing costs on others. However, the designer's choices can also be used to infer their communication goals (or *graphical pragmatics*). Following this logic, there have been attempts to apply the PCP to the development of software that "reverses engineers" displays. That is, the software provides inferences to the user about the designer's underlying communication goals based on the way in which proximity is applied (Elzer et al., 2003). This information may, in turn, be used by viewers to help them decide if the display is likely to suit their information needs and to help automate the textural summary of graphical information for those individuals who cannot access the information visually. More generally, the

**Figure 9** Rankine cycle display for monitoring the health of a nuclear power generating plant. The jagged line indicates the trajectory of the plant parameters (steam pressure and temperature) as they follow the constraints of the thermodynamic laws (proposed but not yet implemented for operational evaluation). (From Moray et al., 1994.)

study of graphical pragmatics highlights the extent to which individual, noninteractive visualizations, no matter how carefully designed, can impose on the viewer the designer's values and assumptions about what is meaningful in the displayed data. In particular, one may argue that in scientific or interpretive endeavors one of the most critical information-processing challenges is integrating data in a variety of different ways in order to obtain unique insights. Hence the importance of flexible data visualization tools that are not constrained by a particular designer's choices (Robertson et al., 2009; North, 2006), which can configure data in different ways, encouraging the use of different aspects of proximity.

In conclusion, forming effective multielement displays can sometimes be as much a creative "art" as it is a science. But effective use of different proximity tools can greatly facilitate information integration without necessarily compromising focused attention.

## 5 COMPREHENSION AND COGNITION

In our discussion of perception and display design, we have treated many of the operator's perceptual tasks as decision-making, problem-solving, or reasoning tasks. Detection involves decisions about criterion setting. Identification involves estimations of stimulus probabilities. Size and distance judgments in 3D space involve the formulation of perceptual hypotheses. For the most part, however, these processes occur rapidly and automatically, and as a result, we are generally not aware of them. In this sense, perceptual reasoning is a far cry from the effortful, deliberate, and often time-consuming process that we are very aware of when trying to troubleshoot a malfunctioning microwave, find our way through an unfamiliar airport, understand a legal document, or choose among several product designs. Before discussing such higher order cognitive tasks, we describe the critical limits of working memory. As we will see, the parameters of working memory constrain, sometimes severely, the strategies we can deploy to understand and make choices in many types of tasks.

### 5.1 Working Memory Limitations

Working memory refers to the limited number of ideas, sounds, or images that we can maintain and manipulate mentally at any point in time. The concept has its roots in William James's (1890) *primary memory* and Atkinson and Shiffrin's (1971) *short-term store*. All three concepts share the distinction between information that is available in the conscious here and now (working, short-term, or primary memory) and information that we are not consciously aware of until it is retrieved from a more permanent storage system (long-term or secondary memory).

Unlike items in long-term memory, items in working memory are lost rapidly if no effort is made to maintain them through rehearsal (Brown, 1959; Peterson and Peterson, 1959). For example, *decay rates* of less than 20 s have been obtained for verbally delivered navigation information (Loftus et al., 1979) as well as for visuospatial radar information (Moray, 1986). However,

even when tasks require minimal delays before recall, working memory is still severely limited in its capacity. Miller (1956) suggested that this capacity, the *memory span*, is limited to about five to nine independent items. The qualifier "independent" is critical, however, because physically separate items that are stored together as a unit in long-term memory may be rehearsed and maintained in working memory as a single entity: a *chunk*. Thus, for most people, the letter string "H–T–E" contains three items to remember, whereas the rearranged string "T–H–E" contains only one.

Baddeley (2003) has integrated information about the limits described above with evidence from neuropsychological and psychometric investigations to develop a four-part model of working memory. First, there are two temporary storage systems, the *phonological loop* and *visuospatial sketchpad*. These subsystems are used by a *central executive* that manipulates information from these stores. The central executive also integrates information from the component storage systems with long-term memory to create more complex, multimodal representations of coherent objects. These integrated representations, in turn, are held in an *episodic buffer*. It should be noted that the proposed episodic buffer is a relatively recent addition to Baddeley's model (2000), which was originally conceptualized as having only three components (Baddeley and Hitch, 1974). Although relatively little is known about the limits of the episodic buffer compared to those of the phonological loop and the visuospatial sketchpad, the notion of a repository for objects of interest that is not limited to a single processing code is relevant to our discussions of virtually all higher order cognitive tasks.

Most research on the limits of working memory have focused on the *phonological loop*, so named because it is associated with our silent repetition or rehearsal of words, letters, and numbers. The phonological loop stores a limited number of sounds for a short period of time; thus, the number of items that can be held in working memory is related to the length of time it takes to pronounce each item (Gathercole and Baddeley, 1993; Gathercole, 1997). This implies that our memory span is slightly lower for words with many syllables.

The *visuospatial sketchpad* holds visual and spatial information as well as visualizations of information acquired verbally (Logie, 1995; Baddeley, 2003). The information held in the sketchpad may be in the form of mental images, and as with the phonological loop, the contents will be lost rapidly if not rehearsed. Research suggests that rehearsal in the visuospatial sketchpad involves repeated switching of selective attention to different positions across these images (Awh et al., 1998). The proposed maintenance function of attention switching may explain why our control of eye movement apparently disrupts some contents of the sketchpad (Postle et al., 2006).

The central executive is aptly named because its functions can be compared to those of a business executive. The central executive's role is not to store information but to coordinate the use of information. This information may come from the phonological loop, the visuospatial sketchpad, or the episodic buffer. The

central executive is presumed to be involved in integrating information from these different stores, and it is also involved with selecting information, suppressing irrelevant information, coordinating behavior, and planning (see Section 5.5 for the relevance of these functions for problem solving). It is important to note that there are limits on how many of these operations the central executive can execute at one time.

The concept of working memory has a number of implications for design. We describe some of these implications below, and in subsequent sections we discuss other implications for higher order tasks such as decision making, problem solving, and creative thinking.

1. The capacity of working memory's short-term storage systems are easily exceeded, resulting in a loss of information that may be necessary to perform an ongoing task (consider rehearsing a 10-digit phone number and area code). The design implication is to avoid, whenever possible, codes that infringe on the limits of these systems.

2. When it is necessary to use codes that exceed the limits of working memory capacity, there are several ways to reduce memory loss. For example, parsing material into three- or four-item units may increase chunking and subsequent recall (Wickelgren, 1964). Thus, 3546773 is more difficult to recall than 354–6773. In addition, information for different tasks may be split between storage systems so that a single system, for example, the visuospatial sketchpad, is not overwhelmed. More will be said about such interventions when we turn to the discussion of multitask performance (see Section 7). Finally, designers should prefer easily pronounced verbal codes. For example, numerical codes that make frequent use of the two-syllable number "seven" will be more prone to loss from the phonological loop than codes that make frequent use of other numbers. It may also suggest that the functional number span for some languages may be larger than those for others.

3. Information from working memory may be lost if there are delays longer than a few seconds between receiving the information and using it. Thus, systems should not be designed so that the user must perform several operations before being able to perform a "memory dump." For example, voice menu systems should always allow users to select a menu option as soon as it is presented rather than forcing them to wait until all the options have been read to make their choice. Methods of responding should be simplified as well, so that users do not have to retain their choice for long periods of time while trying to figure out how to execute it. One aspect of the proximity compatibility principle (Section 4.6) emphasizes working memory limitations on the need to seek a second source of information to be integrated while rehearsing the contents of the first source.

4. The need to scan should be minimized if a person must hold spatial information in the sketchpad. Thus, a first responder who has found the likely location of a victim in cluttered, unfamiliar, and distorted terrain should not have to scan long lists of information to find appropriate communication codes.

5. Avoid the need to transfer information from one subsystem into the other before further transformations or integrations can be made. This reduces the resources available for the primary processing goal. Wickens et al. (1983, 1984) have provided evidence that the display format should be matched to the working memory subsystem that is used to perform the task. Specifically, visual-analog displays are most compatible with tasks utilizing the visuospatial sketchpad (e.g., air traffic controllers' maintenance of a model of the spatial relations among aircraft) and auditory–verbal displays are most compatible with tasks utilizing the phonological loop (e.g., a nurse keeping track of which medications to administer to a patient).

6. If working memory subsystems are updated too rapidly, old information may interfere with the new. For alphanumerical information, Loftus et al. (1979) found that a 10-s delay was necessary before information from the last message no longer interfered with the recall of the current material. As we will see below, when such updating occurs nearly continually, the capacity of working memory is greatly reduced to around its "$7 - 2 = 5$" value.

7. Interference in working memory is most likely when to-be-remembered information is similar in either meaning or sound. Thus, an air traffic controller might have particular difficulties remembering a series of aircraft with similar call signs (UAL 235, UAL 325). Interference will also be greater if there is similarity between material to be remembered and other competing tasks (i.e., listening, speaking) (Banbury et al., 2001).

8. The capacity of working memory varies between people and has been associated with differences in the fluency of the central executive and hence with success in multitasking and general intelligence (Engle, 2002; Engle et al., 1999).

## 5.2 Dynamic Working Memory, Keeping Track, and Situation Awareness

Much of the research devoted to working memory has examined tasks in which information is delivered in discrete batches and the goal is to remember as much of the information as possible. However, there are many other tasks in which the operator must deal with continuous information updates with little expectation of perfect retention. Moray (1981) studied several *running memory tasks* that simulated the demands of a more continuous input stream, and he found the typical

memory span to be less than five chunks. In some cases it was difficult for subjects to keep track of items more than two places back in the queue. Yntema (1963) demonstrated that the way information is organized has a direct impact on supervisors' abilities to keep track of values of multiple attributes of several objects (e.g., status and descriptions of several aircraft). Supervisors had greater success keeping track of a few objects that varied on many different (and discriminable) attributes than in keeping track of variation in a few attributes for many objects. In the former case there are fewer opportunities for confusion than in the latter case, and confusion is a major source of disruption in working memory (Hess and Detweiler, 1995).

This earlier research on running memory anticipates the rapid growth of interest over the last two decades in *situation awareness* (SA) or, colloquially, our understanding and use of information about "what's happening" during dynamic tasks (Wickens, 2008; Tenney and Pew, 2006; Banbury and Treselian, 2004; Endsley and Garland, 2000; Durso et al., 2007; see also Chapter 19). Endsley (1995) provides a more formal definition of SA, one that has been adopted by many current researchers: SA is "...the perception of the elements of the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future." This definition suggests that SA has three stages or "levels": (1) perception or "noticing," (2) understanding or comprehending, and (3) projecting or prediction. These three levels of situation awareness can be tied directly to different aspects of information processing and, therefore, failures at different levels will require different types of training or design interventions.

Stage 1 SA, noticing, traces directly to issues of selective attention and attentional capture, discussed in Section 2. Indeed, Jones and Endsley (1996) found that a majority of aircraft accidents attributable to loss of SA were related to breakdowns at this first stage. Likewise, Durso et al. (2007) found failures of stage 1 SA to be responsible for many SA-related problems encountered in air traffic control. This is not surprising given our previous discussion of how easily we can fail to notice significant changes in dynamic systems (e.g., the "change blindness" phenomenon; see Section 3.1). In general, failures of stage 1 SA typically indicate the need for interventions involving display design, especially the use of alerts and attentional cueing. However, because sampling of information in dynamic environments also involves long-term memory in the form of knowledge about "where and when to look," training interventions may also be considered (e.g., Hoffman et al., 1998).

Stage 2 SA, understanding the implications of events noticed in stage 1, depends heavily on the limits of working memory as they apply to keeping track of evolving situations (e.g., the pilot asks: "Where was that traffic aircraft the last time that I looked?"). The episodic buffer of working memory proposed by Baddeley (2003), with its connections to long-term memory, may be necessary to explain the ability of skilled performers to hold more information for longer periods than would be expected on the basis of the decay rates established

for other working memory stores. Likewise, Ericsson and Kintsch (1995) have used the concept of *long-term working memory* with its automatic activation of relevant knowledge structures in long-term memory to explain the unusual ability of experts to maintain and integrate relatively large amounts of information across time. For operators who may lack extensive experience, and even for experienced operators who may be interrupted by other tasks, displays of system history may also be helpful in understanding the implications of current events in light of prior observations (St. John et al., 2005).

The stage 3 component, prediction and projection, is perhaps the most complex and may depend to a greater extent than the other two stages on the expertise and training of the operator. Accurate prediction of an evolving situation certainly depends on current perception and understanding (stages 1 and 2), but it also requires a well-calibrated *mental model* of the dynamic process under supervision (Gentner and Stevens, 1983; Wilson and Rutherford, 1989), a mental model that can be "played" in response to the current data, in order to predict the future state. For example, an air traffic controller with a good mental model of aircraft flight characteristics can examine the display of the current state and turn the rate of an aircraft and project when (and whether) that aircraft will intersect a desired approach course, thereby attaining a satisfactory separation. A well-calibrated mental model resides in long-term memory, but to play the model with the current data requires perception of those data as well as the active cognitive operations carried out in working memory. In some cases, prediction can be approximated by using an expert acquired *script* of the way a typical situation unfolds. However, unless active processing (stage 1) of incoming perceptual information is carried out, there is a danger that projection will be based totally on expectancies of typical situations and that unusual or atypical events will be overlooked. Naturally, stage 3 SA can benefit greatly from accurate predictive displays (Wickens et al., 2000).

It should be noted, finally, that situation awareness is a construct that is resident within the perceptual–cognitive operations of the brain. It is not itself a part of the action (other than the actions chosen to acquire new information).

## 5.3 Text Processing and Language Comprehension

Comprehension of language, whether written or spoken, shares many of the processes described for situation awareness. Noticing relevant information, understanding its implications, and to varying degrees projecting the content of upcoming messages are all part of the active process of language comprehension. The constraints relevant to information processing at each of these stages helps determine why we find some conversations, lectures, journal articles, instructions, and warnings easier to understand than others.

Of course, factors influencing the detectability and discriminability of the individual speech sounds

(phonemes) and written symbols (letters) will limit the extent to which language can be processed meaningfully. However, recall that easily comprehended phrases or sentences can also influence the detectability of the individual words. See Section 3.2 for a discussion of the effect of context on identification. We are typically able to understand sentences such as the last one despite the absence of many of the correct letters in the words, because of the profound effects of context, expectancies, and the redundancies inherent in language. It is worth noting that just as context can help us recognize familiar words; it can also help us understand the meanings of words that we have never encountered before (Sternberg and Powell, 1983).

As our discussion of context suggests, the comprehensibility of text depends on many factors, from the reader's experience, knowledge, and mental models that drive expectations to the structuring of text so as to make maximum use of these expectancies. It is not surprising, then, that *readability metrics* that attempt to estimate the difficulty of text passages, generally based on average word and sentence length, are not altogether satisfactory. Although it may be true that longer words are generally less familiar and longer sentences place greater demands on our working memory capacities, many other factors influence comprehensibility. Kintsch and Vipond (1979), for example, used traditional readability indices to compare the speeches of candidates in the 1952 presidential campaign. Eisenhower's speeches were generally reputed to be simpler than those of Stevenson, yet formal readability indices indicated that Stevenson used shorter words and sentences. This contradiction between public opinion and the formal metrics corresponds to our experience that some sentences with a few short words can still be very confusing. We now discuss some additional factors that determine comprehensibility and have implications for message design.

Kintsch and colleagues (e.g., Kintsch and Keenan, 1973; Kintsch and Van Dijk, 1978) argue that the complexity of a sentence is actually determined by the number of underlying ideas, or *propositions*, that it contains rather than by the number of words. Although a few specific words may be carried forward in working memory for brief periods, it is the underlying propositions that are used to relate information in different phrases and sentences. Just as Moray (1981) estimates that running memory carries forward less than five chunks of information, Kintsch and Van Dijk (1978) estimate that only four propositions can be held in working memory at one time. There are some exceptions to this general rule, as when a highly skilled reader reads text on a very familiar topic. As we saw in our discussion of situation awareness, the memory effects of such expertise have led some to argue for the existence of a long-term working memory in which long-term memory associations are automatically activated and used during ongoing comprehension at little additional processing cost. However, as a general rule, readers must be very selective in their choices of propositions to retain, usually favoring the most recent propositions and those they believe to be most central to the overall text message.

Problems arise in comprehension when newly encountered propositions cannot easily be related to the propositions active in working memory. Such problems often occur when readers attempt to integrate information across sentence boundaries. Consider, for example, the following sentences:

1.  When the battery is weak, a light will appear.
2.  You will see it at the top of the display panel.

Readers must make the *bridging inference* that the second sentence is telling them where to look for the light rather than where to find the battery. This inference, in turn, depends on their general knowledge of displays: Lights rather than batteries tend to be visible on display panels. A second type of integration failure occurs when a concept introduced earlier in the text is not actually used again until some sentences, paragraphs, or pages later. In fact, even relatively minor delays, such as the need to scroll in order to see additional text on a web page, can lead to comprehension decrements, especially in readers with smaller working memory capacities (Sanchez and Wiley, 2009). Such challenges to text comprehension are often explained by the need to conduct a *reinstatement search*, which requires an effortful search of long-term memory or a rereading of earlier text, in order to clarify the meaning of a proposition in current working memory.

One general goal in striving for comprehensibility is to avoid the need to make bridging inferences or perform reinstatement searches. However, it is clearly impossible to remove the need to make some inferences, and it is probably undesirable given that such elaborations may make the information more memorable. One goal of the text designer is simply to assist the reader in making the *appropriate* inferences. One important way that this can be done is by providing adequate context immediately prior to the presentation of target information (McKoon and Ratcliff, 1992). Because inferences draw on the reader's knowledge of particular topics, it is useful to allow the reader to access the relevant knowledge structures in long-term memory at the outset. Bransford and Johnson (1972) provide a powerful demonstration of the importance of providing context in the form of pictures or descriptive titles presented just prior to textual material. A series of instructions on how to wash clothes was presented with and without the prior context of a title, "washing clothes." When the title was removed, the reduction in readers' abilities to understand and recall the instructions was dramatic.

Other factors that increase the processing demands of verbal material include the use of negations and lack of congruence between word orders and logical orders. With regard to negations, research indicates that it takes longer to verify a sentence such as "the circle is not above the star" compared to "the star is above the circle" (Clark and Chase, 1972; Carpenter and Just, 1975). Results suggest further that the delay is due to something other than the time necessary to process an additional word (i.e., "not"). Instead, it appears that listeners or readers first form a representation of the objects in the sentence based on the order of presentation (e.g.,

circle-before-star in the sentence "the circle is not above the star." However, to make their mental representation congruent with the meaning of the negation, they must perform a transformation of orders (i.e., to end up with a circle that is *not* before/above the star). Similar logic is used to explain why we have trouble processing statements in which there is a mismatch between the underlying logical order and the actual, physical order of the words (DeSoto et al., 1965). Returning to our battery of instructions once again, the underlying causal sequence assumed by most people would be that a weak battery would trigger a warning light. To be consistent with this causal order, it would be better to state that "If the battery is weak, the light will come on" rather than "If the light comes on, the battery is weak."

Finally, the physical parsing of sentences on a page, sign, or computer screen can also influence the comprehensibility of verbal messages. Just and Carpenter (1987) have argued that readers pause and integrate propositions at the end of each phrase in a sentence. This idea may explain why comprehension of sentences that must be split over multiple lines is better when the end of each line of text corresponds to the end of a constituent phrase (Graf and Torrey, 1966). Thus, instructions or warnings that must appear on several different lines (or as a few words on several successive screens) should be divided by phrases rather than, for example, on the basis of the number of letters. "Watch your step . . . when exiting . . . the bus" will be understood more quickly than "Watch your . . . step when . . . exiting the bus."

## 5.4   Spatial Awareness and Navigation

Language comprehension sometimes taxes working memory, particularly the phonological rehearsal loop and central executive. However, as we saw when discussing problems with negation, people may use text to generate representations of spatial relations. This spatial facet of text and language comprehension has been particularly prominent in recent discussion of the "situation models" that we develop when reading or listening to a story (e.g., knowing where in a room all the characters are sitting). We now turn to a task that relies more heavily, for many people, on the capacity limits of the visuospatial sketchpad (Logie, 1995) or, more generally, spatial working memory and spatial cognition (Shah and Iyiri, 2005)—navigating through our worlds, both real (finding our way through a maze of looping suburban streets and cul-de-sacs; Taylor et al., 2008) and virtual (searching a complex computer-displayed multidimensional database; Wickens et al., 2005).

### 5.4.1   Geographical Knowledge

Thorndyke (1980) has studied the knowledge that people use when finding their way about. Of particular interest is Thorndyke's claim that increased familiarity with an area causes changes in more than the amount of detail contained in our mental representation of that area stored in long-term memory. In addition, the actual *type* of mental representation (analog versus verbal/symbolic), as well as its frame of reference, may evolve

in a predictable way. After an initial encounter with a city, neighborhood, or building, we may develop *landmark knowledge*. If told that his or her destination is beside the "telephone tower," a person with landmark knowledge will scan the environment visually until spotting something that appears to be the tower and will then strike off in its direction. Thus, the newcomer has the knowledge necessary to recognize the landmark but has no knowledge about its location. For the person with landmark knowledge alone, wayfinding would be impossible if the landmarks were obscured. This problem has become commonplace as once-salient landmarks have become obscured by new and often taller structures. The problem for urban planners, then, is to ensure that landmarks (both natural and designed) remain easily visible and distinctive in order to serve their navigational function for years to come.

With more experience traveling about an area, we typically develop an ordered series of steps that will get us from one location to another. These sets of directions, called *route knowledge*, tend to be verbal in nature, stated as a series of left–right turns (e.g., "Go left on Woodland until you get to the fire station. Then take a left . . . "). Navigation along these routes may be rapid and very automatic; however, limited knowledge of the higher order relations among different routes and landmarks still limits navigational decision making, making it difficult, for example, to figure out shortcuts and particularly difficult to recover when lost. With still more extensive wayfinding experience, or with specific map study, *survey knowledge* may be acquired. Survey knowledge is an integrated representation of the various routes and landmarks that preserves their spatial distance relations. This analog representation is often referred to as a *cognitive map*.

The type of representation—route versus survey—that best supports performance in various wayfinding tasks, like so many other aspects of mental (and display) representation, depends on the nature of the task or problem. Thorndyke and Hayes-Roth (1982) compared *route training* (actual practice navigating between specific points in a large building) to *survey training* (study of the building map). Route training appeared to facilitate people's estimates of route distance and orientation, while survey training appeared to facilitate judgments of absolute (Euclidean) distance and object localization.

### 5.4.2   Navigational Aids

Although we can often navigate through environments on the basis of our acquired knowledge stored in long-term memory, whether route, survey, or even landmark, there are many other circumstances in which we require displayed *navigational aids* which are perceived. These aids may take on a wide variety of forms, ranging in the degree to which guidance to a target is supported: from tightly guided flight directors in aircraft and turn signs on highways to route lists to electronic maps that highlight one's current position to simple paper maps. Furthermore, electronic maps can vary in the extent to which they rotate so that the direction of travel is "up" on the map, and both electronic and paper maps can vary

in terms of whether they present the world in planar or 3D perspective view as the latter is seen in many in-car navigation displays (see Section 4.4).

To understand which forms of maps support the best spatial information processing to accomplish navigation, it is important to consider briefly the stages involved in this process. The navigator must engage in some form of visual search of both the navigational aid (to locate the final destination, intermediate goals, and current location) and the environment or a displayed representation thereof (to locate landmarks that establish the current location and orientation). The navigator must then establish the extent to which the former and the latter are congruent, determining the extent to which "where I am" (located and oriented) agrees with the intermediate goal of "where I want to be." Finally, the traveler must choose an action (e.g., turn right) to move from the current location toward the goal. Establishing this congruence as well as choosing the action may require any number of different *cognitive transformations* that add both time and effort to the navigational task (Aretz, 1991; Hickox and Wickens, 1999; Gugerty and Brooks, 2001; Wickens et al., 2005, 2010).

An example of two of these transformations is represented in Figure 10, which represents the information processing of a pilot flying south through an environment depicted on a north-up contour map. To establish navigational congruence, the pilot must rotate the map mentally to a track-up orientation and then envision the contour representation of the 3D terrain to determine its congruence with the forward view. Both of these information transformations are effortful and time consuming and provide sources for error. In particular, those sources involved with mental rotation of maps have been well documented (Levine, 1982; Eley, 1988; Warren et al., 1990; Aretz, 1991; Olmos et al., 1997; Gugerty and Brooks, 2001; Macedo et al., 1998.

Different transformations may be required when other navigational aids than the 2D map are provided. For example, verbal descriptions of landmarks will also require some transformations to evaluate against their visible 3D spatial counterparts. Transformations may also be required to "zoom in" to a large-scale map (Kosslyn, 1987) in order to establish its congruence with a close-in view of a small part of the environment. Modeled in terms of processing operations such as visual search and spatial transformations, one can then determine the form of navigational aids that would be of benefit for certain tasks. For example, electronic maps are beneficial if they highlight the navigator's current location, thus obviating visual search of the map. Highlighting landmarks on the map, which are salient in the visual world, will correspondingly reduce search.

**Figure 10** Mental rotation required to compare the image seen in an ego-referenced forward field of view (top) with a world-referenced north-up map (below) when the aircraft is heading south. The map image is mentally rotated (right) to bring it into lateral congruence with the forward field of view. It is then envisioned in three dimensions to compare with the forward field of view.

Rotating maps in a track-up orientation will help navigation by eliminating mental rotation (Aretz, 1991; Olmos et al., 1997; Wickens, 1999). Presenting guidance information in a 3D format (Section 4.4), like one would see looking ahead into the environment itself, will also reduce the magnitude of any sort of transformations and considerably improve navigational performance (Wickens and Prevett, 1995; Wickens et al., 2005). The benefits of a 3D view will be enhanced if the viewpoint of the display corresponds to the same zoom-in viewpoint as that occupied by the navigator, looking forward, rather than a viewpoint that is behind and from the outside (Wickens and Prevett, 1995; Prinzel and Wickens, 2008–2009). These viewpoint relationships are shown in Figure 11, which depicts the viewpoint location (top) and the view seen by a pilot (bottom row) in an immersed or *egocentric view* (a and b). (These two views differ in terms of their geometric field of view.) Panel (c) represents an external or exocentric view. Panel (d) represents a 2D coplanar view, which was discussed in Section 4.4.

Expressing navigational guidance in terms of command *route lists* (e.g., "turn left at X; go three blocks until Y") will also eliminate the need for many of the spatial cognitive transformations that may be imposed when spatial maps are used, since the language of command is thereby expressed directly in the language of action. Such congruence can account for the benefits of route lists over spatial maps in certain ground navigation tasks (Streeter et al., 1985). A second advantage to such route lists is that they can be presented verbally and represented in working memory mentally in a phonetic or verbal code, thus reducing competition for the spatial processing resources involved in many aspects of environmental scanning and vehicle navigation (Section 7). The verbal descriptions inherent in route lists are well suited for some navigational environments, particularly human-designed environments (cities) with objects that are easily labeled, have distinct unambiguous landmarks,

and can easily be discriminated by counting (the "fourth house"). In many naturalistic environments, however, where features are defined by continuous, not categorical, properties and may be confusable, route lists are more problematic and should be coupled with redundant spatial or pictorial guidance.

The most direct levels of navigational guidance that eliminate most or all levels of mental transformations (e.g., a flight director, the 3D forward-looking display shown in Fiigure 11a, or a verbal route list) will provide for effective navigation while en route. However, such displays may do a disservice to the navigator who suddenly finds himself lost, disoriented, or required to make a spontaneous departure from the planned route. Also, those features that make a navigational display best for guidance will harm its effectiveness to support the spatial situation awareness (Section 5.2) that is necessary for a successful recovery from a state of geographical disorientation (Wickens and Prevett, 1995; Wickens, 1999). This is an important trade-off between the immersed 3D view of Fiigure 11a, which is good for guidance, but because of its "keyhole view" of the world, it is poor for maintaining global situation awareness, a task better supported by the exocentric view of Fiigure 11c. Finally, we note that the immersed 3D view makes a poor tool for route planning, an activity that we turn to in the following section.

## 5.5 Planning and Problem Solving

Our previous discussion has focused on cognitive activities that were heavily and directly driven by information in the environment (e.g., text, maps, or material to be retained in working memory). In contrast, the information-processing tasks of planning and problem solving are tied much less directly to perceptual processing and are more critically dependent on the interplay between information available in (and retrieved from) long-term memory and information-processing transformations carried out in working memory.

**Figure 11** Display viewpoints in an aircraft display that require varying degrees of transformations to compare with a pilot's direct view forward from the cockpit, looking at a virtual "highway in the sky" The lower figures illustrate schematically what would be seen by the pilot with the viewpoint shown above. The transformation in (a) is minimal; in (b) and (c), modest; and in (d), large. Views (a) and (b), however, reduce more global situation awareness.

### 5.5.1 Planning

The key to successful operation in many endeavors (Miller et al., 1960) is to develop a good plan of action. When such a plan is formulated, steps toward the goal can be taken smoothly without extensive pauses between subgoals. Furthermore, developing contingency plans will allow selection of alternative courses of actions should primary plans fail. As an example, pilots are habitually reminded to have contingency flight plans available should the planned route to a destination become unavailable because of bad weather.

Planning can typically depend on either of two types of cognitive operations (or a blend of the two). Planners may depend on scripts (Schank and Abelson, 1977) of typical sequences of operations that they have stored in long-term memory on the basis of past experience. In essence, one's plan is either identical to or involves some minor variation on the sequence of operations that one has carried out many times previously. Alternatively, planning may involve a greater degree of guess work, and some level of mental simulation of the intended future activities (Klein and Crandall, 1995; see Chapter 37). For example, in planning how to attack a particular problem, one might play a series of "what-if" games, imagining the consequences of action, based again on some degree of past experience. Hence a surgeon, in planning how to manage a potential future operation, might mentally simulate the future body conditions and reactions of the patient under different proposed surgical procedures to see if the intended commands would resolve the conflict and would stay clear of other aircraft.

Consideration of human performance issues and some amount of experimental data reveals three characteristics of planning activities. First, they place fairly heavy demands on working memory, particularly as plans become less script based and more simulation based. Hence, planning is a task that is vulnerable to competing demands from other tasks. Under high-workload conditions, planning is often the first task to be dropped, and operators become less proactive and more reactive (Hart and Wickens, 1990). The absence of planning is often a source of poor decision making (Orasanu, 1993; Orasanu and Fischer, 1997). Second, perhaps because of the high-working-memory demands of planning, in many complex settings, people's *planning horizon* tends to be fairly short, working no more than one or two subgoals into the future (Tulga and Sheridan, 1980). To some extent, however, this characteristic may be considered as a reasonably adaptive one in an uncertain world, since many of the contingency plans for a long time horizon in the future would never need to be carried out and hence are probably not worth the workload cost of their formulation. Finally, given the dependency of script-based planning on long-term memory, many aspects of planning may be biased by the *availability heuristic* (Tversky and Kahneman, 1974; Schwarz and Vaughan, 2002), discussed in more detail in Chapter 8. That is, one's plans may be biased in favor of trajectories that have been tried with success in the past and therefore are easily recalled.

Consideration of such vulnerabilities leads inescapably to the conclusion that human planning is a cognitive information-processing activity that can benefit from automated assistance, and indeed, such planning aids have been well received in the past for activities such as flight route planning (Layton et al., 1994) and industrial scheduling (Sanderson, 1989). Such automated planners provide assistance that need not necessarily replace the cognitive processes of the human operator but merely provide redundant assistance to those processes in allowing the operator to keep track of plausible courses of future action.

### 5.5.2 Problem Solving, Diagnosis, and Troubleshooting

The three cognitive activities of problem solving, diagnosis, and troubleshooting all have similar connotations, although there are some distinctions between them. All have in common the characteristic that there is a goal to be obtained by the human operator; that actions, information, or knowledge necessary to achieve that goal is currently missing; and that some physical action or mental operation must be taken to seek these entities (Mayer, 1983; Levine, 1988). To the extent that these actions are not easy or not entirely self-evident, the processes are more demanding.

Like planning, the actual cognitive processes underlying the diagnostic troubleshooting activities can involve some mixture of two extreme approaches. On the one hand, situations can sometimes be diagnosed (or solutions to a problem reached) by a direct match between the features of the problem observed and patterns experienced previously and stored in long-term memory. Such a *pattern-matching technique*, analogous to the role of scripts in planning, can be carried out rapidly, with little cognitive activity, and is often highly accurate (Rasmussen, 1981). This is a pattern of behavior often seen in the study of *naturalistic decision making* (Zsambok and Klein, 1997; Kahneman and Klein, 2009; see Chapter 8).

At the other extreme, when solving complex and novel problems that one has never experienced before, a series of diagnostic tests must often be performed, their outcomes considered, and based on these outcomes, new tests or actions taken, until the existing state of the world is identified (diagnosis) or the problem is solved. Such an iterative procedure is typical in medical diagnosis (Shalin and Bertram, in press). The updating of belief in the state of the world, on the basis of the test outcomes, may or may not approach prescriptions offered by guidelines for *optimal information integration*, such as Bayes's theorem (Yates, 1990; see Chapter 8).

In between these two extremes are hybrid approaches that depend to varying degrees on information already stored in long-term memory on the basis of experience. For example, the sequence of administering tests (and the procedures for doing so) may be well learned in long-term memory even if the outcome of such tests is unpredictable and must be retained or aggregated in working memory. Furthermore, the sequence and procedures may be supported by (and therefore directly perceived from) external *checklists*, relieving cognitive demands still further. The tests themselves might be physical tests, such as the blood tests carried out by

medical personnel, or they may involve the same mental simulation of what-if scenarios that was described in the context of planning (Klein et al., 1993).

As with issues of planning, so also with diagnosis and problem solving, there are three characteristics of human cognition that affect the efficiency and accuracy of such processes. First, as these processes become more involved with mental simulation and less with more automatic pattern matching, their cognitive resource demands grow and their vulnerability to interference from other competing tasks increases in a corresponding fashion (see also Chapter 9). Second, as we noted, past experience, reflected in the contents of long-term memory, can often provide a benefit for rapid and accurate diagnosis or problem solutions. But at the same time, such experience can occasionally be hazardous, by trapping the troubleshooter to consider only the most *available* hypotheses: often those that have been experienced recently or frequently and hence are well represented in long-term memory (Tversky and Kahneman, 1974; Schwarz and Vaughn, 2002). In problem solving, this dependence on familiar solutions in long-term memory has sometimes been described as *functional fixedness* (Adamson, 1952; Levine, 1988).

Third, the diagnostic/troubleshooting process is often thwarted by a phenomenon referred to alternatively by such terms as *confirmation bias* and *cognitive tunneling* (Levine, 1988; Nickerson, 1998; Woods et al., 1994; Wickens and Hollands, 2000). These terms describe a state in which the troubleshooter tentatively formulates one hypothesis of the true state of affairs (or the best way to solve a problem) and then continues excessively on that track even when it is no longer warranted. This may be done by actively seeking only evidence to confirm that the hypothesis chosen is correct (the confirmation bias) or simply by ignoring competing and plausible hypotheses (cognitive tunneling).

Collectively, then, the joint cognitive processes of planning and problem solving (or troubleshooting), depending as they do on the interplay between working memory and long-term memory, reflect both the strengths and the weaknesses of human information processing. The output of each process is typically a decision: to undertake a particular course of action, to follow a plan, to choose a treatment based on the diagnosis, or to formulate a solution to the problem. The cognitive processes involved in such decision making are discussed extensively in Chapter 8, as are some of the important biases and heuristics in diagnosis discussed more briefly above.

### 5.5.3 Creativity

In general, creativity involves human problem solving that is relatively free from the confirmation bias, cognitive tunneling, and functional fixedness, each of which restricts the number of problem solutions we consider. For most theorists, creativity refers to the production of *effective novelty* (Cropley, 1999; Mayer, 1999). This is a process that involves thinking of a variety of previously untried solutions *and* judging their probable effectiveness. Finke et al. (1992) argue that *generating*

novel cognitive structures involves retrieving, associating, synthesizing, and transforming information, while *evaluating* novel structures involves inferring, hypothesis testing, and context shifting, among other strategies. It is clear from this analysis that the cognitive load imposed by creative tasks can be immense and that working memory, including the storage systems and the central executive, will be taxed.

Novelty production may be particularly difficult to maintain for long periods of time for at least two reasons. First, the cognitive load imposed by creative problem solving, as we have described above, is high from the outset. Second, because novel stimuli often increase arousal levels, it is likely that the *production* of novelty will create a cycle of upward-spiraling arousal in the problem solver. This, in turn, will cause some degree of cognitive tunneling, making continued novelty production and evaluation difficult (Cropley, 1999). This may suggest that, unlike some other tasks, where higher levels of arousal may be desirable to maintain performance (e.g., long-duration search tasks for low-probability targets), creativity may be fostered by low initial levels of arousal.

The idea that novelty production may cause spiraling levels of arousal also provides one explanation for the often-discussed benefits of *incubation* for creative problem solving. Smith (1995) describes incubation in terms of the general finding that people are more likely to solve a problem after taking a break rather than working on a solution without interruption. In controlled trials, incubation effects are not invariably found (Nickerson, 1999); however, research continues to focus on the conditions under which incubation works. It is possible that a break from the act of novelty generation may serve to reduce arousal levels to more task-appropriate levels. Another explanation is that the probability of a new *problem representation* being put into action (e.g., the mental image or list of procedural steps being manipulated to generate solutions) is greater when a person disrupts his or her own processing. The person may simply be more likely to have forgotten components of a previous, ineffective representation upon returning to the task.

The importance of the cognitive representation of problems, and the different display formats that support these representations, has been demonstrated for a variety of problem-solving tasks (Davidson and Sternberg, 1998). Flexible scientific, information, and design visualization tools may prove to be particularly valuable for creative problem solving, because changing the orientation, color scheme, format, or level of focus will change the salience of different aspects of the problem. For example, when designers were asked to generate a design for a new lamp, Damle (2010) found that the use of design software that permitted monochromatic viewing of the otherwise multicolored designs helped the designers avoid fixating prematurely on design details. Presumably, this relatively simple change in the design software influenced designers' self-evaluations of their evolving designs, shifting their attention to global characteristics such as symmetry and

balance. Developing software tools that reduce problems like functional fixedness, that instead encourage the perception of different aspects of the problem, are an important focus of current work on the design of *creativity support tools* (Schneiderman, 2009).

## 5.6 Metacognition and Change Blindness Blindness

We end our discussion of higher order cognitive processes by discussing a type of knowledge that may have a profound impact on the successful performance of any task, but especially on tasks involving problem solving, comprehension, and the maintenance of situation awareness. The term *metacognition* was introduced by Flavell (1979) to indicate a person's knowledge about his or her own cognitive processes and, further, the use of this information to regulate performance (Reder, 1996). The most active area of research on metacognition has been in education, where researchers have looked at how students' beliefs about their own information-processing capabilities influence learning strategies and ultimate academic success (Veenman et al., 2006; Bjork, 1999). However, the concept has important implications for the practice of human factors and ergonomics as well.

When describing metacognition, most researchers distinguish between *metacognitive knowledge* and *metacognitive control processes*. In general, metacognitive knowledge includes beliefs about one's own processing capacity, about potential strategies that enhance performance (or minimize capacity limits), and about when and why such strategies are appropriate (Schraw and Moshman, 1995). For example, an expert operator may come to the conclusion that it is more difficult to notice critical signals when they occur in a particular region of a visual display. Further, the operator may believe that he or she can compensate by oversampling that region but may also believe that oversampling will come at the cost of much greater mental effort. In contrast, Levine et al. (2000) have noted that most people are unaware of their strong tendencies toward change blindness, a metacognitive phenomenon referred to as "change blindness blindness." Clearly, such beliefs can influence the strategies an operator chooses. And it is important to realize that these beliefs may not be accurate and, further, that individuals, especially experts, may sometimes be unaware of the assumptions they are making (Chi et al., 1988).

Metacognitive control processes include planning, monitoring, and evaluating one's own performance (Schraw and Moshman, 1995). We might associate many of these processes with the functions of Baddeley's (2003) central executive in working memory. Planning includes determining the appropriate allocation of attention and time to different parts of a task as well as decisions about what aspects of performance to sacrifice if capacity limits create mandatory trade-offs (e.g., would a fast but inaccurate strategy be better than an accurate but slow one?). Monitoring involves keeping track of the quality of performance as a task progresses, for example, our ability to know whether or not we comprehend some written instructions well enough to act on them; or for the learner, whether we have studied enough on one lesson to have mastered the material and move on to the next. Finally, evaluation looks at the products of task performance and the control processes used to obtain them. This allows an assessment of how effectively we deployed our limited cognitive resources and may further elaborate our metacognitive knowledge in long-term memory.

Metacognitive knowledge and control processes are important for understanding human performance in a variety of domains. One important application is to determine how metacognitive knowledge may shape users' preferences for and use of specific interface and product designs. Users' choices may sometimes seem less than optimal based on existing performance data or predictions of formal performance models (Andre and Wickens, 1995). Cases in point are users' "intuitive" judgments of product usability. Payne (1995; see also Vu and Proctor, 2003), for example, explored users' judgments about the compatibility of different arrangements of multielement displays and controls. These judgments were not accurate predictors of actual performance using the different display–control arrangements, and the naïve judgments seemed to be based on the average "goodness" of the individual matches between each display and its associated control rather than on the match between the configuration of displays and controls. In short, the participants undervalued (or, perhaps, did not understand) the importance of configural properties on memory and performance.

Smallman and St. John (2005) propose that many users and designers alike fall prey to naïve realism, a tendency to prefer more realistic-looking displays, even when simpler formats would support better performance. In general, these authors attribute users' preferences to faulty metacognitive knowledge. For example, most individuals seem unaware of the inherent ambiguities of size and depth found in more realistic-looking 3D displays (see Section 4.4). They were also unaware of the relatively small portion of complex displays that they could process in a single glance, and they seemed not to consider the visual search costs that could result from increased display complexity.

Other examples of the impact of both metacogntive knowledge and control processes are found in drivers' overconfidence in their driving abilities in a variety of situations. For example, nighttime driving, as well as the use of devices such as cell phones, selectively degrades focal (central) vision which is critical for detecting hazards. Peripheral vision, which provides sufficient information for lane keeping, is relatively unimpaired by such factors. However, drivers may not appreciate the distinctive functions of each visual subsystem and may take satisfactory lane keeping as evidence that they have suffered no impairment from nighttime viewing conditions or in-vehicle distractions. This leads to dangerous overconfidence in their ability to detect and identify hazards, a task using a very different visual system and resources (see Section 7.2). In this case, metacognitive monitoring and performance evaluation are impaired, in part because the drivers have continuous feedback about lane keeping but only infrequent feedback about hazard detection. In addition, the

driver's knowledge about their own perceptual systems may not lead them to suspect that one visual subsystem can be spared while another is degraded. Similar sorts of overconfidence may also be implicated when operators fail to use automation or decision support tools in circumstance where their own performance is deficient without these aids (e.g., McGuirl and Sarter, 2006).

When correctly diagnosed, metacognitive errors can be addressed in a variety of ways. Training is one approach, for example, providing information about the types of displays that best support different types of tasks (Milkman et al., 2009). Shen et al. (in press) found that the failure of users to select the appropriate perspective views to use when performing different emergency management tasks could be partially corrected with very simple verbal guidance about the best use of 2D versus 3D displays. Alternatively, poor strategy choices (or poor use of technology ) might be addressed by providing better performance feedback to help users recalibrate their perceptions of their own skill levels, knowledge, and capabilities and to allow them to learn which performance strategies are most effective.

In this section we have discussed information-processing tasks that are time consuming, require extensive cognitive resources, and for which the "correct" response is poorly defined and multiple responses are possible, even desirable. We turn now to characteristics of actions that are typically selected rapidly, sometimes without much effort, and often without great uncertainty about their outcome.

## 6  ACTION SELECTION

### 6.1  Information and Uncertainty

In earlier sections we discussed different stages at which humans process information about the environment. When we turn to the stage of action selection and execution, a key concern addresses the *speed* with which information is processed from perception to action. How fast, for example, will the driver react to the unexpected roadway hazard or pedestrian or how rapidly will the help desk access computer information in response to a client's question. Borrowing from terminology in communications, we describe information-processing speed in terms of the *bandwidth*, the amount of information processed per unit time. In this regard, a unit of information is defined as a *bit*. One bit can be thought of as specifying between one of two possible alternatives, two bits as one of four alternatives, three bits as one of eight, or, in general, the number of bits (conveyed by an event) $= \log_2 N$, where $N$ is the number of possible environmental events that could occur in the relevant task confronting the operator. In the following pages, after we describe a taxonomy of human actions, we will see how information influences the bandwidth of human processing.

The speed with which people perform a particular action depends jointly on the uncertainty associated with the outcome of that action and the skill of the operator in the task at hand. Rasmussen (1986; Rasmussen et al., 1995) has defined a behavior-level continuum

that characterizes three levels of action selection and execution that is characterized by both uncertainty and skill. *Knowledge-based behavior* describes the action selection of the unskilled operator or of the skilled operator working in a highly complex environment facing a good deal of uncertainty. In the first case, we might consider a vehicle driver trying to figure out how to navigate through an unfamiliar city; in the second case, we consider the nuclear reactor operator trying to diagnose an apparent system failure. This is the sort of behavior discussed in Section 5.5.

*Rule-based behavior* typically characterizes actions that are selected more rapidly based on certain well-known rules. These rules map environmental characteristics (and task goals) to actions, and their outcomes are fairly predictable: "If the conditions exist, do $X$, then $y$, then $z$." The operator response in executing rule-based behavior is fairly rapid but is still "thought through" and may be carried out within the order of a few seconds. Working memory is required. Finally, *skilled-based behavior* is very rapid and nearly automatic in the sense that little working memory is required, performance of concurrent tasks is possible, and the action may be initiated within less than a second of the triggering event. Skill-based behavior, for example, characterizes movement of the fingers to a key to type a letter, the sequence of steering wheel turns used to back out of a familiar driveway or compensate for a wind gust, or the response of the pilot to an emergency ground proximity warning that says "pull up, pull up."

Human factors designers are quite interested in the system variables that affect the speed and accuracy of behavior of all three classes. Typically, those variables affecting knowledge-based behavior are discussed within the realm of problem solving and decision making (see Section 7 and Chapter 8). We discuss below the variables that influence rule- and skill-based behavior [see Wickens and Hollands (2000) for a more detailed discussion].

### 6.2  Complexity of Choice

Response times for either rule- or skill-based behavior become longer if there are more possible choices that could be made and therefore more information transmitted per choice (Hick, 1952; Hyman, 1953). The rule-based decision to go left or right at a Y fork in the road is simpler (i.e., 1 bit) and made more rapidly than at an intersection where there are four alternative paths (i.e., 2 bits). Menu selections take longer on a page where there are more menu options, and each stroke on a typewriter (26-letter options) takes longer to initiate than each depression of a Morse code key (two options). Indeed, the time to select an option is roughly proportional to the number of bits in the choice (Hick, 1952). As a guideline, designers should not give users more choices of action than are essential, particularly if time is critical. Long menus, with lots of rarely chosen options, may not be desirable. The consequences of offering many choices are not only longer response time but also an increased possibility that the wrong option will be chosen by mistake. More items typically lead to greater similarity between items and hence an invitation for confusion.
**Figure 12** Decision complexity advantage: (*a*) total time required for three "simple" (low-complexity) choices; (*b*) time required for a single high-complexity choice. The total amount of information transmitted is the same in both cases.

The guidance for avoiding very complex choices presented above does not necessarily mean that very simple choices (e.g., 1 bit per choice) are necessarily best. Indeed, generally *an operator can transmit more total information per unit time with a few complex* (*information-rich*) *choices than several simple* (*information-poor*) *choices*. This conclusion, referred to as the *decision complexity advantage* (Wickens and Hollands, 2000), can be illustrated by two examples: First, an option provided by a single computer menu with eight alternatives (one complex decision) can be selected faster than an option provided by three consecutive selections from three two-item menus (three simple decisions; see Figure 12). Second, voice input, in which each possible word is a choice from a potentially large vocabulary (high complexity), can transmit more information per unit time than typing, with each letter indicating 1 of only 26 letters (less complex); and typing in turn can transmit more information per unit time than can Morse code. The general conclusion of the decision complexity advantage drawn from these examples and from other studies (Wickens and Hollands, 2000) points to the advantage of incorporating keys or output options that can select from a larger number of possible options, such as special service "macro" keys, keys that represent common words, or "chording" keyboard devices (Baber, 1997) that allow a single action selection (a chord depression using several fingers simultaneously) to select from one of several options.

In conclusion, it may seem that two contradictory messages were offered in the paragraphs above: (1) Keep choices simply, but (2) use a small number of complex choices. In resolving these two guidelines in design, it is best to think that the first guideline pertains to not providing a lot of *rarely* used options, particularly in time-stressed situations and when errors of choice can have high-risk consequences. The second guideline pertains to how to structure a choice among a large number of remaining and *plausible* options. A single choice among a larger list is often better than multiple sequential choices among smaller lists.

### 6.3 Probability and Expectancy

People respond more slowly (and are more likely to respond erroneously) to signals and events that they do not expect. Generally, such events are unexpected (or surprising) because they occur with a low probability in a particular context. This is consistent with our discussion of context effects on object identification in Section 4.2. Low-probability events, such as events with a greater number of alternatives, are also said to *convey more information*. The information in bits, conveyed by a single event that occurs with probability $P$, is $\log_2(1/P)$. As we noted above, greater information content requires more time for processing (Fitts and Peterson, 1964). For example, system failures usually occur rarely and as such are often responded to slowly or inappropriately. A similar status may characterize a driver's response to the unexpected appearance of a pedestrian on a freeway or to a traffic light that changes sooner than expected. The maximum expected response times to truly unexpected events provide important guidance to traffic safety engineers in determining issues related to speed limits and roadway characteristics (Evans, 1991; Summala, 2000). Often more serious than the slower response to the unexpected event is the potential failure to detect that event altogether (see Section 4.1). It is for this reason that designers ensure that annunciators of rare events are made salient and obtrusive or redundant (to the extent that the rare event is also one that is important for the operator's task; see Section 3).

### 6.4 Practice

Practice has two benefits to action selection. First, practice can move knowledge-based behavior into the domain of rule-based behavior and sometimes move rule-based actions into the domain of skill-based ones. The novice pilot may need to think about what action to take when a stall warning sounds, whereas the expert will respond automatically and instinctively. In this sense, practice increases both speed and accuracy. Second, practice will provide the operator with a sense of expectancy that is more closely calibrated with the actual probabilities and frequencies of events in the real world. Hence, frequent events will be responded to more rapidly by the expert; but ironically, expertise may lead to *less* speedy processing of the rare event than would be the case for the novice, for which the rare event is not perceived as unexpected.

### 6.5 Spatial Compatibility

The compatibility between a display and its associated control has two components that influence the speed and accuracy of the control response. One relates to the *location* of the control relative to the display, the second to how the display reflects (or commands) control *movement*. In its most general form, the *principle of location compatibility* dictates that the location of a control should correspond to the location of a display. There are several ways of describing this correspondence. Most directly, this correspondence is satisfied by the *principle of colocation*, which dictates that each display should be located adjacent to its appropriate control. But this is not always possible in systems when the displays themselves may be closely grouped (e.g., closely clustered on a display panel) or

may not be reached easily by the operator because of other constraints (e.g., common visibility needed by a large group of operators on a group-viewed display or positioning the control for a display cursor on a head-mounted display).

When colocation cannot be maintained, the spatial compatibility *principle of congruence* takes over, which states that the spatial arrangement of a set of two or more displays should be congruent with the arrangement of their controls. One example of congruence is that left controls should be associated with left displays and right associated with right. In this regard, the distinction between "left" and "right" in designing for compatibility can be expressed either in relative terms (indicator A is to the left of indicator B) or in absolute terms relative to some prominent axis. This axis may be the body midline (i.e., distinguishing left hand from right hand) or it may be a prominent visual axis of symmetry in the system, such as that bisecting the cockpit on a twin-seat airplane design. When left–right congruence is violated such that a left display is matched to a right response, the operator may have a tendency to activate the incorrect control, particularly in times of stress (Fitts and Posner, 1967).

Sometimes an array of controls is to be associated with an array of displays (e.g., four-engine indicators). Here, congruence can be maintained (or violated) in several ways. Compatibility will best be maintained if the control and display arrays are parallel. It will be reduced if they are orthogonal (Figure 13; i.e., a vertical display array with a horizontal left–right or fore–aft control array). But even where there is orthogonality, compatibility can be improved by adhering to two guidelines: (1) The left end of a horizontal array should map to the near end of a fore–aft array (Figure 13b) and (2) the particular display (control) at the end of one array should map to the control (display) at the end of the other array to which it is closest (Andre and Wickens, 1990). It should be noted in closing, however, that the association of the top (or bottom) of a vertical array with the right (or left) level of a horizontal array is not a strong one. Therefore, ordered compatibility effects with orthogonal arrays will not be strong if one of those arrays is vertical (Chan and Hoffmann, 2010). Hence, some augmenting cue should be used to make sure that the association between the appropriate ends of the two arrays is clearly articulated (e.g., a common color code on both, or a painted line between them; Osborne and Ellingstad, 1987).

The movement aspect of SR compatibility may be defined as *intention–response–stimulus* (*IRS*) *compatibility*. This characterizes a situation in which the operator formulates an intention to do something (e.g., increase, activate, set, turn something on, adjust a variable). Given that intention, the operator makes a response or an adjustment. Given that response, some stimulus is (or should be) displayed as feedback from what has been done (Norman, 1988). There is a set of rules for this kind of mapping between an intention to respond, a response, and the display signal. The rules are based on the idea that people generally have a conception of how a quantity is ordered in space. As we noted in Section 4, when we think about something increasing, such as temperature, we think about a movement of a display that is upward (or from left to

**Figure 14** Examples of population stereotypes in control–display relations. (From Wickens, 1984.)

right, or clockwise). Both control and display movement should then be congruent in form and direction with this ordering. These guidelines are shown in Figure 14. Whenever one is dealing, for example, with a rotary control, people have certain expectations (a mental model) about how the movement of that control will be associated with the corresponding movement of a display. These expectancies may be defined as *stereotypes*, and there are three important stereotypes.

The first stereotype is the *clockwise increase stereotype*: A clockwise rotation of a control or display signals an increasing quantity (Figures 14*c* and *d*). The *proximity of movement stereotype* says that with any rotary control the arc of the rotating element that is closest to the moving display is assumed to move in the same direction as that display. In panel (*c*) of Figure 15, rotating the control clockwise is assumed to move the needle to the right, while rotating it counterclockwise is assumed to move the needle to the left (Chan and Hoffmann, 2010). It is as if the human's mental model is one that assumes that there is a mechanical linkage between the rotating object and the moving element, even though that mechanical linkage may not really be there.

Designers may sometimes develop control display relations that conform to one principle and violate another. Panel (*e*) shows a moving vertical-scale display with a rotating indicator. If the operator wants to increase the quantity, he or she rotates the dial clockwise. That will move the needle on the vertical scale up, thus violating the proximity-of-movement stereotype. The conflict may be resolved by putting the rotary control on the right side rather than the left side of a display. We have now created a display–control relationship that conforms to *both* the proximity-of-movement stereotype *and* the clockwise-to-increase stereotype.

The third stereotype of movement compatibility relates to *global congruence*. Just as with location compatibility, movement compatibility is preserved when controls and displays move in a congruent fashion: linear controls parallel to linear displays [(*f*), but not (*g*)] and rotary controls congruent with rotary displays [(*b*) and (*h*)]. Note, however, that (*h*) violates proximity of movement. When displays and controls move in orthogonal directions, as in (*g*), the movement relation between

**Figure 15** Solutions of location compatibility problems by using cant. (*a*) The control panel slopes downward slightly (an angle greater than 90°), so that control A is clearly above B and B is above C, just as they are in the display array. (*b*) The controls are slightly angled from left to right across the panel, creating a left–right ordering that is congruent with the display array. (From Wickens and Hollands, 2000.)

them is ambiguous. Such ambiguity, however, can often be reduced by placing a modest "cant" on either the control or display surface, so that some component of the movement axes are parallel, as shown in Figure 15.

## 6.6   Modality

Skilled responses in most human–machine systems are typically executed by either the hands or the voice. With increasingly sophisticated automated voice recognition systems, the latter option is becoming progressively more feasible. Although the particulars of voice control are addressed in more detail in Chapter 24, at least three characteristics of voice control are relevant here in the context of information processing:

1.   Voice options allow more possible responses to be given in a shorter period of time without imposing added time-consuming finger movement components (i.e., keys), although this requires more sophisticated software in the voice recognition algorithms. Providing more options, enabling more complex decisions to be selected, is a positive benefit because it exploits the decision complexity advantage, as we saw in Section 6.2.

2.   Voice options represent more compatible ways of transmitting symbolic or verbal information than are possible with spatially guided manual options (Wickens et al., 1984), including sequential keypresses. In contrast, voice responses make relatively poor candidates for transmitting continuous analog–spatial information, particularly in dynamic situations (e.g., tracking; Wickens et al., 1985), since spoken vocabulary is better equipped to generate categorical commands (e.g., "left," "right") than continuously modulated closed-loop commands (e.g., "a little more to the left").

3.   Voice options are valuable in environments when the eyes, and in particular the hands, are otherwise engaged; but, conversely, voice options can be problematic in environments in which a large amount of other verbal activity is required, either by the user or by other people in the nearby workspace. The former causes competition for processing resources within the operator (see Section 7.2.3), while the latter creates the possibility of confusion on the part of the voice recognizer.

## 6.7   Response Discriminability

Whenever a set of manual responses are specified, any increases in the similarity between them (decreases in discriminability) will increase the likelihood of confusion. Thus, movement of the control stick to either one of two forward positions is a response choice that has greater opportunity for confusion than movement in either a forward *or* backward direction. Correspondingly, two buttons that look alike are more confusable (and hence error prone) than are two that are differently colored or shape coded. Although making controls physically distinct from each other may sometimes

destroy a sense of aesthetics in design, such distinctions will generally lead to improved human reliability (Norman, 1988). Incidentally, increased similarity between voice control options (Section 6.6) will also produce the same increase in error likelihood, although here the mediating agent is the voice recognition agent (whether human or computer) rather than the human responder. Thus, the vocabulary selected for use in an application should be chosen with a mind to avoiding confusable-sounding articulations, such as "to" and "through."

## 6.8   Feedback

The quality of feedback provided by control manipulation (or action expression) is often critical to the speed of information transmission (Norman, 1988). Indeed, sometimes the problems of poor response discriminability discussed in Section 6.7 can be addressed and at least partially remedied by providing clear, salient, and immediate feedback as to which (of several confusable) response alternatives has been chosen. This feedback may be in the form of a visible light or an auditory or tactile "click" as the control reaches its appropriate destination.

It turns out, however, that salient feedback is not always necessary or even desirable. In particular, expert or highly skilled users rely far less on feedback than do novices (e.g., the skilled typist, when transcribing, rarely looks at the keyboard or the screen). Thus, if the feedback is salient (and hence intrusive), it may be distracting to the expert, even as it is valuable for the novice. This will be particularly true whenever the feedback is *delayed*, a quality that is especially disruptive for relatively continuous tasks such as data transcription or voice translation (Smith, 1962).

## 6.9   Continuous Control

Our discussion in Section 6.8 focused on the selection of *discrete* actions, such as a keypress or lever movement. Equally important are the *continuous* movements of some controls to reach targets in space. These movements may refer, for example, to the movement of the hand to a point on a touch screen, the movement of a cursor to an icon or word on a computer screen, or the movement of a pointer to a set point on a meter. Generically, then, we can speak of these skills involving movement of a *cursor* to a *target*.

To an even greater extent than the discrete movements discussed in Section 6.8, performance of these continuous-movement skills depends greatly on *visual feedback*, depicting the difference between the current cursor location and the desired target. Performance on control tasks in which a cursor is moved a certain distance into a target is well described by *Fitts's law* (Fitts, 1966; Jagacinski and Flach, 2003):

$$\text{Movement time} = a + b \log_2(2D/W)$$

where $a$ and $b$ are constants, $D$ is the distance to the target, and $W$ is the target width. This very robust law can accurately predict the movement of all sorts of devices, from microscopic pointers (Langolf et al., 1976) to cursor movements by mice (Card, 1981) to

foot movement around a set of pedals (Drury, 1975) to the manipulation of endoscopic surgical instruments (Zheng et al., 2003). The basis of Fitts's law lies in the processing of visual feedback such that movement toward a target is maintained at a rate that is inversely proportional to the momentary distance of the target from the cursor (or other controlled object).

Just as Fitts's law nicely describes continuous movement toward a static target, it can also characterize movement of a cursor toward a *continuously* moving target, a process typically described as *tracking* (Wickens, 1986; Jagacinski and Flach, 2003). When operators engage in continuous tracking, however, whether keeping a car in the center of the highway, flying an airplane down a glide path, or moving one's viewpoint through a virtual environment via some control device, interest is more focused on minimizing the deviation from the target than on the time required to reach the target. Also, concern is less with the amplitude of the required movement than it is with other variables, such as the frequency with which corrections must be made (the *input signal bandwidth*), the complexity and lag of the *system dynamics* mediating between hand movement and cursor or output movement, and the manner in which feedback is displayed. These issues extend well beyond the scope of the current chapter and are covered in more depth in Chapter 5. We also note that compatibility effects in continuous control are also addressed in Section 4.5.

## 6.10 Errors

The previous discussion has focused primarily on the *time* required to process and respond to various items of information. Yet in many systems the occurrence of *errors* is more critical than the occurrence of delays in processing. That is, the loss of information, rather than its transmission delay, is the factor of greatest concern. Although errors are treated extensively in Chapter 27, we wish here to highlight the manner in which different classes of errors can be categorized in the context of the flow of information as depicted in Figure 1*a* (Norman, 1981; Reason, 1990, 1997, 2008).

First, *mistakes* represent errors of the earlier stages of information processing, in which incorrect action is carried out as a result of a failure to *understand* the nature of a situation (i.e., a failure of stage 2 or stage 3 situation awareness, as discussed in Section 5.2). This may result from a breakdown in perception or working memory or from insufficient knowledge to interpret the available cues (i.e., *knowledge-based errors*). Second, while a situation may be diagnosed and understood correctly, *rule-based errors* may result from a failure to apply the correct rules appropriately for selection of a response (Reason, 1990). Third, errors may result from *slips* of action, when the correct response is intended but an incorrect action is actually released (i.e., an unintended response "slips" out of the hands or mouth) (Norman, 1981). Slips of this sort are typically the result of poor human factors design, such as incompatible control–display relationships (see Section 6.5), confusable displays (Section 1) or controls (Section 6.7), coupled with an operator who is well skilled and performing a task in a highly automated

mode, thereby not carefully monitoring his or her own action selections.

A particular version of the slip is called the *mode error*, often observed in multimodal systems, where the operator forgets that the system is in one mode, thinking it is in another one, and executes a series of actions which have a very different effect on the system than intended. A trivial case is when a typist, without using visual feedback, is unaware that the keyboard is in the caps mode. In safety-critical systems, however, mode errors can have major consequences, as, for example, when a speed control can be set to a digital value which controls kilometers per hour or meters per second, depending on the mode setting. Clearly, such multimode systems must be accompanied by salient feedback of the existing mode.

Errors can also be attributed directly to a breakdown of *memory*. As noted in Section 2, working memory breakdowns may lead to forgetting or confusion of material, whereas *errors of prospective memory* may lead operators to forget to perform some action that was previously intended (Loukopopolous et al., 2009). Often described as *errors of omission*, these are typified by leaving the last copied paper on the glass of a photocopier or failing to tighten the bolts after completing a maintenance task (Reason, 1997).

It is usually the case that the conditions that are associated with slower processing are those that also produce more errors, and hence design remediation based on measures of processing speed will be productive in improving overall system accuracy. However, in certain circumstances, a strategic adjustment in how an operator performs a task will lead to an inverse relationship between speed and accuracy: the *speed–accuracy tradeoff*. In this case, a "set" to respond rapidly will lead to more rather than fewer errors (Drury, 1994). An example here would be that of the effects of time stress in emergencies, which may lead to hasty but error-prone actions in the processing of information.

## 7 MULTIPLE-TASK PERFORMANCE

Many task environments require operators to process information from more than one source and to perform more than one task at a time (Damos, 1991; Loukopopolous et al., 2009; Wickens and McCarley, 2008; Salvucci and Taatgen, 2011; Regan et al., 2009). Such environments are as diverse as that confronting the secretary conversing with the supervisor while typing, the maintenance technician who performs and observes diagnostic tests while keeping active hypotheses about possible faults rehearsed in working memory, the vehicle driver placing a cell phone call while searching for a road sign and steering (Regan et al., 2009; Collet et al., 2010), or the basketball point guard dribbling, while scanning the defense, and looking for the cutting forward.

In such multiple-task environments requiring divided attention, we may distinguish between three qualitatively different *modes* of multiple-task behavior: *perfect parallel processing*, in which two (or more) tasks are performed concurrently as well as either is performed

alone; *degraded concurrent processing*, in which both tasks are performed concurrently but one or both suffers relative to its single task level; and *strict serial processing*, during which only one task is performed at a time. Each of these modes is observed under different circumstances and has somewhat different implications for design.

## 7.1 Serial Processing and Interruption Management

The concerns of serial processing result when performance of one task or the other is delayed undesirably because of sequential constraints. Such a delay might characterize the behavior of a pilot who fails to check the aircraft altimeter sufficiently often because he is engaged in other visual tasks, leading to dangerous "altitude busts" (Raby and Wickens, 1994; Dismukes, 2001). Typically, the interests of human factors in sequential task performance are in modeling the decision process whereby the operator chooses to perform one task (and, by necessity, neglects another) at any given moment in time. This choice process is often modeled by *queuing theory* (Kleinman and Pattipati, 1991; Meyer and Kieras, 1997; Liu et al., 2006) or variants thereof (Moray, 1986; Wickens et al., 2003), which specify when a task should be sampled (performed) as a function of that task's importance (cost of not performing it) and the frequency with which it should be carried out. When evaluated against these optimal benchmarks, human performance appears to be reasonably optimal subject to the constraints of working memory.

However, reasonably optimal is not the same thing as perfectly optimal, and others have focused interest on the occasional breakdowns in optimality that do occur. Thus, a different approach to human multiple-task performance is to focus on the accidents and incidents that have apparently resulted from failures of effective task management (Raby and Wickens, 1994; Chou et al., 1996; Loukopopolous et al., 2009; Schutte and Trujillo, 1996; Orasanu and Fischer, 1997; Wickens, 2003b); that is, what causes people to neglect a task.

Here the answers based on empirical research are not entirely clear, although two prominent factors do appear to emerge. First, visible, and in particular audible, reminders to do a task increase the likelihood that that task will be done, compared to circumstances in which task initiation must be based on prospective memory alone (Norman, 1988; Dismukes and Nowinski, 2007). The vulnerability of such memory highlights the value of checklists as visual reminders for people to carry out certain actions at certain times (Degani and Wiener, 1993; Herrmann et al., 1999; Wickens, 2003b). Second, heavy involvement (high workload) with one task may lead an operator to neglect a second task and perhaps fail to return to an activity at a time when that return should be critical. Such high workload can amplify the negative effects of change blindness discussed in Section 3.1, given that such environmental changes often announce a task to which attention should be redirected. This deficiency may be addressed through task or workload management training programs (Loukopopolous et al., 2009).

Of course, task switching is a two-way street. The desirable properties of having the waiting task call attention to itself may also have the undesirable properties of interrupting an ongoing task, to the detriment of the latter (McFarlane and Latorella, 2002). Recently, study has focused on the concept of *interruption management.* This domain of interruption management embodies the research on situations which represent an operator performing an ongoing task (OT), being interrupted by an interrupting task (IT) and then returning to the OT (Trafton and Monk, 2007; Iani and Wickens, 2007; Latorella, 1996). This sequence (OT–IT–OT) can be thought of as a "unit of interruption." If the cycle is repeated many times, it represents the more general paradigm of task switching (Monsell, 2003), or task interleaving (Wickens and McCarley, 2008). Because interruptions and task switching seem to be an inevitable part of the modern workplace (Gonzales and Mark, 2004; Wolf et al., 2006), we ask if there are any general rules, tendencies, or factors that make interruption management more or less fluid.

One approach to the study of IM has focused on the first attention switch, from the OT → IT, and the extent to which *preemption* of the OT by the IT is optimal or not. IT modality certainly makes a difference here, as auditory and tactile alerts are more preferred than visual, but the two nonvisual modalities can sometimes be sufficiently intrusive that they can lead to abandoning the OT at nonoptimal times; auditory interruptions, like a phone call, are often hard to ignore. A promising approach is one in which the IT event can signal its own degree of importance, so that the performer can establish whether a switch need be immediate (Ho et al., 2004) before the OT is abandoned.

A second approach, related to *cognitive tunneling*, has been to focus on properties of an OT that will prevent the switch when in fact it should have occurred. This is the study of "engagement." For example, studies of cell phone use in cars suggest that the more "engaging" is the conversational task, the less likely is the driver (or simulated driver) to switch attention from the task to address an unexpected event in the driving task (Horrey and Wickens, 2006; Collet et al., 2010). Failure or fault management in complex systems (the OT) has also been associated with such tunneling, where attention is not switched to deal with other high-priority events that may occur as the operator is trying to deal with the fault (Dismukes and Nowinski, 2007). Aviation data also suggest that compelling immersive 3D displays can lead to this sort of attentional tunneling in the OT, causing a failure to switch to unexpected IT events (Wickens and Alexander, 2009; Wickens et al., 2009a).

A third approach to interruption management is to examine the resumption of the OT after an interruption. Much of this work is based on a theory of "memory for goals" or "goal activation" (Trafton and Monk, 2007), in which the critical determinant of resumption is how well the goals of the OT are mentally preserved during the IT period. For example, actions taken prior to IT switching (i.e., active "placekeeping" or "bookmarking," or rehearsal) can serve to maintain the goal in a more active state at the time of the second (IT → OT)

switch and hence increase the fluency of restarting the OT (McDaniel and Einstein, 2007). The state of the OT at the time of the interruption can also be briefly rehearsed (Trafton et al, 2003). In a corresponding fashion, strategically postponing switch 1 until a subgoal in the OT has been completed ("let me just finish this paragraph") will better enable starting the OT where it was left off, rather than having to "start from scratch." A closely related factor is the modality of the OT. When this involves processing speech, because speech is transient and vulnerable and must be rehearsed, there is more of a tendency to delay the abandonment of the OT when it is in the vocal, rather than the text modality, because in the former case an instant switch may lead to forgetting what was just said and require a request for a repeat upon return to the OT; in the latter, with print, one can simply go back and read the still-present text (Latorella, 1996).

Designers of human–computer interfaces are considerintg ways in which intelligent automation can postpone interruptions of a user's ongoing task until the inference is made that a subgoal has been completed (Bailey and Konstan, 2006).

We also note that similar strategic factors in interruption management influence switching in dynamic control tasks; people do (or at least should) schedule switches when the system is in a more stable state. For example, in driving, it is more optimal to look downward to a secondary task, when the car is centered in the lane and heading straight, than when the car may be veering toward one side or the other. Switching in stable states during dynamic control is analogous to switching cognitive states after subgoal completion.

In closing, it should be noted that some concurrent task performance may be invoked during interruption management to the extent that the operator may be attempting to rehearse the goals or status of the OT while addressing the IT. We now turn to this issue of concurrent task performance.

## 7.2 Concurrent Processing

In contrast to sequential processing, an understanding of concurrent processing, whether in degraded mode or perfect parallel mode, depends on somewhat different mechanisms. These mechanisms are as closely related to the structure of the information-processing sequences within the tasks themselves as they are to the operator's knowledge of task importance and priority (although there are interactions between these two influences; Gopher, 1992). Here human factors interest is in the task features that can enable any sort of concurrent processing to emerge from serial processing and that can enable that concurrent processing to be perfect rather than degraded. Four characteristics appear to influence this degree of success: task similarity, task demand, and task structure and resource allocation (Wickens, 2002, 2007; Wickens and Hollands, 2000), although how these influences are exerted is somewhat complex.

### 7.2.1 Task Similarity

A high degree of similarity between two tasks may induce confusion, just as similarity between perceptual signals will cause confusion (Section 3.3), high similarity between items held in working memory will increase the degree of interference between them (Section 5.1), or high similarity between two response devices will increase the possibility of confusion of actions (Section 6.7). In the context of interruption management, high similarity between the OT and the IT will degrade performance, because the remembered status of the OT will get confused with material from the IT (Dismukes and Nowinski, 2007; Cellier and Eyrolle, 1992).

In contrast to similarity of material, making the *rules* governing two tasks more similar may allow the tasks to be better integrated, fostering *more* effective concurrent processing. This may involve using similar control dynamics on two axes of a tracking task (Chernikoff and LeMay, 1963; Fracker and Wickens, 1989) or using similar rules to map stimuli (events) to responses (actions) (Duncan, 1979). Rule similarity also facilitates the ability of an operator to *switch* attention between two tasks in sequential fashion when in the serial mode of processing. That is, it is easier to keep doing alternative versions of the same task than it is to switch between different tasks, as if there is some "overhead" penalty for switching rules (Rogers and Monsell, 1995).

### 7.2.2 Task Demand

Easier tasks are more likely to be performed concurrently (and perfectly) than are more difficult or demanding tasks, an intuitive effect well documented in the study of cell phone interference with driving (Collet et al., 2010). We argue that easier tasks are generally more automated and consume less mental effort or resources than do more difficult ones (see Chapter 9). Such automaticity can often be achieved by extensive practice on what are called *consistently mapped tasks* (Fisk et al., 1987). These are tasks in which in each encounter by the learner, certain properties of the relation between the displayed elements, cognitive operations, and responses remain constant. These mimic many properties of skill- and rule-based tasks, as described in Section 6.5. Such consistent mapping will lead to not only more rapid performance but also performance that is relatively attention free and hence will allow other tasks to be time shared successfully.

### 7.2.3 Task Structure

Certain structural differences between two time-shared tasks increase the efficiency of their concurrent processing, as if the two tasks demand entirely (or partially) separated resources within the human processing system, such that it is easier to distribute tasks across *multiple resources* than to focus them within a single resource (Wickens, 1991, 2002; Wickens et al., 2003). These resources appear to be defined by *processing code* (verbal or linguistic versus spatial), *processing stage* (perceptual–cognitive operations versus response operations), *perceptual modality* (auditory versus visual), and *visual subsystems* (focal vision, required for object recognition, versus ambient vision, required for orientation and locomotion; Previc, 1998).

To briefly illustrate these dichotomies of resources, it is because of the separate spatial and verbal code

resources that spatially guided manual responses may be more effective than vocal responses when operators must also rehearse verbal material, but vocal responses will be more effective than spatially guided manual ones when the operator must concurrently perform another spatial task, such as tracking (e.g., the disruption of driving caused by cell phone dialing, Collet et al., 2010). As another example of code interference, we saw in Section 5.4 that the spatial cognitive processes involved in navigation and vehicle control are better time shared with the verbal input of a memorized verbal route list than the spatial input of a memorized map. It is because of the separate stage-defined resources that we are often able effectively to time share responding operations (e.g., talking) with perceptual ones (e.g., scanning). It is because of the separate perceptual resources that designers have chosen to offload the heavy visual processing load of pilots and vehicle drivers with some information presented on auditory channels (Wickens et al., 2003). Finally, it is because of the separate visual channels that we can effectively keep a car centered in the lane (using ambient vision) while searching for and reading road signs (a task requiring focal vision).

### 7.2.4 Resource Allocation

Multiple resource demand (the converse of automaticity) and resource type can predict the total amount of interference between two tasks (Wickens, 2005), but the two constructs together say nothing about the extent to which one task or the other suffers the greater decrement or bears the brunt of that interference. This relative decrement is predicted by *task priority* or the *resource allocation policy* between the two, the third element of multiple resource model (Wickens, 2007). Such policy will be at least partially influenced by task importance, but other factors may come into play here, such as the difficulty of the task (greater emphasis is given to the harder task) or the task's intrinsic interest or *engagement* value, the latter describing the occasional interference of cell phone conversation with safe driving, despite the driving tasks' generally greater importance.

## 8 CONCLUSIONS

In conclusion, the systems with which people must interact vary vastly in their complexity, from the simple graph or tool to things like nuclear reactors or the physiology of a patient under anesthesia. As a consequence, they vary drastically in terms of the type and degree of demands imposed on the varying information-processing components we have discussed in this chapter. In some cases, systems will impose demands on components that are quite vulnerable: working memory, predictive capabilities, and divided attention, for example. At other times they may impose on human capabilities that are a source of great strength, particularly if these sources rely on the vast store of information that we retain in long-term memory, information that assists us in pattern recognition, top-down processing, chunking, and developing plans and scripts on the basis of past experience are examples. The

importance of practice and training in the development of this knowledge base cannot be overestimated.

In addition to facilitating the performance of experts in many ways, long-term memory has a second implication for the practice of human factors. This is that predictions of human performance in many systems can be based only partially on an understanding of the generic information-processing components described in this chapter. An equal and sometimes greater partner in this prediction is extensive *domain knowledge* regarding the particular system with which the human is interacting. As several of the chapters in this handbook address, the best prediction of human performance must be based on the intricate interaction between the information-processing components discussed here, the domain knowledge employed by the human operator, and the physical environment within and tools with which the operator works. The reader will find all of these issues covered from multiple perspectives in subsequent chapters of the handbook.

## 1 INTRODUCTION

Internet and ubiquitous mobile access to information and services, together with the globalization of companies, has transformed our world into a truly international marketplace. Users cross international boundaries to access an enormous range of information. Products and services are developed in one country and traded in another. In this new international marketplace, the cultural characteristics of users have become increasingly important. There is an expectation that products and services marketed globally will be sufficiently compatible with local cultures to ensure a highly usable and satisfying user experience.

People with different cultural backgrounds think and behave differently. Examined closely, these differences go way beyond speaking and writing in different languages. Cultural differences are present in values and attitudes, social relationships, communication styles, visual preferences, and cognitive styles. All of these potentially affect the design of highly usable and satisfying user interfaces for users from different cultures. Anthropometry also varies across different world populations, which needs to be considered in the design of physical interfaces and devices for global use. Finally, we are just beginning to discover that users in one culture may emphasize and place value on

different characteristics of usability than those in another. Understanding those differences is essential to designing and bringing a product to market successfully in different world cultures.

Designing user interfaces and products for different cultures also affects human factors design methodology. Careful user needs research conducted in the target cultures at the very beginning of a development will ensure that the product, service, or application concept and requirements will support the tasks and lifestyle of the intended users and be compatible with their environment. The methodology for user needs research must be adapted to the local customs, attitudes, and behaviors of the culture being studied. Recent research on cross-cultural usability testing has revealed a host of issues inherent in evaluating user interfaces across cultures. Discovering the most important usability problems during an evaluation requires an understanding of these issues and willingness to adapt the test methodology to local cultures.

This chapter provides human–computer interaction (HCI) researchers and human factors design practitioners a comprehensive perspective on cross-cultural issues in user interface design. It first presents a definition of culture and various dimensions that are relevant to human information processing and hence user interface design. It then reviews the literature on cross-cultural

usability within this framework of cultural dimensions and human information processing. Where supported by the literature, design guidelines are presented for anthropometry, languages and format, presentation, graphics, cultural preferences, information architecture, searching, and interaction. Recent cross-cultural design research for a variety of paradigms—Web and mobile services design and tangible interfaces—is presented. Suggestions for conducting international user needs research and usability testing are also provided.

## 2 THEORY AND METHODOLOGY

### 2.1 Cross-Cultural Psychology

#### 2.1.1 Framework

The metamodels of culture (Trompenaars, 1993; Hoft, 1996; Stewart and Bennett, 1991; del Galdo and Nielsen, 1996) almost universally conclude that a significant portion of what can be called "culture" is embodied in the psychology of people. This includes (1) their values and attitudes, (2) preferred communication style, and (3) cognitive style. A look at research into these core dimensions of culture provides some insight into how these dimensions might affect user interactions with technology and hence the design of user interfaces. The role played by values and attitudes and the preferred communication style in the framework of culture are discussed below. Culture and cognitive style are discussed in Section 2.1.2.

*Values and Attitudes* Hofstede (1991) believed that patterns of thinking, feeling, and acting are mental programs, or, as he dubbed them, software of the mind. These mental programs vary as much as the social environments in which they were acquired. The collective programming of the mind is what distinguishes the values and attitudes of one cultural group from another.

In his classic study of cultural variations in workplace values and attitudes, *Culture and Organizations: Software of the Mind*, Hofstede (1991) reports and interprets his findings from administering his Value Survey Module (VSM) to over 116,000 people in 50 countries, mostly white-collar workers at IBM. Hofstede statistically extracted four dimensions along which his subjects in different national cultures systematically differed: (1) power distance, (2) uncertainty avoidance, (3) individualism–collectivism, and (4) masculinity–femininity. Later, he added a fifth dimension, long-term orientation. These are described briefly below:

- **Power Distance** Power distance is defined as the extent to which the less powerful members of institutions and organizations within a society accept that power is distributed unequally. Cultures in which high power distance is the norm tend to have highly demarcated levels of hierarchy. People from the lower rungs of the hierarchy have considerable difficulty in crossing the "boundaries." Malaysia, Philippines, India,

and Arab countries were examples of high-power-distance cultures. Austria, Israel, Ireland, New Zealand, and the Scandinavian countries all ranked very low on Hofstede's power distance scale. The United States ranked in the neutral range on this dimension.

- **Uncertainty Avoidance** Uncertainty avoidance is the extent to which members of organizations in a society are threatened by uncertainty, ambiguity, and unstructured situations. High-uncertainty-avoidance cultures tend to have a greater need for formal rules and have less tolerance for people or groups with deviant ideas or behaviors. Latin American countries, Greece, Portugal, Turkey and Belgium in Europe, and Japan and South Korea in Asia scored high on uncertainty avoidance in Hofstede's research. The Scandinavian countries, Ireland and Great Britain in Europe, Singapore, Hong Kong, and Malaysia in Asia showed the lowest uncertainty avoidance. The United States scored in the middle of the countries sampled.

- **Individualism–Collectivism** Individualism describes a society in which the ties between individuals are loose. Everyone is expected to look after him or herself. Collectivism exists in societies in which people are integrated into strong cohesive groups, which serve to protect them throughout their life. The group receives loyalty in return. The United States, Great Britain, Australia, and Canada had the highest individualism scores in Hofstede's research. The most collectivist countries were in Latin America. Certain Asian countries such as Pakistan, Indonesia, South Korea, and Taiwan also were strongly collectivist.

- **Masculinity–Femininity** Masculinity is found in a society in which social gender roles are very distinct. Men are expected to be assertive, tough, and oriented around material success. Women are supposed to be modest, nurturing, and concerned with the quality of life. In feminine cultures, the gender roles overlap. It is OK for both men and women to show traits of nurturing and concern for quality of life. Japan had the highest score for masculinity in Hofstede's study, followed by Austria, Switzerland, Italy and Germany in Europe, and numerous Caribbean countries. The United States ranked on the masculinity side of the middle range. The Scandinavian countries and The Netherlands were the most feminine countries studied by Hofstede.

- **Long-Term versus Short-Term Orientation** Long-term orientation is found in a society that is oriented toward future rewards. Perseverance and thrift are valued. Cultures with short-term orientation promote the virtues of the past and present. These include respect for tradition, preserving "face," and fulfilling social obligations. China, Hong Kong, Taiwan, Japan, and South Korea all are good examples for long-term oriented cultures. In Hofstede's survey, Pakistan,

Nigeria, Philippines, Canada, Great Britain, and the United States were among the most short-term-oriented cultures.

Since Hofstede's results were originally published, they have been widely used in international management to explain business-related behaviors in different countries (e.g., Trompenaars, 1993). They have been used to understand human-induced causes of airline crashes (Krishnan et al., 1999; Helmreich and Merritt, 1998) and medical errors (Helmreich and Merritt, 1998). Krishnan et al. (1999) proposed a range of cockpit user interface enhancements that would potentially counter certain culturally linked attitudinal tendencies that can lead to errors in the cockpit. Principles relating Hofstede's cultural dimensions and the affect evoked by the visual composition of website content have been proposed by Gould (2001). Finally, much has been written about the implications of these value and attitude dimensions for user interface design (Marcus, 2001).

There is no question that Hofstede's cultural framework can illuminate certain aspects of user interface design, particularly those of an affective or social nature. But as these relationships are postulated and applied to design, one needs to be sensitive to certain issues in applying it to new contexts. First, Hofstede believed that his framework tapped into some of the most fundamental and deeply engrained aspects of national culture. However, he predicted that several of his cultural dimensions, namely uncertainty avoidance and individualism–collectivism, might be influenced by social, economic, and political change. He envisioned that populations might slowly change over time along these attitudinal dimensions. Results from an application of Hofstede's VSM in China (Plocher et al., 2001) provide some evidence for this. Their engineering student subjects at Tsinghua University scored about as expected on four of the Hofstede dimensions. However, their score on the scale of individualism–collectivism was strongly in the opposite direction (strong individualism) to that predicted by the literature. The authors speculated that this particular result may reflect the effects of the rather dramatic social and political upheaval in China over the past 50 years caused by the Chinese revolution and Communist era and, more recently, Western social and economic influences. Young professionals in China may be eschewing the traditional and Communist-era collectivist Chinese values and attitudes for a more Western-like individualist orientation.

In a major research project aimed at understanding national, organizational, and professional influences on the team-related behaviors of commercial airline pilots, Helmreich and Merritt (1998) found the Hofstede (1991) framework to be extremely useful. Many of the airline crashes they reviewed had a significant cultural component when interpreted within the framework provided by Hofstede. However, Helmreich and Merritt sometimes observed behavior that appeared to contradict their expectations based on national culture alone. They concluded that national culture is only one influence on pilot behavior. In some situations the value and attitudinal dimensions of national culture give way to overriding influences imposed by the culture of the organization (e.g., the airline) or by the piloting profession itself. Hofstede's framework provides valuable insights into cross-cultural behaviors but must be applied with an understanding of other influential factors at work in the organization and profession.

Finally, as Bosland (1985) has pointed out, we must remember that Hofstede's cultural dimensions are characteristics of societies that share the same culture. The variables reflect the dominant values of the majority of people living in a given culture. But they do not necessarily reflect the values of every individual person in that culture. Individuals within one culture will have a greater likelihood of holding certain values and attitudes about work than their counterparts in another culture and thus will have a greater likelihood of reacting to events in certain ways. However, within both cultures there will be significant variation, even to the extent of some overlap.

### Preferred Communication Style: Use of Context

Context refers to the amount of information packed into a specific instance of communication (Hall, 1976, 1990). It is one basis for describing communication styles. "High-context" communication style uses terse messages, short on background details. It assumes that the receiver of the message is familiar with the subject matter. "Low-context" communication style uses more lengthy or elaborate messages, contains a lot of background information on the subject of the communication, and assumes that the receiver of the message may not necessarily be familiar with the subject. When high- and low-context people attempt to communicate, misunderstanding or frustration often results. The low-context person wants more detail and background information than the high-context person is willing or able to provide. The high-context person is impatient listening to "information that she already knows" from a low-context person who is only presenting his usual complete and thorough message.

Hall believed that communication style, high or low context, was deeply rooted in culture. While there will be significant variation in style within any one culture, one style will tend to be dominant. Germans, Dutch, English, and Americans tend to prefer low-context communication. French, Italians, Spanish, Latin Americans, and Japanese prefer high-context communication. In their popular book, *Understanding Cultural Differences*, Hall and Hall (1990) describe and interpret the stereotypical business-related behaviors of French, Germans, and Americans in terms of communication style and discuss the kinds of conflicts and misunderstandings that can occur when high context meets low context.

Communication style also affects how people interact with information systems, particularly nonlinear, hypertext systems such as the web (Rau, 2001). High-context people browse information faster and require fewer links to find information than low-context users. However, high-context users also have a greater tendency to become disoriented and lose their sense of location and direction in hypertext. Low-context users

are slower to browse information and link more pages but are less inclined to get lost.

### 2.1.2 Cognition and Human Information Processing

People interact with the world around them by sensing and perceiving the stimuli presented to them, making sense of the information perceived, deciding if a response is needed, then executing the response. It is stated in many cognitive theories how humans perceive (Card et al., 1983), store, and retrieve information from short- and long-term memory (Shiffrin and Atkinson, 1969; Norman and Rumelhart, 1970; Shiffrin and Schneider, 1977; Wickens and Hollands, 2000), manipulate that information to make decisions and solve problems (Newell and Simon, 1972), and carry out responses. The stages in human information processing are represented in a general qualitative model by Wickens and Hollands (2000).

The physiological mechanism of human information processing is universal to all people and can be viewed as culturally independent. The organization and structure of the information at each stage are affected by the experience of each individual. One important factor that governs such experience is culture. As noted in the previous section, culture not only affects the values and attitudes held by people but also can affect people's cognition interacting with the world around them.

***Perception*** Meaningful interaction with the world requires pattern recognition. Reading, understanding speech, and distinguishing the familiar from the unfamiliar all require the recognition of patterns. Our brains organize and give meaning to the constant input of sensory messages through an active process of selecting, ordering, synthesizing, and interpreting.

Everyday objects, symbols, and gestures provide design inspiration and are commonly used in user interfaces, but they can be perceived differently in various parts of the world (Table 1). For example, while a U.S. rural mailbox has been widely used to represent the concept of an email account, it cannot be assumed that people from various cultures will perceive and recognize it as a mailbox. A common Japanese street mailbox looks like a U.S. trashcan (Fernandes, 1995). The use of hand gestures in symbol or icon design also is problematic. The same hand gesture can be perceived differently, sometimes the opposite, by people with different cultural backgrounds. "Thumb up" is well known as "fine" or "good going" in North America and much of Europe, but it is perceived as insulting in Australia (Axtell, 1991). The "thumb up" gesture is also used in counting. For example, in Germany, a person uses the upright thumb to signal "one," and in Japan, the upright thumb is used to signal "five."

***Cognitive Style*** From the 1980s, many researchers have studied the fundamental differences in cognitive behavior between people of different national cultures. The classic paper by Liu (1986) was the first attempt at describing a Chinese cognitive style and the experiential factors that shape Chinese cognitive style during development: the family order, the Chinese educational system, and the nature of the Chinese language. Hall (1984, 1989, 1990) and Hall and Hall (1990) wrote extensively about time cognition, how it was expressed in many different behaviors of daily life, and how it varied across national cultures. Later, Nisbett (2003) and his colleagues in Asia (Nisbett et al., 2001) developed a significant body of experimental evidence characterizing fundamental differences between Easterners and Westerners in reasoning style.

Perhaps the most clearly understood and documented differences in ways of thinking are the differences between Americans and Chinese. The cognitive style of Americans is inferential–categorical (functional), which means that they have a tendency to classify stimuli on the basis of functions or inferences made about the stimuli that are grouped together accordingly (Chiu, 1972). In contrast, Chinese people have a relational–contextual or thematic cognitive style. They tend to classify stimuli on the basis of interrelationships and thematic relationships (Chiu, 1972). The American way of thinking tends to be analytic, abstract, and imaginative. The Chinese way of thinking tends to be synthetic and concrete.

Nisbett theorizes that these cognitive differences result from the fundamental philosophical differences—Aristotelean versus Confucian—which permeate almost every aspect of these societies from childrearing to education to social structure. According to Nisbett, Westerners tend to be analytical–logical in reasoning style. Easterners tend to be holistic–dialectical. He describes these stereotypical differences in reasoning style in the ways (Nisbett, 2003) shown in Table 2.

It is illustrative to consider what can happen when a Western analytical thinker attempts to solve problems or work globally with an Eastern holistic thinker. Two individuals from different cultures might:

- Look at the same information or picture and draw different conclusions.
- Pay different attention to minor evidence and be more or less conclusive about their predictions of actions.

**Table 1 Guideline for Metaphors**

| Category | Guidelines | Supporting Research/ Best Practice |
| --- | --- | --- |
| Symbols and icons | Everyday objects, symbols, and gestures may have different meaning in different cultures. They should be used with an awareness of their meaning in the target culture. | Fernandes, 1995 |

**Table 2  Western and Eastern Reasoning Styles**

| Western Analytical–Logical Thought | Eastern Holistic–Dialectical Thought |
| --- | --- |
| Focus on objects, attributes, categories | Focus on the field surrounding objects; sensitive to covariation in the field; little relevance seen in categories |
| Apply rules based on the categories to predict and explain the objects' behavior | Little use of universal rules; behavior of an object is explained by situational forces and factors in the surrounding field |
| Find category learning easy | Find category learning difficult |
| Organize things functionally (focus on what an object ''does'') | To the extent they use categories, they prefer to organize things thematically (e.g., use the context or environment as a basis for identifying similarities) |
| Use formal logic for reasoning, making categories, and applying and justifying rules | Not much use of formal logic; prefer dialectical reasoning such as synthesis, transcendence, and convergence |
| Eager to resolve contradictions (logic); when logic and experiential knowledge are in conflict, adhere to formal logical rules | Less eager to resolve contradiction; prefer a logic that accepts contradiction |
| Interpret individual's behavior as a result of their disposition or personality | Interpret peoples' behavior as the result of situational pressures |

- Look at opposition leaders and predict different actions based on their preference for dispositional-versus- situational explanations.
- Come to different conclusions about the properties of an object when presented with identical evidence from two other seemingly familiar objects.
- Disagree or miscommunicate over how to group things.

**Organizing and Searching Information**  One basic mental process is that how people group things together into categories. Based on the similarities, people categorize objects perceived to have some certain characteristics. People often decide whether something belongs in a certain group by comparing it to the representative member of that category. Some categories seem to be universal across cultures. For example, facial expressions that signal basic emotions—happiness, sadness, anger, fear, surprise, and disgust—are widely agreed-upon across cultures. Likewise, there is widespread agreement across cultures about which colors are primary and which are secondary. The way people select and remember colors appear to be largely independent of both culture and language.

People categorize items of information, objects, and functions according to perceived similarities and differences. If the items have two or more attributes, then there is a basis for variation in how they are grouped together. Some people will emphasize a certain attribute and sort items into categories accordingly. Others will focus on another attribute and sort accordingly. Chiu (1972) found that Chinese prefer to categorize on the basis of interdependence and relationship, whereas Americans prefer to analyze the components of stimuli and to infer common features. The difference between the analytical and relational thinking styles is mainly based on how subjectivity is treated. The analytical style

separates subjective experience from the inductive process that leads to an objective reality, whereas the relational style of thinking rests heavily on experience and fails to separate the experiencing person from objective facts, figures, or concepts (Stewart and Bennett, 1991).

Choong (1996) conducted research which showed that different cultures often focus on different attributes of the same items or objects. For example, Americans tend to focus on functional attributes, whereas Chinese tend to focus on thematic attributes. As a result, Chinese and Americans tend to group items in fundamentally different ways. The experimental results provide insights for cross-cultural design. The results showed that Chinese and American users of an online department store performed better if the contents of the store were organized in a manner that was consistent with their natural way of organizing objects—functional for Americans and thematic for Chinese. In other words, Americans would prefer to see products in a department store organized by function: cleaning supplies, linens, and furniture. Chinese prefer to organize products by themes, in the case of a department store, the different rooms of a house: kitchen, bathroom, and bedroom. Rau et al. (2004) conducted a cross-cultural study to compare the impact of knowledge representation (abstract and concrete) and interface structure (functional and thematic) on Chinese and American performance. Their study provided additional evidence in line with results from previous studies that the Chinese employ a different thinking style from Americans. It also agreed with the previous study (Choong, 1996) that thematic interface structure was advantageous to Chinese users, especially when error rate is an important factor in task performance.

When performing searching tasks, the structure of information is very important. Zhao (2002) studied the effect of information structure on performance of information-acquiring tasks by people of monochronicity or polychronicity time behaviors (see next section). She first classified users as monochronic or polychronic

by means of a standard survey instrument. Then, she measured their speed of performance on information search and retrieval tasks using two different information structures, hierarchical and network. The hierarchical information structure was basically a tree. It placed information in categories and subcategories, with the vertical structure going up to six levels deep. Crossing over from one vertical branch of the tree to another was possible only at the topmost level. The network information structure allowed more flexible searching based on relationships between items of information, regardless of their place in a hierarchy of categories. The results showed that performance of the monochronic users performed significantly better using a hierarchical information structure. In contrast, polychronic users were significantly faster using a network information structure.

Finally, placing objects into categories may simply be less important for people from Eastern cultures. In a picture-sorting task Nawaz et al. (2007) found that Chinese made less use of specific categories and more use of the category "other" than Danish users.

So what does this mean for user interface design? Categories form the basis for the information architectures underlying user interfaces of software systems. The content and organization of menus in graphical user interfaces, links in websites, and file directories in most software applications are based on categories. Databases are built on domain ontologies that rigorously apply categories to organize the concepts and objects in a domain. Different cultures will have different ways of categorizing concepts and objects. Furthermore, the concepts, per se, may differ among cultures. Some concepts used in one culture may not even exist in another culture. What happens when a user from one culture, say, the United States, attempts to use a software application that is based on categories (e.g., an information architecture) developed in another culture, such as India? If the information architecture has not been carefully localized to American culture or carefully internationalized to remove the biases of the Indian culture, this will result in products with poor usability. The user will be frustrated as he or she attempts to locate functions in menus or information organized in an unfamiliar way by an original designer or engineer thinking with a different style.

In the design process, preferred categories and information structure can be determined by card sorting. Two methods can be used for card sorting, one is by hand with paper note cards, the other is by a computer program. Anderson et al. (2004) describe a method for computing "edit distance" from card sort data as a method for revealing the underlying categories and concepts. Their software tools for conducting edit distance analysis are available on the Web at http://www.cs.washington.edu/research/edtech/CardSorts/.

**Spatial Cognition**   Spatial cognition is the process through which individuals gain knowledge of objects and events linked to space (Gauvain, 1993; Mishra, 1997). Frake (1980) analyzed the use of absolute directions and contingent directions in Southeast Asia

and California. The conclusion shows that cultures influence the use of directions. The research of Spencer and Darvizeh (1983) concludes that the Iranian children gave more detailed object information on the way but less directional information compared with British children.

Ji et al. (2000) conducted rod-and-frame tests to detect the field dependence between Chinese and Americans. They showed that Chinese participants made more mistakes on the rod-and-frame test, reported stronger association between events, and were more responsive to differences in covariation, whereas American participants made few mistakes on the rod-and-frame test, indicating that they were less field dependent than their Chinese counterparts.

**Time Cognition**   Though time should be technically and objectively the same for everyone, Hall's (1984) classic ethnographic observations showed that different cultures have different attitudes toward time. He classified two ways in which people understand time: monochronic and polychronic time systems. The different attitudes toward time are reflected in many aspects of peoples' lives, including how they adhere to schedules, approach the tasks of their job, and cope with competing task demands (Bluedorn et al., 1999; Haase et al., 1979; Kaufman-Scarborough and Lindquist, 1999; Lindquist et al., 2001).

Monochronic time is dominant in Germany, the United Kingdom, the Netherlands, Finland, the United States, and Australia (Hall, 1984; Hall and Hall, 1990). Cultures with a monochronic time orientation treat time in a linear manner. Time is divided into segments that can be easily scheduled and "spent." Monochronic people prefer to follow clear rules and procedures. They prefer to work on one task at a time and are frustrated when other competing tasks disrupt that focus. Monochronic people have a narrower view of the overall situation or activity and may miss significant events related to the waiting tasks (e.g., alarms). Clear procedures are important to monochronic users. They are less inclined to invent procedures in new situations or where standard procedures are not available. Monochronic computer users search for information in hypertext in a deliberate and linear manner, making more links than polychronic users to find the same information (Rau, 2001). Hence, they are slower at searching hyperspaces than polychronic users.

Polychronic time is dominant in Italy, France, Spain, Brazil, and India (Hall, 1984; Hall and Hall, 1990). In contrast to monochronic people, polychronic people perceive time in a less rigid, more flexible way. Adhering to rules, procedures, and schedules are not that important to them. Polychronic users are more inclined to switch back and forth between tasks and applications (Zhang et al., 2004). They have a broader view of the overall situation or ongoing activity, but they are prone to task-switching errors. When they try to resume a task, they may "forget where they left off," resuming at the wrong place in the procedure or process. Standard procedures are less important to polychronic users, and they are more inclined to invent procedures to deal with new situations.

Time orientation, either monochronic or polychronic, is deeply rooted in a culture. Within any one culture, one style tends to be dominant, but there will be significant variation in time orientation and related behaviors. In another word, it is possible that time cognition can be influenced by factors other than national culture. Zhao et al. (2002) found that the natural or preferred time orientation of Chinese industrial workers (monochronic) was quite different from what they displayed on the job (polychronic). During a debriefing of the study, participants revealed that there were many factors at work in the Chinese industrial workplace and in society that simply made polychronic behavior more adaptive.

**Problem Solving and Decision Making**   Problem solving is the process by which people attempt to discover ways of achieving goals that do not seem readily attainable. Cross-cultural research on decision making finds that people of many different cultural groups may use different types of decision-making strategies. Americans may favor considering many possibilities, evaluating each possibility as a hypothesis, and then choosing the best one based on the available information. Other cultures high in uncertainty avoidance, like Chinese, may have a greater tendency to make judgments based on representativeness.

In the research of Yi and Park (2003), more than 800 college students from five countries, Korea, Japan, China, the United States, and Canada, joined the experiments. The conclusion found that cultural differences result in different types of decision making. Compared to Americans and Canadians, Korean students showed higher levels of cooperative decision making. However, Japanese students exhibited the lowest levels of cooperative decision making.

Geary et al. (1992) compared the performance of Chinese and American children on the calculation of simple addition. The experiment concludes that Chinese children solved three times more correctly than the Americans did. They also did it with greater speed, because Chinese children calculate by the strategies of direct retrieval and decomposition, whereas Americans depended mainly on counting.

**Language**   Every human society, however primitive in other terms, has a language. The ability to use language is perhaps the most profound indicator of the power of human cognition (Miller, 1981). Without language, our ability to remember, to reason, and to solve problems would be severely limited, since so much of human information processing and thinking occur at the abstract level of language symbols.

Language is key to meaningful communication among people. The communication will be most effective when the first languages, or "mother tongues," of the peoples of the world are used. There are between 3000 and 4000 spoken languages, with numbers ranging from many millions of speakers down to a few dozen or even fewer. There are hundreds of different written languages represented by scripts in use around the world.

Although a writing system is generally viewed as a system for representing a spoken language, it should

be noted that written language is not always a direct transcription of spoken language (Sampson, 1990). For example, in the Arabic-speaking world, vocabulary, grammar, and phonology between spoken and written varieties of Arabic are different. While it is possible to transcribe Arabic speech directly into Arabic script, the transcription will strike Arabic speakers as bizarre and unnatural.

The means to transcribe spoken words are different for different writing systems. For example, Chinese transcribes whole morphemes, the units of meaning. Each single syllabic character represents a unit of meaning(s) which can be a word itself or sometimes two or more characters form a word. The alphabetic systems such as English transcribe phonemes, the units of sound. There is distinction in accessibility of meanings between morphemic and alphabetical symbols. The meaning of Chinese characters is more manifest perceptually than the meaning of words in alphabetical systems (Hoosain, 1986).

There is evidence showing that language can influence thinking. Hoffman et al. (1986) asked bilingual English–Chinese speakers to read descriptions of individuals and to provide free interpretations of the individuals described. The descriptions were of characters exemplifying personality schemas with economical labels either in English or Chinese. Bilingual subjects thinking in Chinese used Chinese stereotypes in their free interpretations, whereas those thinking in English used English stereotypes. This indicates that languages can affect people's impressions and memory of other individuals.

Logan (1987) claims that the phonetic alphabet is more than a writing system; it is also a system for organizing information. The alphabet has contributed to the development of codified law, monotheism, abstract science, deductive logic, and individualism, each a unique contribution of Western thought. East Asian languages are highly "contextual." Words or phonemes typically have multiple meanings, so they require the context of sentences to be understood. Western languages force a preoccupation with focal objects as opposed to context. For Westerners, it is the self who does the acting; for Easterners, action is something that is undertaken in concert with others or that is the consequence of the self operating in a field of forces (Nisbett, 2003).

## 2.2   Physical Ergonomics and Anthropometry

### 2.2.1   Body Dimension

The study of body sizes and other associated characteristics is generally referred to as anthropometry (Lehto and Buck, 2008). The anthropometry typically refers to the measurements of body size, shape, strength, mobility and flexibility, and working capacity (Pheasant and Haslegrave, 2006). Anthropometric measurements are essential when designing devices, equipments, and systems for users. Humans vary in body dimensions, shapes, and other characteristics; thus ergonomics design requires an understanding of the variability of human beings.

Anthropometry data can be classified by the sample of the subjects: military soldiers or civilians. Anthropometric information about military soldiers has a long history and is rather complete (Kroemer et al., 1990). The military has always had a particular interest in the body dimensions of soldiers in order to provide fitting uniforms, armor, and other equipments. The recently published *Human Integration Design Handbook* (HIDH), NASA/SP-2010-3407 [National Aeronautics and Space Administration (NASA), 2010], provides a good overview of the anthropometry as well as provides guidance for human factors design, especially for human space flight programs and projects. However, military data should be used with caution when applied to a civilian population because of the selection biases of the young and healthy sample. In the recent 10 years, many institutes, libraries, and commercial companies across the world conducted large surveys on collecting anthropometric data of the civilians in different nationalities. The anthropometric data of civilians from different nationalities can be used for designing products for people from different nationalities.

### Traditional One-Dimensional Anthropometry and Three-Dimensional Body Scanning

For years, the measurement of body dimensions used traditional tools to generate one-dimensional measurement data. The tools includes calipers, measuring tapes, anthropometers, weight scales, sliding compasses, head spanners, and other similar instruments. In the recent decade, the emerging and fast development of three-dimensional scanning technology greatly changed the way of anthropometric studies. The three-dimensional body-scanning technology has many advantages over the traditional measurement system. It is capable of capturing hundreds of thousands of points in a few seconds. Moreover, it provides details about the surface shape and three-dimensional locations of measurements relative to each other. The digitalized measurements can be easily transferred to computer-aided design and manufacturing tools. In all, the noncontact, instant, and accurate three-dimensional measurement has made anthropometry studies more convenient.

In recent years, several national-level three-dimensional anthropometric surveys have been conducted. They provided online databases that either can be freely used or have to be purchased for uses. The Civilian American and European Surface Anthropometry Resource (CAESAR) collected 2400 U.S. and Canadian and 2000 European civilians aged 18–65. They provide a three-dimensional as well as one-dimensional database on 40 anthropometric measurements. The U.K. National Sizing Survey (Size UK) collected data from 11,000 subjects aged 16–90+ from U.K. populations. It used three-dimensional whole-body scanners to automatically extract 130 body measurements for standing and seated poses. Size USA conducted a comprehensive sizing survey of the U.S. population by three-dimensional body-scanning technology. It collected data of nearly 11,000 subjects from 12 locations across the United States. Size China collected

the head and face sizes of Chinese population aged 18–70 in six different locations in mainland China. It is the first three-dimensional database of Chinese head and face sizes which can be used for international manufacturers and designers. In Japan, the Research Institute of Human Engineering for Quality Life conducted many three-dimensional anthropometric measurements on the Japanese population. Different from the database listed above, the World Engineering Anthropometry Resource (WEAR) is an international organization which organizes a group of interested experts involved in the application of anthropometry data for design purposes. They collected different anthropometric data across the world as well as the methods in a wide variety of innovative applications. Its aim is to develop data models and software tools of an online worldwide information system for utilizing the latest anthropometric databases in engineering environments.

Besides the databases listed above which can provide up-to-date three-dimensional measurements, there are many anthropometric databases which provide one-dimensional measurements for researchers and designers. For example, PeopleSize 2008 provides 289 body measurement dimensions of American, Australian, Belgian, British, Chinese, French, German, Japanese, and Swedish populations. DINED provides an extensive database for the Dutch population aged 2–80+. The DINBelg 2005 provides body measurements for the Belgian population. The AnthroKids provides children's anthropometric data of the North Americans.

### Application of Anthropometry to Cross-Cultural Designs

Ergonomics and anthropometry are very important in the creation of usable products. Anthropometry data drive the guidelines for the design of a product (NASA, 2010). First, knowing the target user population determines which database defines the anthropometric data to be used. Second, once the target population is defined, designers must decide on the range of the personnel in that population who will be operating and maintaining the product. People from different nationalities vary in their body dimensions; thus designers should carefully consider the culture difference on different body dimensions for people in different nationalities. Lin et al. (2004) compared the anthropometric characteristics among four populations in East Asia. They found significant morphological differences among these peoples on the following four aspects. First, the Mainland Chinese body shape has a narrower body with midrange limbs. Second, the Japanese body shape is wider with shorter limbs. Third, the Korean body shape is midrange among the four peoples, but the upper limbs are longer. Fourth, the Taiwanese body shape has wide shoulders and narrow hips with large hands and long legs.

The revolutionary developments of three-dimensional body scanning bring tremendous benefits to product design. Niu et al. (2009) extensively summarized the benefits of three-dimensional anthropometry in product design as well as in crash test, e-commerce, forensic sciences, and videos and animations.

### 2.2.2 Movement/Reach Zone

Classical anthropometric data provide information on static or structural dimensions of the human body in standard postures. However, these data cannot describe functional performance capabilities, such as reach capabilities and movements. When performing a task, humans do not maintain standard and static postures. Furthermore, human movement varies from whole-body movement (e.g., locomotion or translation) to partial-body movement (e.g., controlling a joystick with the right arm) to a specific joint or segment movement (e.g., pushing a button with a finger while holding the arm steady) (NASA, 2010). Thus, the static postures cannot provide the advantages of dynamic posture that are involved in the design.

***Movement of Human Body*** An ergonomic designer must be familiar with how the human body moves, especially when designing workspaces (Lehto and Buck, 2008). In ergonomic design, the movements often of interests are the movements around a joint, for instance, shoulder movement, wrist movement, hip movement, and ankle movement. Table 3 provides a summary of the resources of human body movement data across the world.

The human body movement data can help designers to determine the proper placement and allowable movement of controls, tools, and equipment (NASA, 2010). Body movement data can be combined with the static body dimensions to calculate the movement ranges and reach zones in the workplace. Table 4 provides a guideline of body dimension and movement.

***Reach Zone*** The reach constraint includes the ability to grasp and operate controls. The area within which manual tasks can be performed easily is defined by the workspace (or reach) envelope (Pheasant and Haslegrave, 2006). In ergonomic design, two aspects of reach should be carefully designed: zones of convenient reach (ZCR) and the normal working area. The zone of convenient reach is the appropriate zone or space in which an object may be reached conveniently by an individual. The normal working area is described as a comfortable sweeping movement of the upper limb, about the shoulder, with the elbow flexed to $90°$ or a little less (Pheasant and Haslegrave, 2006). The data of ZCR for a full grip and the coordinates of the normal working area can be found in the book of Pheasant and Haslegrave (2006). Besides, NASA (2010) provides the data for grasp reach limits with right hands for Americans.

### 2.2.3 Biomechanics

Biomechanics explain characteristics of the human body as a biological system in mechanical terms (Kroemer et al., 1990).

NASA (2010) collected biomechanics data of body surface area, body segment volume, body segment mass properties, body segment center-of-mass location, and body segment movement of inertia of female and male crewmembers. In addition, it also provides strength data for the unsuited, unpressurized suited, and pressurized suited condition. The Chinese standards institute published a series of ergonomic standards (National Technical Committee of Ergonomics Standard, 2009). The GB/T 17245-2004 is the standard of body segment movement of inertia.

## 2.3 Methodology

### 2.3.1 Cross-Cultural User Research

Culture is a complex and multidimensional concept. People from different cultures are different in their perception, cognition and thinking styles, language, color coding and affect, and so on. Thus, a better understanding of different cultural traits in the design process is imperative in cross-cultural design. This is particularly true in the Asian Pacific area, especially in China, since in the future the Chinese will comprise one of the largest user populations.

Chinese users include people in Mainland China, Taiwan, Hong Kong, Singapore, and other areas with Chinese heritage. Chinese people speak Mandarin and other dialects, and even within the Chinese population,

**Table 3  Human Body Movement Database**

| No. | Author | Nationality | Sample | Data |
|---|---|---|---|---|
| 1 | Barter (1957) | U.S. | Military | 19 joint movements |
| 2 | Lehto and Buck (2008) | U.S. | Civilian | 21 joint movements |
| 3 | NASA (2010) | U.S. | Military | 25 joint movements |
| 4 | Hu et al., (2006) | Chinese | Civilian, elderly | 18 joint movements |
| 5 | DINED | Dutch | Civilian | 11 joint movements |

**Table 4  Guidelines for Physical Ergonomics and Anthropometry**

| Category | Guidelines | Supporting Research/ Best Practice |
|---|---|---|
| Body dimension and movement | When designing devices, equipments, and systems, target user's body measurements and movement measurements should be checked and designed to accord with the critical measurements in the anthropometric database for different nations. | Refer to the Appendix. |

there are diverse Chinese subcultural groups. For example, Chinese users in Mainland China use a simplified Chinese writing system and Chinese users in Taiwan use a traditional Chinese writing system. In general, Chinese users in Taiwan have had more opportunities to learn American culture than Chinese users in Mainland China within the past 50 years. Thus, it is expected that the differences between users in Taiwan and users in the United States would be smaller than the differences between users in Mainland China and users in the United States (Rau et al., 2004).

Bonds (1986) presented an extensive overview of the psychology of the Chinese people. In his book, he discussed Chinese patterns of socialization, perceptual processes, cognition style, personality traits, psychopathology, social psychology, and organizational behavior. The book provides insights of the culture differences between the Chinese and people from other cultures.

In addition, Yang (2001a) collected her previous published papers on how to study the Chinese, the indigenous approach. She systematically summarized the ways to conduct studies in China and how to localize studies in China. The indigenous approach Yang adopted is based on local materials and observations, a set of commonly shared meaning systems with which the people under investigation make sense of their lives and their experiences and give out and derive meanings while interacting with each other (Yang, 1991, 2000a, 2000b, 2001b). This also helps indigenous researchers understand and interpret the behaviors manifested by the people under study. The indigenization movement flourished from a general dissatisfaction among psychologists and other social scientists over employment of the Western cross-cultural approach for understanding non-Western peoples (Li et al., 1985).

When conducting cross-cultural studies in China, special issues concerning cross-cultural comparison should be carefully considered to ensure the reliability and validity of the study.

First, cautions should be taken in the explanation of culture differences by different countries. Researchers normally use country as a proxy for culture, for example, they select participants from China and the United States to represent Eastern and Western cultures. According to the results from Schaffer and Riordan (2003), 79% of the cross-cultural organization studies use country as a proxy for culture. That would be very dangerous, since, for example, even within the Asia Pacific Chinese population multilingual and cultural issues exist. Chu et al. (2005) compared the decision process of two closely related nations in East Asia. These results demonstrate the danger of generalizing decision theories across national boundaries, even when the nations are seemingly closely related. The results also indicate that the differences in decision processes among nations cannot be easily characterized as East versus West. Therefore, a better approach for researchers is to start from the theoretical framework to select and collect data, rather than simply characterize the cultural differences by countries.

Second, cautions should be taken in the equivocation of concepts in different cultures. Many studies have been extensively conducted in the United States, and many concepts in academia come from U.S. standards. However, some of the concepts may not carry the same meanings in the Chinese culture. For example, the concepts of personality traits, self-construal, achievement, and so on, may be different. Farh et al. (2004) have compared the forms of organizational citizenship behavior (OCB) that have appeared in the Chinese and Western literature. They found 10 dimensions of OCB in China, with at least one dimension not evident at all in the Western literature. Thus, careful analysis should be performed when examining the equivalence of concepts in different cultures.

Third, caution should be taken on the equivocation of measurements in different cultures. This is especially important in the use of questionnaires. Back-translation is essential for researchers conducting cross-cultural studies with subjects whose native languages are different from the researchers' mother tongue. Brislin's (1970) classic paper investigated the factors that affect translation quality and how equivalence between the source and target versions can be evaluated.

### 2.3.2 International Usability Evaluation

***The Moderator and the Test Subject*** Usability testing involves human social interaction between a test moderator and a test subject. Social and cultural norms affect this interaction just as they affect other interpersonal interactions. There is a growing literature on how Easterners and Westerners react in usability tests. A number of best practices now can be described that help to mitigate cultural bias in usability tests resulting from social interaction effects.

First, it is a good practice to use moderators, evaluators, or interviewers from the same culture as the test subjects. Vatrupu and Pérez-Quiñones (2006) studied how test participants from different cultures behaved in a structured interview setting in which the participant's task was to comment on a website. Indian participants found more usability problems and made more suggestions with an Indian interviewer than with an Anglo-American interviewer, but the comments they made to the Anglo-American interviewer tended to be more positive than negative. With an Anglo-American conducting the interview, Indians also were reluctant to discuss culture-related problems with the website and kept their comments quite general. The participants were more detailed and candid with the Indian interviewer. Yammiyavar et al. (2008) found that when subjects were paired with evaluators from the same culture, they used more head and hand gestures to communicate than if the evaluator was from a different culture, providing a richer source of nonverbal data to analyze. Sun and Shi (2007) studied how using one's primary versus secondary language (English versus Chinese in this case) in a think-aloud test affected the process of the test. Chinese evaluators speaking Chinese to Chinese test users gave more help to users and a more complete introduction to the product being tested and encouraged

users more frequently than Chinese evaluators speaking English during the test.

A second good practice is to avoid pairing evaluators and test users who differ in their perceived status or authority. Particularly in cultures with high power distance, such as China and Malaysia, the behavior of both the test user and the test evaluator is affected by perceived differences in status or authority. Participants in high-power-distance cultures do not challenge or question the evaluator because of the perception of the evaluator as a person of authority (Burmeister, 2000). Yeo (1998) illustrated this with an example of a usability test conducted in Singapore in which a participant broke down and cried from frustration. A posttest interview revealed that the participant's behavior was in part due to the Eastern culture, in which it is not acceptable to criticize the designer openly, because it may cause the designer to lose face. Evers (2002) evaluated cultural differences in the understanding of a virtual campus website across four culturally different user groups (England, North America, the Netherlands and Japan) by using the same methods for each group. The results indicated that Japanese participants who were secondary school students felt uncomfortable speaking out loud about their thoughts and seemed to feel insecure because they could not confer with others to reach a common opinion.

But the effect of culture can go both ways. In a pilot study of think-aloud tests, Sun and Shi (2007) found that evaluator's behavior is also affected by differences in level of perceived authority. When the evaluator's academic title or rank was higher than that of the users, the evaluator tended to more frequently ask the user what he or she was thinking during the test. The evaluator also tended not to provide the user with more detailed instructions during the test.

The third guideline is to train evaluators to combat the "conversational indirectness" of Asian users. Subjects from Asian cultures will tend to seek a compromise and be indirect when evaluating user interfaces. For example, Herman (1996) studied cultural effects on the reliability of objective and subjective usability evaluation. The results of objective and subjective evaluation correlated poorly in Herman's study. The Asian participants were less vocal, very polite, and not inclined to express negative comments in front of observers, so that the results of subjective evaluation tended toward the positive despite clear indication of poor user performance. Herman's solution was to invite test participants to work in pairs to evaluate the interface and make the usability test more of a peer discussion session.

Shi (2008) conducted observations of usability tests in China, India, and Denmark and, like Herman, also noted that Chinese users often kept silent and did not speak out actively, particularly in formative evaluations. Two studies (Shi, 2008; Clemmensen et al., 2009) explained this observation in terms of Nisbett's (2003) cultural theory of Eastern and Western cognition. Accordingly, Chinese people tend to have a holistic process for thinking as opposed to the more analytic style of Westerners. Holistic thought is not as readily verbalized as analytic thought. So, they theorized that

Chinese users in a think-aloud test situation are thinking about the user interface in holistic terms and simply have a more difficult time putting those holistic thoughts into spoken words.

Shi recommended that evaluators receive special training to conduct testing with Chinese users that is based on think-aloud methods. Evaluators should be trained to use reminders and questions, "digging deeper probes," to get the users to talk. For example, evaluators in Shi's study reported that if they knew users were looking for some object or feature on the screen, they would ask, "what are you looking for?" Then, immediately, the user would tell them about what they were looking for. This method of asking related questions to encourage speaking aloud was found to be more natural than just asking people to "keep talking." Evaluators also should be trained to be patient with Eastern participants as they pause and think in between verbalizations (Shi, 2009). All of the above suggestions require a significant amount of training and skill on the part of the evaluator. If such resources are not available to support the test, then perhaps the best approach is to consider an alternative to the think-aloud method for conducting the evaluation.

Shi (2009) found no significant differences in the set of usability problems reported by Chinese and Danish evaluators. However, their ratings of the severity of the usability problems did differ significantly. Chinese evaluators rated problems less severely than Danish evaluators and often rated problems in the middle of the five-point severity scale. Shi (2009) suggests that if problem severity rating is part of the test, then a four-point, rather than five-point, scale should be used to prevent middle-of-the-scale ratings.

***Participant and Evaluator Recruiting***   Recruiting participants with similar background in different places at the same time has made international usability evaluation very difficult. The experimenters have options to carry out international usability evaluation such as going to the foreign country, running the test remotely, hiring a local usability consultant, or asking help from staff in a local branch office (Nielsen, 1990, 2003). Many researchers (Choong and Salvendy, 1998, 1999; Dong and Salvendy, 1999; Fang and Rau 2003; Fukuoka et al., 1999; Prabhu and Harel, 1999; Evers, 2002) chose to recruit participants in two or more countries by going to the countries. The Web has made conducting international usability evaluation a new option. Lee and Harada (1999) conducted an evaluation by recruiting participants on the Web. However, for countries with no experimenters present, they found it difficult to recruit participants on the Web.

Clemmensen et al. (2007) address the problem of "hidden user groups," groups of people who represent significantly different target user segments within the same culture. They suggest that test planners attempt to balance out potential hidden user groups within user segments. For example, users who are accustomed to foreigners and adapt quickly to international test conditions should be balanced by users who are not accustomed to foreigners. Traditional and culturally

sensitive users such as those one might find in rural areas need to be balanced in the pool of test participants by more modern, urbanized people who are less influenced by a country's local culture. To avoid missing critical usability problems during the test, they recommend that evaluators be chosen carefully from evaluator groups suitable to the members of the identified hidden user groups.

### Language

**Verbal Language-Using Interpreters and Translators** Language is a significant factor in international usability evaluation. Without translated content, the target audience may be limited to Web users with a certain education and social background. Nielsen (2003) indicated that the first two concerns for international usability testing are displaying in the user's native language, character set, and notations and translating the user interface documentation into the user's native language. Rau and Liang (2003b) conducted a card-sorting test with Chinese users in Taiwan for an international website. Even though all the information items were translated into Chinese, a dictionary and instructions also were made available to participants. Also, anything offensive in the user's cultural background should be avoided. The testing materials and procedure should accommodate the way business is conducted and the way people communicate in various countries (Nielsen 2003). Interpreters are necessary if the evaluators are not able to speak the user's native language well. The evaluators need to avoid any important information lost in translation so that videotaping and audio recording are useful for further analysis. Nielsen (2003) suggests meeting interpreters beforehand and reminding them that they should not help users during the test.

**Nonverbal Language** Non verbal language displayed in the form of hand and head gestures is commonly used by test participants as an occasional substitute for verbal language or to elaborate on or supplement it. Hand and head gestures also often communicate the comfort level of the participant and his or her readiness to communicate with the evaluator. Observing and analyzing gestures during a test can provide a rich source of data that adds context to the verbal data being recorded.

Yammiyavar et al. (2008) questioned whether users from different cultures exhibited similar or different patterns of nonverbal communication, including the type, frequency, and usage of gestures. They analyzed the occurrence of gestures in video recordings of think-aloud tests that used subjects from Denmark, India, and China. Gestures were grouped into four types (Ekman and Friesen 1969): emblems, illustrators, adapters, and regulators. Emblems replace words with gesture-based signs like nods of head for "yes" or a V sign for victory. They tend to be culture-specific. Illustrators include such actions as banging on the table or sketching shapes in the air. They help the subject to verbalize their thoughts. Yammiyavar et al. (2008) discovered that these can be quite important markers for usability problems because illustrator gestures frequently precede the verbalization of a usability problem to the evaluator. Adapter gestures are actions of the body that convey feeling of pressure or discomfort, for example, cracking one's knuckles, tapping one's feet, stroking hair or chin while in deep contemplation, and "squirming" in one's seat. They indicate the subject's comfort level with the test situation. Finally, subjects control the flow of conversation with the evaluator by using regulator behaviors such as nodding the head up and down to indicate agreement.

Yammiyavar et al. (2008) found that the frequency of using gestures during the test was not significantly different across the three cultural groups. This contradicts the popular belief that Indians, for instance, use more gestures to communicate than other cultural groups. Also, regulator gestures appeared to be used similarly across the cultures studied, but with some tendency for Chinese to use them the least. In contrast, there were significant differences across the cultural groups in specific emblem gestures used to replace words and in adapter behaviors. Certain illustrators appeared to be culture specific as well. The researchers concluded that there is a need to benchmark gestures used in these different cultures and their meanings and then provide those to usability test evaluators to guide observations and understand what they observe.

The facial expression associated with surprise often is used as a marker by evaluators to indicate that a usability problem has been detected by the user. Clemmensen et al. (2009) have questioned the validity of this practice in cross-cultural usability tests. From Nisbett's (2003) theory of cultural cognition, they hypothesize that Easterners will experience less surprise than Westerners when presented with inconsistencies in user interfaces. With their logical, analytic orientation, Westerners tend to focus on fewer causes of observed events, while Easterners, with their holistic orientation, tend to consider more causal factors as well as the context of the event. As Clemmensen et al. (2009) point out, this makes it easier for them to identify a rationale for why the event occurred in the way it did, resulting in less surprise.

***Instructions, Tasks, and Scenarios*** Instructions to the test participant can vary significantly in how much contextual information they provide. At the one extreme, instructions are strictly focused on the task to be performed with the application being tested. No explanation is given about the purpose of the application, when you might use it, or why. At the other extreme, the explanation of the task is embedded in a rich context provided by a real-life scenario. Clemmensen et al. (2009) suggest that Westerners, with their tendency to focus on the central elements presented, such as the details of the task, will be able to obtain that in either presentation of instructions. Easterners, however, will find that the stark instructions are insufficient. With their holistic style of thinking, they will prefer to have the task explanation embedded in the context of a real-life scenario. The recommendation from Clemmensen et al. (2009) is that if cross-cultural testing is to be conducted; then the test planner should

consider adapting the instructions to the cultures of the participants. Planners might want to have different versions of the test protocol prepared that include different types and amounts of background information.

A classic example of adapting test scenarios to the target culture is from Chavan (2005), who engaged Indian test participants by embedding the test tasks in "Bollywood" scenarios. The method capitalizes on the popularity in India of watching Bollywood movies and the fun of openly critiquing them. The test participant is asked to imagine a dramatic scenario similar to a movie script, perform the desired tasks using the application in that context, and critique it.

***Questioning Universal Constructs of Usability*** Underlying much of what is done in user-centered design is the notion that people worldwide understand the fundamental attributes of "good usability" in the same way—effectiveness, ease of use, visual appearance, efficiency, satisfaction, fun, and nonfrustration [International Organization for Standardization (ISO) 9241, 1998; Frandsen-Thorlacius et al., 2009]. As the preceding sections of this chapter have shown, we may culturally adapt specific local instantiations of a user interface to the preferences of local cultures. But it is assumed that the local instantiations are all done with the goal of enhancing the universal construct of usability as defined by these basic attributes.

Recent research questions this assumption of universal constructs of usability (Frandsen-Thorlacious et al., 2009; Hertzum et al., 2007). Frandsen-Thorlacious et al. sampled 412 users from China and Denmark to determine how they understood and prioritized attributes of usability. Chinese users placed greater value on visual appearance, satisfaction, and fun than Danish users. Danish users valued effectiveness, efficiency, and lack of frustration more highly than Chinese users. Clearly, dimensions of usability were weighted differently for these two cultural groups in the study. Hertzum et al. (2007) used repertory grid interviews, a method for identifying how users give meaning to their experience, to explore how personal constructs of usability differed between people from three different cultures, Denmark, China, and India. They found that some of the constructs verbalized by study participants were consistent with common notions of usability such as ease of use and were important at least to some degree to participants from all three cultures. But other constructs differed from commonly used attributes of usability, for example, the attribute of "security." The most important usability attributes for Chinese subjects involved issues of security, task types, training, and system issues. In contrast, Danish and Indian participants focused on more traditional aspects of usability such as "'easy to use," "intuitive," and "'liked." None of the Chinese subjects verbalized these as primary constructs of usability.

These two studies are just a start in understanding what aspects of usability people value in different cultures. However, they raise questions about how user interfaces are currently designed and how they are tested across cultures. If the testing assumes that everyone values the same attributes of usability, then usability test participants from all cultures would be expected to find the same number of usability problems related to the same usability attributes. The two studies reviewed here raise the possibility that test participants in one culture may not identify problems related to a particular attribute of usability simply because that attribute is not as important to them as it is to a participant from another culture. The absence of verbalized problems in a particular area of the user interface design could be misinterpreted as an indication that no problems exist.

From a business perspective, one would have to question why a company would invest scarce development dollars to perfect aspects of a user interface that are not particularly important to a targeted user group. These findings should make companies aware that basing usability requirements for a global product on just one or two cultural groups runs the risk of minimizing attributes that turn out to be important to a second, third, fourth, $n$th, cultural group of users somewhere in their market space, perhaps even to the majority of potential product users. Perhaps a means to identify and weigh what attributes of usability are important to test subjects must become a standard part of global usability testing methodology. And the global locations for usability testing should reflect the segments of the intended global market.

### 2.3.3 Internationalization and Localization

Internationalization is the process of designing a product or system so that it is generic enough to accept many variations and cultural contexts and can be adapted to various languages and regions without engineering changes. Localization, on the other hand, is the process of adapting a product or system so that it can be used by people of a particular cultural context, locale, and area. Many companies perform localization by adapting a product created specifically for its domestic market. A product designed for its creator's domestic market is often embedded with the cultural markings of the creator's cultural context (Hoft, 1996). Any localization after the product has been developed will require recoding and possibly reengineering to accommodate the cultural context of a target locale. Employing internationalization provides the framework and structure in which localization takes place more easily and more efficiently (Luong et al., 1995). Internationalization is the preparatory stage of product development where the embedded culture and language are extracted and generalized (Taylor, 1992). For any company who intends to extend its products in the global market, the approach of product globalization is recommended. Globalization consists of a minimum of two steps: starting with internationalization of a base, culture-free product followed by localization of the base product for each target locale.

Product globalization poses many challenges to product developers beyond text extraction and translation as commonly assumed by people as the only task for global market.

***Cultural Biases*** Designers should avoid using cultural-specific references as they are prone to misunderstanding and misinterpretation cross-culturally.

Visual and verbal puns should not be used since they cannot be translated well. For example, a very popular icon with a light bulb is used to represent "bright idea" in the United States. However, to the rest of the world, it might merely mean a light bulb so that the concept will be easily lost during the localization process.

Designers should stay alert with any potential political, religious, culture-specific values and taboos or other symbolism which may affect the meanings perceived in a particular country.

Also, providing culturally sensitive aesthetics can play a major role in the product acceptance of the target locales as people have internalized perceptions of what looks local and what looks foreign. Culturally sensitive aesthetics should be implemented during the localization process, such as the use of familiar objects, colors, typography, architecture or landmark, and influential geometry.

## 3  USER INTERACTION PARADIGMS AND TECHNOLOGIES

### 3.1  Graphical User Interface

As discussed in previous sessions, how people interact with objects around them is determined by their past experiences with these objects (or similar objects) and their expectations of how things should work when they use the objects. A graphical user interface (GUI) is the graphical and visual representation of, and interaction with, programs, data, and objects on the display of a system. An important feature of GUIs is the ability for users to directly manipulate elements and information on the screen display. A GUI system is portrayed as an extension of the real world. Thus, the users' experiences and expectations play a critical role in the usability of GUI systems. The same is true when it comes to design for users with different cultural backgrounds in that the cultural experiences and expectations of the target audience need to be considered throughout the development lifecycle.

A GUI system usually includes four basic elements: window, icon, menu, and pointing device (WIMP). The WIMP interaction was first developed at Xerox PARC in the 1970s with the desktop metaphor on a personal computer. The WIMP interaction and its variations and extensions are widely used in computing technologies today, including desktop applications, Internet browsing, Web applications, and mobile computing.

#### 3.1.1  Information Organization and Representation

As discussed earlier, differences in cognitive styles exist among people of different cultural backgrounds. Those differences have implications on how information should be represented and organized on GUIs to accommodate different thinking styles due to cultural differences.

Oftentimes on a GUI the information is organized into hierarchical structures. For example, menus display listings of choices or alternatives that users have at appropriate points while using the system or create a set of listings that guide a user from a series of general descriptors through increasingly specific categories on following listings until the lowest level listing is reached. Design guidelines and best practices have been developed for designing usable menus (e.g., ISO, 1997; Galitz, 1997; Weinschenk et al., 1997). Those guidelines call for logical and meaningful organization of menu options. The menu options should be arranged into conventional or natural groups known to users and follow logical order. The groupings should be logical, distinctive, meaningful, and mutually exclusive.

Designing menu structures for people with different cognitive styles cross-culturally needs to accommodate the differences in the tendency of information organization and represent the information accordingly. As Choong (1996) points out when representing information of a system on a GUI, Chinese users will benefit from a thematically organized information structure, whereas American users will benefit from a functionally organized structure. Nawaz et al. (2007) report similar results of cultural differences on the ways the Chinese and Danish group objects, functions, and concepts into categories. In the card-sorting tasks, the Danish subjects prefer to highlight category name by its physical attributes, whereas the Chinese subjects highlight the category by identifying the relation between different entities. The Chinese subjects also utilized more thematic categories than the Danish subjects in the study by Nawaz et al. (2007). Kim et al. (2007) report similar findings with Korean and Dutch users interacting with menu structure designed for mobile phone interfaces. The relational grouping participants (Koreans) were more likely to select and prefer the thematically grouped menu, whereas taxonomic grouping participants (Dutch) had the tendency to select and prefer the functionally grouped menu.

All user interfaces use some forms of metaphors to provide visual and conceptual representations of major user interaction objects and their associated actions. A well-chosen metaphor can be helpful when all or part of the interface includes functions or features that are new to the target users. Metaphors are used to help users connect what they do not know with what they have known. It is imperative that the metaphors are simple, easily understood, and quickly learned. Metaphors should allow target users to easily relate to their real-world experiences. When designing cross-cultural user interfaces, the use of metaphors becomes a challenge as the real world changes from culture to culture. Many companies choose to localize metaphors in their user interfaces by only redesigning the objects or translating the text in a certain metaphor. However, "translating" a metaphor is not sufficient; the entire metaphor will need to be reevaluated and replaced to make the interface mapped to the target users' cultural experience (Evers, 1998). For example, for designing multicultural applications, Salgado et al. (2009) propose five

conceptual metaphors to accommodate users' attitudes and cultural variables: located "at home" metaphor, telescope observer metaphor, close observer metaphor, foreigner "with subtitles" metaphor, and foreigner "without subtitles" metaphor. Salgado et al. expect that those five conceptual metaphors will help designers think about their own cultural perspective and also help the designers to think about how such perspectives can be experienced in different ways.

### 3.1.2  Graphics, Symbols, and Icons

Icons are an essential part in any system with a GUI, that is, WIMP interaction. Icons are small pictorial symbols used on GUIs to represent certain capabilities of the system and to be animated for bringing forth these capabilities for use by the users. The benefits of using icons include to represent visual and spatial concepts, to save screen space, for immediate recognition, for better recall, to reduce user's reading time, and to help products go global (Horton, 1994).

A number of researchers have written about designing icons for specific cultures or for international use. Shen et al. (2007) report on Chinese Web design with cultural icons. Cultural issues in designing international biometric symbols are described in Rau and Liu (2010) and Choong et al. (2010). Pappachan and Ziefle (2008) discuss cultural influences on comprehensibility of icons. Kim and Lee (2005) report on cultural differences in icon recognition on mobile phones. From these we can conclude that a good icon for cross-cultural use has the following properties:

- Mimics both the physical appearance and the function or action of the object it represents
- Clearly represents the state of the object if it is an object that can assume more than one state
- Uses only widely recognized conventions for color and shape
- Is not directional and can be used without rotation
- Is not culture bound
  - No embedded text characters
  - No culture-specific metaphors

### 3.1.3  Presentation, Navigation, and Layout

There are existing guidelines (e.g., ISO, 1997) for designers to follow on how to develop usable presentation and layout of GUI components as well as the navigation among those components. The key is that the design has to match the user's work flow, experience, and expectation. In addition to following GUI design guidelines, there are considerations that need to be addressed in cross-cultural GUI design. For example, different cultures employ different format conventions and measurement systems that will affect the presentation of such information on the GUIs. The arrangement of information on the screen affects how efficiently and comfortably people can scan, read, and find information.

The information should be laid out on the screen in a natural orientation for the target users. For example, in cultures where traditional Chinese form is used, such as Hong Kong and Taiwan, people tend to scan the screen "across the columns" following an "N" pattern. In countries where simplified Chinese is used, for example, China and Singapore, information is mostly printed in rows and read from left to right and top to bottom, that is, a "Z" pattern.

***Language Issues***  The textual information on a GUI imposes significant challenges in cross-cultural design. First, if English is the language of the base product, it is important to start with unambiguous language that minimizes the use of technological jargon, avoids abbreviations, and uses plain, simple English. Second, the same language used in different locales can have dialect differences, including spelling, word usage, grammar, and pronunciation. Third, literal translation of terms often fails to accurately translate the meaning or concept underlying a word.

Linguistic differences should be taken into account, such as text directionality, linguistic boundaries, text wrappings, justifications, and punctuations. When presenting an ordered list or information, a single sequence or ordering of textual information should not be assumed, even if the languages share the same alphabetical system. Collating ideographic characters, such as Chinese Hanzi and Japanese Kanji, is more complex than sorting Latin characters. There are four different collating methods that GUI designers should be aware of and take into consideration: radicals, number of strokes, phonetic sequence, and frequency of use (Rau et al., 2010). Cross-cultural design also will need to take into account physical language variations such as directionality, hyphenation, stressing, fonts, sizes, orientation, layouts, spaces, wrapping, and justification. In European languages, such as German, words tend to be long strings of characters. In contrast, Asian words tend to be shorter, but the characters are much more complex (such as Chinese) and will require more pixels to render clearly on a display screen. Cross-cultural GUI designers should be aware of the possible text expansion required both horizontally and vertically.

Conventional guidelines assume that people read left to right and thus use a left-to-right orientation for labeling text boxes, presenting text, scrolling text within a text box, and presenting a series of control buttons. However, designers should take note that some languages are read from right to left, for example, Arabic or traditional Chinese writing. When designing for such languages, the display features should accommodate the text direction as well as navigation flow.

There are some key linguistic differences to be considered when translating a user interface from one language to another. For user interfaces, adequate screen space needs to be allocated for possible text expansion due to translation. For example, German words are usually longer than their counterpart English words. Composite messages should be avoided, such as warnings with a word or words dynamically determined. The

composite messages will not be translated well since sentence structures could vary dramatically across languages. The rules for word wrapping can also be very different from one language to another.

Sometimes, it is essential to support multiple languages simultaneously. The product designers should avoid using national flags to toggle among languages or using words in one language for selecting among languages. Using national flags for language selection may be offensive to some users since there can be more than one country using the same language. For example, English is used in the United States, United Kingdom, Canada, and many other countries. Using words in one language as language-selecting options is also inappropriate since the users will have to know that language to make the selection. For example, in an English user interface, a Chinese user will have a problem in picking out the word *Chinese* from a list consisting of language options written in English if the Chinese user does not understand English.

Scripts are a collection of characters and glyphs that represent a written version of a spoken language. In many cases, a single script may serve to write tens or even hundreds of languages, for example, the Latin scripts. In other cases, only one language uses a particular script, for example, Hangul, which is used only for the Korean language. The writing systems for some languages may also use more than one script; for example, Japanese makes use of the Han (or Kanji), Hiragana, and Katakana scripts.

Written language can be bidirectional or unidirectional. Most languages are unidirectional. For example, English is written from left to right in a unidirectional fashion. Chinese is another example of unidirectional scripts, but the direction can be left to right, right to left, or top to bottom. A bidirectional script, such as Arabic, can be written from right to left and left to right (in certain situations, such as numbers) in the same context.

Some languages, such as Chinese, demand special consideration of alternative methods of text input. Niu et al. (2010) of Nokia developed a new method called Stroke++ for Chinese character input on mobile phones with the goal of making keypad typing more accessible to novice mobile phone users. Chinese mobile phone input methods use either standardized phonetic notations, such as Pinyin and Zhuyin, or structural information about characters, such as Wubihua or Cangjie. Pinyin requires knowledge of Latinized Chinese Pinyin, which presents difficult barriers to elderly people and nonusers of Pinyin. Wubihua, or Stroke, another popular input method, accepts five distinguishing strokes only when the input sequence is the same as the standard writing order of the character. These methods are difficult to learn because the standard varies between mobile phone manufacturers and there is significant variation in writing habits between different people. The new Stroke++ method exploits the fact that the 600 most frequently used characters in Chinese (out of 20,000 total) can cover 92.9%.of the user's needs in short messages, thus greatly reducing the required set of radicals. However, rather than defining rules to restrict the sequence of entry, this method allows users to input radicals in arbitrary order to form a character, the desired character being selected from a pull-down list of possibilities organized according to frequency of use. In addition, the keypad layout is designed according to Chinese characters' square shape. The radicals are grouped to make the keypad meaningful. For example, the radicals 金 (Metal), 木 (Wood), 水 (Water), 火 (Fire), and 土 (Earth) representing the five elements in traditional Chinese culture are arranged in a single line to help users to remember. 女 and 人 are put together in the middle to make the Chinese word for "woman." Table 5 provides guidelines for use of language.

### Format Conventions and Measurement Systems

Formats are an artifact and are specific to different locales. Numeric values can be represented in different ways. Separators are not always used; even if they are used, different locales use different symbols for separators and with different formats. For the same number, 1,234.56 is used in the United States and

**Table 5 Guidelines for Use of Language**

| Format conventions and measurement systems | Consider the measurement conventions of the target culture, e.g. weights, dimensions, temperatures, and paper sizes. | Rau et al., 2010 |

Canada; "1.234,56 is used in Germany, Holland, and Italy; and 1.234,56 is used in France and Sweden. The numeric glyph shapes can be different as well.

Other format conventions that need to be taken into account include currency, calendars, date and time formats, names and addresses, and telephone numbers. Research and practice in cross-cultural user interface design have focused on the internationalization and localization of display codes, such features as formats, colors, icons, and graphics (Liang and Plocher, 2003).

Designers need to be aware of different measurement conventions for different locales, for example, dimensions, weights, temperatures, and paper sizes. Adequate accommodations need to be provided so that the product uses the appropriate measurements for the target locales. Table 6 provides guidelines for format conventions and measurements.

### 3.1.4  Color Coding and Affect

***Color Associations and Common Safety Words***
There is no difference between cultures in the actual perception of colors since there are common physiological bases for color vision (Bonds, 1986). Further, in technical applications, there is considerable agreement between Asians and Americans about how common safety words are associated with colors (Courtney, 1986; Luximon et al., 1998; Liang et al., 2000; Kaiser, 2002):

- Danger—red
- Go—green
- Hot—red
- Stop—red
- Safe—green
- Caution—yellow

However, a few color associations have been found to be similar in some cultures (Courtney, 1986; Liang et al. 2000; Kaiser, 2002) but different in others:

- Cold—white: Chinese, Japanese; blue: American
- On—green: Chinese; red: American

The point is that most colors have at least some ambiguity associated with their meaning and should be avoided for signaling important or safety-critical concepts unless they are combined with other coding such as text or icon or both. Designers should be aware of ambiguities and use color coding with caution.

***Color and Affect***  What people feel about colors is more subject to cultural variation. Colors and the combination of colors have different meanings in different cultures. Many researchers have conducted studies on color and its impact for different product design.

Early studies on color codability demonstrated that people in different societies did not have the same array of colors to partition the color spectrum (Whorf, 1956). Berlin and Kay (1969) argued that, if the mechanism underlying color perception is universal, there should be agreement on colors among those who speak different languages from different cultural environments in spite of variations in color vocabulary. They studied 20 languages and discovered meaningful regularities in the use of basic color terms which are names of color categories consisting of only one morpheme. They also noted an evolutionary progression in color terms in the sense that culturally simpler societies tended to have fewer basic color terms than culturally complex societies, for example, large-scale, industrial countries. MacLaury's (1991) work also demonstrates the effect of cultural factors on color coding. A comprehensive study of color naming has been presented by Russell et al. (1997). Davies and Corbett (1997) studied speakers of English, Russian, and Setswana languages, which differ in their number of basic color terms and in how the blue-green region is categorized.

Prabhu and Harel (1999) studied users' needs and preferences for digital imaging products in Japan and China. They found that Japanese men preferred single color fonts and simple fonts without emphasis on all the three lines of help, whereas Japanese women and Chinese men and women preferred multiple colors and highlighted or emphasized fonts. Also, Japanese preferred pastel colors for both the welcome screens and the interaction screens. Though Chinese men preferred Chinese colors, preference for women was mixed between Chinese and Japanese pastel colors.

Minocha et al. (2002) conducted informal observations and analysis for the choice of colors on some e-finance sites in India and Taiwan. Three e-finance

|---|---|---|
| Color | Avoid using color to signal important or safety-critical concepts unless they are combined with other coding such as text or icon or both. Use the most commonly accepted color–safety word associations. | Courtney, 1986; Luximon et al., 1998; Liang et al., 2000; Kaiser, 2002 |
| Color | If you must use color in your design, be aware of the affective associations common in the target culture(s). | Spartan 1999; Osgood et al., 1975 |

websites in India were studied for Indian cultures, values, and customs: (1) ICICI Bank, the second largest commercial bank in India that has pioneered Internet banking, (2) Allahabad Bank, an interesting and prominent example of a dual-language (Hindi and English) site, and (3) the State Bank of India, India's largest commercial bank. The authors analyzed the website of ICICI Bank as the representative Indian choice of colors. For Indian users, use of red is associated with vitality, energy, prosperity, and health. Red is considered stimulating and shows ambition and initiative. In religious ceremonies and marriages, the guests dress in red-colored clothes. Besides, use of saffron is considered auspicious among the Hindus, Sikhs, Jains, and Buddhists. The combination of red and saffron can be considered to signify prosperity and growth for current and prospective customers.

While color vision is universal, what people feel about color is definitely more subject to culture differences. In a cross-cultural study of color affective meaning, Osgood and his colleagues (1975) compared differential measurements of about 600 concepts in over 20 communities all over the world. Color names were included in the experiment into subjective culture. Results were expressed in terms of three dimensions. *Evaluation* indicates whether subjects felt that concepts were something like good or bad, nice or awful, and so on; *potency* indicates big or small, powerful or powerless, and so on; and *activity* indicates fast or slow, young or old, and so on. Across the language communities tested, color terms produced some universals for affect. These included that the feature brightness universally showed high evaluation, the colors black and grey showed low evaluation and activity, and red showed high potency as well as high activity.

Color has very different meanings around the world and therefore it is a significant element for all forms of international interaction. Holzschlag (1999) and Morton (2003) point out that the color purple represents death in Catholic parts of Europe and that Euro Disney should have done its homework well before choosing purple as a signature color. There are numerous excellent resources that deal with color usage. Jill Morton's colormatters.com website has extensive information on color studies and online books on color. Spartan (1999) gives many examples related to different cultures in their association with colors. For example, in the United States, Americans tend to relate blue to authority whereas in Canada red relates to authority

as well as inspirer of nationalism. In the British Isles, black is commonly used for authority figures. As in China, red and gold are used for honor and authority.

Although the strict meanings of colors may be fading across culture, it is still a good practice to use colors carefully. If the same color is to be used across locales, it would be a good idea not to use primary colors in design because they may still carry negative or positive meanings in some cultures. Table 7 provides guidelines for using color.

## 3.2  Web/Hypermedia

Although designing for the Web and hypermedia is relatively new compared to conventional GUI design, the key components for a good user interface design can be applied to Web and hypermedia design as well.

Information structure and searching are the two important aspects for Web design. The information structure of the Web is concerned with how to organize the information and how to navigate Web users. Searching is concerned with what searching mechanisms should be provided to users and how to present searching results.

### 3.2.1  Information Structure (Navigation and Hyperlinks)

As noted in previous section, people around the world hold different thinking styles. The differences in thinking could affect their performance interacting with computers. Researchers have highlighted that different cultures often focus on different attributes of the same items or objects (Choong, 1996; Choong and Salvendy, 1999). How items or functions should be grouped in pages and how links on a website or buttons and menus on the user interface should be labeled are highly affected by culture. The information of the website should be structured in association with the target user's cultural traits.

Marcus and Gould (2000) contend that navigation will be impacted by cultures. Users from cultures that feel anxiety about uncertain or unknown matters would prefer navigation schemes intended to prevent being lost.

Luna et al. (2002) suggested that websites should be structured to conform to the target cultures, for example, the site could have a hierarchical or a search-based structure, depending on whether the target visitors

belong to a high-context culture (e.g., Japan) in which hierarchical structures might be preferred or a low-context culture (e.g., Germany) in which search-based structures might be preferred. Furthermore, Luna et al. (2002) pointed out that it is important to provide users with a culturally congruent site by offering links to pages that address the respective values, symbols, heroes, and rituals of a particular culture. The culturally appropriate navigation patterns will lead to less confusing and more satisfactory user experience.

Rau and Liang (2003a, 2003b) pointed to well-designed navigational supports to combat the tendency toward disorientation of users in high-context cultures. Rau and Liang (2003a) used a survey designed by Plocher et al. (2001) to classify Web users as either high or low context on Hall's communication style dimension. They postulated that communication style would affect how people interact with information systems, particularly nonlinear, hypertext systems such as the Web. In their experiments, they found that high-context people browsed information faster and required fewer links to find information than did low-context users. However, high-context users also had a greater tendency to become disoriented and lost their sense of location and direction in hypertext. Low-context users were slower to browse information and linked more pages but were less inclined to get lost. In another study, Rau and Liang (2003b) investigated the effects of communication style on user performance in browsing a Web-based service. The results showed that participants with high-context communication style were more disoriented during browsing than were those with low-context communication style.

Cyr and Trevor-Smith (2004) conducted an empirical comparison of German, Japanese, and U.S. website characteristics. They found preference for different navigation and search capabilities across different cultures. The Japanese sites were twice as likely to use symbolic navigation tools as were the German or the American sites. Preferences for vertical and horizontal menus are statistically significant. German and Japanese sites used a "return to home" button twice as much as the U.S. sites. As to the type of hyperlinks used, the results found that the number of external links and the functionality of links differ across cultures. External links are used in almost all Japanese sites, compared to only two-thirds of U.S. and German sites. The Japanese use symbols for links significantly more than do German and U.S. sites. They concluded that providing navigation appropriate to cultures is important in order to avoid the "disorientation" when users make navigational errors when searching for information.

Lo and Gong (2005) studied the cultural impacts on the format and layout design of e-commerce websites. They examined 50 leading e-commerce websites in the United States and 50 leading e-commerce websites in China. They found that the U.S. sites showed a clear trend of using blue color for hyperlinks. But in the Chinese sites three colors, black, blue, and red hyperlinks, are equally likely to be used. Although there is some evidence on the emergence of a global e-commerce culture or some common standards on the color of hyperlinks, there is also clear evidence of the need for e-commerce website designers to consider the impact of local culture, for example, the higher frequency of using red color in Chinese websites.

Lo and Gong (2005) also examined the navigation model of the e-commerce websites in the United States and China. In terms of direction of navigation, five navigation models are possible: left oriented, right oriented, top oriented, bottom oriented, and center oriented. In terms of the appearance of navigation buttons, it can be text based or it can be GUI based. The results showed that the Chinese sites favor the top-oriented navigation model, while the United States is roughly equal in left-, top- and center-oriented navigation models. It is not surprising that Chinese sites favor the top-oriented navigation model, because traditionally Chinese writings are read from top to bottom and right to left. As to the appearance of navigation buttons, it was found that U.S. sites favor GUI-based navigation buttons, while Chinese sites favor text-based navigation buttons. They further discussed the reasons that Chinese sites employ the top-oriented and text-based navigation model on the cultural aspects. Yahoo is one of the early entries to China's e-commerce market, and it was quite successful. The Chinese Yahoo site employs the top-oriented and text-based navigation model. This mode was also used by the other two leading e-commerce sites in China: sina.com and sohu.com. China has a high-power-distance, collectivism, and high-uncertainty-avoidance society, the success of the above three websites are clearly recognized, and thus subsequent entries into the Chinese e-commerce market tend to imitate their approach using the same navigation model. In the United States, the situation is quite different. Because the United States is rated higher in individualism, a greater variety of navigation styles and site design approaches were found at U.S. sites.

Kralisch et al. (2005) studied the impact of culture on website navigation behavior. In their study, they were concerned with the impact of cultural dimensions (Hofstede's long-term orientation and uncertainty avoidance and Hall's mono-/polychronicity) on user behavior. They collected behavioral data by sorting through records of navigation steps in the Web server log of a frequently used international multilingual website. The results demonstrated the impact of culture on website navigation behavior. Members of short-term oriented cultures spent less time on visited pages than members of long-term oriented cultures. In addition, more information is collected by members of high-uncertainty-avoidance countries than members of low-uncertainty-avoidance countries. Finally, monochromic cultures showed more linear navigation patterns than polychromic cultures and vice versa. They recommended that for monochromic users information should be placed in linear order and links should emphasize hierarchical structure. Table 8 provides guidelines for information architecture.

**Table 8 Guidelines for Information Architecture**

| Category | Guidelines | Supporting Research/ Best Practice |
| --- | --- | --- |
| Information architecture (navigation and hyperlinks) | When designing hypermedia, be aware of the structure of information and the navigation in association with the target user's cultural traits. | Choong (1996), Choong and Salvendy (1999), Marcus and Gould (2000), Luna et al. (2002), Cyr and Trevor-Smith (2004) |
| Information architecture (navigation and hyperlinks) | The navigation of a website should be designed to meet users' expectation by clearly indicating where they are, where they have been, and what they can access to and how they can proceed. | Luna et al. (2002) |
| Information architecture (navigation and hyperlinks) | Provide extra navigational aids for Japanese, Arabic, and Mediterranean users or users in high-context communication style. | Rau and Liang (2003a, 2003b) |
| Information architecture (navigation and hyperlinks) | The color of the hyperlinks should be designed considering the impact of local culture. | Lo and Gong (2005) |
| Information architecture (navigation and hyperlinks) | Provide top-oriented navigation model for Chinese sites. Provide left-, top-, and center-oriented navigation models for American sites. | Lo and Gong (2005) |
| Information architecture (navigation and hyperlinks) | Provide text-based navigation buttons for Chinese sites. Provide GUI-based navigation buttons for American sites. | Lo and Gong (2005) |
| Information architecture (navigation and hyperlinks) | Information should be placed in linear order, and links should emphasize hierarchical structure for monochromic users. | Kralisch et al. (2005) |

### 3.2.2 Searching

Searching is a key element in Web design. Researchers have indicated the significance of searching mechanisms for Web design. Morkes and Nielsen (1997) suggested that designers should provide search mechanisms and structure information to facilitate focused navigation on all websites. They found that 79% of participants scanned text and only 16% read word for word. Users with different cultural background may have different needs for searching mechanisms. Most websites have two types of search mechanisms built in: Web directories and search engines.

Fang and Rau (2003) examined the effects of cultural differences between Chinese and Americans on the perceived usability and search performance of Web portal sites. They found that Chinese participants tended to use keyword search to start a task. If they failed after one or more trials, they would then try to browse the categories to complete the task. On the other hand, American participants tended to browse categories at the beginning of a task. If they failed, they might use keyword search to supplement category search.

Besides color and graphics, discussed earlier, which are affective surface characteristics, the searching outcomes and user satisfaction associated with them also influence the user's affective experience. Fang and Rau (2003) found that Chinese participants were less satisfied with their searching performance than their American counterparts, even though no significant difference was found on their browsing performance for most of the searching tasks. The differences in consequence attribution of American and Chinese users may explain their differences in satisfaction. The Chinese tend to attribute consequence of events more internally than the Americans. The Chinese participants might think that if they had tried harder or had paid more attention than they did in the test, they would have done better. Therefore, providing possible outcomes and results of operations as much as possible is recommended for Asian users.

Kralisch and Berendt (2004) studied the searching behavior on websites for different cultures. They found that cultural dimensions, in particular amount of information needed and the perception of time and space, have an impact on the users' search behavior. The differences in search behavior are likely to be caused by the inherent thinking patterns determined by different cultural backgrounds. Website providers offering information to an international audience should take these results into consideration when designing search options and information access on their websites. The results of their study showed a clear stronger preference for search engines among the high-uncertainty-avoidance (UA) group and stronger preference for content-organized links among the low-UA group. The higher use of search engines among the high-UA group is consistent with the higher amount of information needed by these users. Table 9 provides guidelines for searching.

**Table 9 Guidelines for Searching**

| Category | Guidelines | Supporting Research/ Best Practice |
|---|---|---|
| Searching | Inherent thinking patterns determined by different cultural background influence the search behaviors. | Kralisch and Berendt (2004) |
| Searching | Be aware if user's satisfaction of searching is influenced by cultures. | Fang and Rau (2003) |

## 3.3  Mobile Computing

### 3.3.1  Usage Behaviors

Some recent studies investigated how mobile phone usage differs between cultures and how to design mobile services accordingly. Two studies designed mobile entertainment services in this way. The culture in Latin America focuses on interacting with other people. People there "like to contact with people, listen to music on loudspeakers and avoid being alone" (Otero et al., 2010). Therefore, mobile phones should focus on social connection when isolated (Otero et al., 2010). The culture difference also exits in different regions of China. Northern China is more traditionally interdependent while Eastern China is more independent. This results in different acceptance behaviors toward mobile entertainment service. Rural people in Northern China are most influenced by social influence while those in Eastern China are most influenced by self-efficacy (Liu et al., 2010). Similarly, a difference in mobile browsing is found. Kaikkonen (2008) found differences in mobile phone browsing between people in Asia and other continents. Users in Asia were less technical and preferred a mobile tailored Web. In contrast, users in North America and Europe are more technical and preferred full Web content.

Nokia researchers Nettamo et al. (2006) studied how users in New York and Hong Kong acquired, retrieved, consumed, and shared music on mobile devices. The Internet and one's friends played important roles in discovering and acquiring music in both cultures and music was shared in both cultures by means of emails and instant messaging. However, in New York, emphasis was placed on mobile music as a means of emphasizing individualism, while in Hong Kong the emphasis was on music as a means of bonding with friends. Also, the New York participants retrieved a greater variety of sources and carried a larger selection of music with them compared to the Hong Kong participants. They tended to listen to their mobile music player when commuting to create a private space, whereas in Hong Kong mobile music was valued primarily for entertainment value. Owning a device of a specific brand, such as the Apple iPod, was more important in New York than in Hong Kong. In the latter location, the style and industrial design of the player in general were perceived as more significant than any given brand.

According to an online survey with a large sample size of 3518 respondents from Korea, Hong Kong, and Taiwan (Kim et al., 2004), four cultural factors, that is,

uncertainty avoidance, individualism, contextuality, and time perception, have significant influences on users' postadoption perceptions of mobile Internet services. The service may offer functions with limited options and free trials if the user has a strong inclination to uncertainty avoidance (Lee et al., 2007).

### 3.3.2  Acceptance of Mobile Phones and Services

Many studies have analyzed culture traits of one specific culture, but few have compared different cultures. One important study investigated purchase intentions. Mobile phones are an important item with which to express oneself. Self-expression is different among different cultures. For example, Filipinos with high income or those at a lower social status tend to be flashy in their lifestyle, especially in dressing up. The flamboyance influences their choice of personal items. In contrast, Singaporeans dress up simply and do not outwardly demonstrate an extravagant way of living. Seva and Helander (2009) investigated how the cultural differences between Filipinos and Singaporeans influence their intention to purchase mobile phones. In the field experiment at mobile phone stores, participants were asked to choose one positively attractive and one negatively attractive mobile phone. Then they filled in questionnaires to indicate their affect and rate purchase intention. The results indicated that culture differences do influence emotional responses. Aesthetic attributes influence prepurchase attraction of Filipinos to a particular phone design, while functional attributes (e.g. display area, weight thickness) influence the Singaporeans.

Many studies have focused on cross-cultural design of icons in mobile phones. This is very important to launch mobile phones in the international market. The metaphors and contextual information for the objects to be represented as icons should consider the local culture (Krisnawati and Restyandito, 2008). Cultural differences between Americans and Koreans influence mobile phone icon styles. Among abstract, semiabstract, and concrete icons, Koreans performed significantly better with concrete icons while Americans showed the opposite tendencies (Kim and Lee, 2005). One example in this area is the Apple iPhone. To tailor to users in China, India, and the United States, Oren et al. (2009) investigated how easily users in each country found the icons and redesigned the current Apple iPhone icons based on their investigation. Since there are solutions for different cultures, is it possible to design for all? Pappachan and Ziefle (2008) answered affirmatively.

**Table 10 Guidelines for Mobile Computing**

| Category | Guidelines | Supporting Research/ Best Practice |
|---|---|---|
| Mobile computing | Be aware of the difference of culture on using mobile services. | Kim et al. (2004); Nettamo et al. (2006); Seva and Helander (2009); Otero et al. (2010); Liu et al. (2010) |

Regardless of cultural backgrounds, people can interpret icons better if an icon is more concrete and contains more information. They investigated mobile phone icon design differences between India and Germany. The results identified two critical issues for cross-cultural design of icons, domain knowledge and cultural-specific concept. Table 10 provides guidelines for mobile computing.

## 4 CONCLUSION

Prior to the Year 1995, relatively little attention in human factors design was devoted to consideration of cross-cultural issues. The research and design guidelines that were available at that time focused on surface issues such as the use of colors, symbols, language, and numbers. Fernandes's 1995 book, *International User Interfaces*, remains the classic design reference for many of these issues. Prabhu and Harel's (1999) extensive study of cross-cultural design issues in Japan and China also was a benchmark in this line of human factors research.

By the Year 1999, concomitant with the explosive growth in the use of mobile phones, the Internet, and online services, research in cross-cultural design greatly expanded. That research took two directions. One direction, typified by Marcus (2001), extrapolated user interface design guidelines from the classic work of Hofstede (1991) on cultural differences in attitudes and values and the work of Hall (1976, 1984, 1989, 1990) on time orientation and communication. A significant amount of research has followed Marcus's lead in that direction. A second and relatively less explored direction of cross-cultural design research has focused on cultural differences in cognition. Choong and Salvendy's (1999) research on cultural differences in user interface information structure launched this line of research. Nisbett's basic research (Nisbett et al., 2001) on the broad differences in cognitive style between Confucian and Aristotelian cultures has made us aware of the significant role these differences might play in user interface design for users in the East and the West. Unfortunately, very little research on these cognitive issues in cross-cultural user interface design has followed. It remains a relatively unexplored, yet extremely vital area for cross-cultural design research in the future.

Finally, many new types of technologies, products, and services are still in their infancy but are just beginning to emerge on the global market. Among the most important ones are those associated with global megatrends such as energy management and health care

accessibility. All of these new initiatives will succeed only if they are designed with the needs, preferences, anthropometry, and information-processing styles of their intended users in different cultures.

For example, online health information systems have great potential to reach users in areas of the world that are underserved with local medical services. However, across different cultures, the concepts of disease, symptomology, treatment, and even the human body itself vary widely. An online health information system based on Western concepts of medicine will most certainly fail if launched in China. It is doubtful that all or even many of the concepts of Western medicine could be expressed in the Chinese language. Even more importantly, Chinese users would have difficulty searching and understanding an online system based on unfamiliar concepts of medicine. Carefully aligning the underlying information model and structure in the online health information system with the concepts of the target culture will result in a much more highly usable and successful health information service.

Another example, smart home energy management, also has great promise to help solve another global problem, the difficulty in matching energy supplies with energy demands. The human factors problem begging to be solved here is that of consumer motivation. Wide variations exist in how consumers, both within and between cultures, perceive and define comfort and convenience. Further, there is great variation in consumer tolerance for trading off comfort and convenience against energy cost savings. Research shows that monetary rewards for more careful energy management increase compliance with conservation programs only to a certain level but then reache an asymptote (Wilson and Dowlatabadi, 2007). To motivate homeowners to higher energy conservation levels, other incentives must be used (Peterson et al., 2009; Faruqui et al., 2009; McMakin et al., 2002). The nature of these incentives will depend on the values, attitudes, and lifestyle of the target culture. For example, one might speculate that in a highly collectivist culture such as China effective incentives might be found in appeals to the common good of neighborhood, community, and country. In a highly individualist culture such as the United States, other incentives would likely have to be designed. In all cases, one cannot assume that incentives that are effective in one culture will be effective in another. The success of home energy management on a global scale absolutely depends on understanding the target cultures, their values, attitudes, lifestyles, and needs, and designing an incentive system that is compatible with them.

**APPENDIX: SUMMARY OF ANTHROPOMETRIC DATABASE FOR DIFFERENT NATIONS (ONLINE RESOURCES)**

| Database | Institute/Author | Nationality | Age range | Dimension | Data | Methodology | Link | Product |
|---|---|---|---|---|---|---|---|---|
| CAESAR® | Government and industry | North American; European | 18–65, civilian | 1D 3D | 40 body dimensions | From April 1998 to early 2000, the project collected data on 2400 U.S. and Canadian and 2000 European civilians. | http://store.sae .org/caesar/ | CAESAR™ |
| Size UK | Collaboration of the U.K. government, 17 major U.K. retailers, leading academics, and technology companies | United Kingdom population | 16–90⇓, civilian | 3D | 130 body measurements | The U.K. National Sizing Survey collected data on 11,000 subjects from three geographic regions. | http://www .size.org/ | Sizemic |
| Size USA | [TC]2 | U.S. | Civilian | 3D | — | Size USA collected data of nearly 11,000 individuals in 12 locations across the U.S. | http://www .sizeusa.com/ | SizeUSA |
| ERGODATA | Laboratory of Applied Anthropology, France | North American, European, Asian, Central American, South American, African, Oceania | Civilian | 1D 3D in the development process | Body measurements; biostereometric data | The Individual data file (DI) including 64 inquiries, with 60,000 subjects coming from 20 different countries. The Aggregate data file (DA) including 160 articles, which represent more than 1 million subjects, with 60 represented countries. Tridimensional data file (3D) which is in the development process. | http://www .biomedicale .univ-paris5 .fr/LAA/ eindex.htm | Free |

| Database | Institute/Author | Nationality | Age range | Dimension | Data | Methodology | Link | Product |
|---|---|---|---|---|---|---|---|---|
| Size China | Hong Kong Polytechnic University | Chinese | 18–70, civilian | 3D | Head and face size | From 2006 to 2007, the project collected data on 2000 male and female volunteers in six diverse locations in China. | http://www.sizechina.com/html/index.html; http://www.certiform.org/products.html | Certiform™ |
| Size Japan | Research Institute of Human Engineering for Quality Life | Japanese | Civilian | 3D | Body measures | — | http://www.hql.jp/ | — |
| WEAR | Global partners | Depends on different studies | Depends on different studies | Depends on different studies | Depends on different studies | WEAR is a group of interested experts involved in the application of anthropometry data for design purposes. | http://wear.io.tudelft.nl/ | Free |
| PeopleSize 2008 | Open Ergonomics Ltd. | American, Australian, Belgian, British, Chinese, French, German, Japanese, Swedish | Infant, child, and adult | 1D | Body measures | 289 individual body measurement dimensions | http://www.openerg.com/psz/index.html | PeopleSize |

| Database | Institute/Author | Nationality | Age range | Dimension | Data | Methodology | Link | Product |
|---|---|---|---|---|---|---|---|---|
| DINED | Delft University of Technology | Dutch; International: North American; Latin American (Indians); Latin American (rest); North Europe; Central Europe; Eastern Europe; Southeast Europe; France; Spain and Portugal; North Africa; West Africa; Southeast Africa; Middle East; North India; South India; North India; South China; South East Asia; Australia (European); Japan) | 2–80⇓ Dutch civilian | 1D | Body measures, force exercise, and joint excursion | Long-term project collecting data from different nations. Latest version for Dutch adults is dined 2004, for Dutch elderly is geron 1998, Dutch children is kima 1993. The version for international is 1989. | www.dined.nl | DINED, free |
| AnthroKids | Information Technology Laboratory (ITL) at the National Institute of Standards and Technology (NIST) and the CPSC | North American | Children | 1D | Body measurements | Two studies performed in the years 1975 and 1977 | http://ovrt.nist .gov/projects/ anthrokids/ | Free |
| DINBelg 2005 | Several Belgium schools | Belgian | 2–80, civilian | 1D | Body measurements | The aim of DINBelg 2005 is to gather up-to-date anthropometric dimensions of the Belgian population. | http://www .dinbelg.be/ anthropometry .htm | Free |

## 1 INTRODUCTION

This chapter focuses on the broad topic of human decision making. Decision making is often viewed as a stage of human information processing because people must gather, organize, and combine information from various sources to make decisions. However, as decisions grow more complex, information processing actually becomes part of decision making, and methods of decision support that help decision makers process information become of growing importance. Decision making also overlaps with problem solving. The point where decision making becomes problem solving is fuzzy, but many decisions require problem solving, and the opposite is true as well. Cognitive models of problem solving are consequently relevant for describing many aspects of human decision making. They become especially relevant for describing steps taken in the early stages of a decision where choices are formulated and alternatives are identified.

A complete treatment of human decision making is well beyond the scope of a single chapter.[*] The topic has its roots in economics and is currently a

---

[*] No single book covers all the topics addressed here. More detailed sources of information are referenced throughout the chapter. Sources such as von Neumann and Morgenstern (1947), Savage (1954), Luce and Raiffa (1957), Shafer (1976), and Friedman (1990) are useful texts for readers desiring an introduction to normative decision theory. Raiffa (1968), Keeney and Raiffa (1976), Saaty (1990), Buck (1989), and Clemen (1996) are applied texts on decision analysis. Kahneman et al. (1982), von Winterfeldt and Edwards (1986), Payne et al. (1993), Svenson and Maule (1993), Heath et al. (1994), Yates (1992), Koehler and Harvey (2004), and Camerer et al. (2004), among numerous others, are texts addressing elements of behavioral decision theory. Klein et al. (1993) and Klein (1998, 2004) provide introductions to naturalistic decision making.

focus of operations research and management science, psychology, sociology, and cognitive engineering. These fields have produced numerous models and a substantial body of research on human decision making. At least three objectives have motivated this work: to develop normative prescriptions that can guide decision makers, to describe how people make decisions and compare the results to normative prescriptions, and to determine how to help people apply their "natural" decision-making methods more successfully. The goals of this chapter are to synthesize the various elements of this work into a single picture and provide some depth of coverage in particularly important areas. The integrative model presented in Section 1.3 focuses on the first goal. The remaining sections address the second goal.

## 1.1 Role and Utility of the Chapter

This chapter is intended to provide an overall perspective on human decision making to human factors practitioners, developers of decision tools (e.g., expert systems), product designers, and others who are interested in how people make decisions and how decision making might be improved. Consequently, we present a broad set of prescriptive and descriptive approaches. Numerous applications are presented and strengths and weaknesses of particular approaches are noted. Emphasis is also placed on providing useful references containing additional information on topics that the reader may find to be of special interest.

Section 2 addresses various decision-making models, which are grouped into normative decision models (Section 2.1), behavioral decision models (Section 2.2), and naturalistic decision models (Section 2.3). Normative decision models are based on principles of rational choice and they prescribe how decisions should be made. In contrast, behavioral and natural decision models focus more on describing human decision making. Several descriptive models of human judgment, preference, and choice are discussed and compared to normative models in Section 2.2. Naturalistic decision models should be of interest to practitioners interested in the process to which many real-world decisions are made, the quality of these decisions, and why people use particular methods to make decisions. The discussion provides insight into how people perform diagnostic tasks, make decisions involving risks, and develop expertise.

Section 3 introduces the topic of group decision making. The discussion addresses conflict resolution both within and between groups, group performance and biases, and methods of group decision making.

The next section addresses the topic of decision support and problem solving. The discussion begins by addressing the topic of decision analysis (Section 4.1), which refers to the application of normative decision theory to improve decisions. The discussion considers the advantages of the various approaches, how they can be applied, and what problems might arise during their application. Sections 4.2 and 4.3 cover methods of assisting or supporting the decision making of individuals, groups, and organizations. Section 4.4 discusses the implication of problem-solving research for decision making.

## 1.2 Elements of Decision Making

Decision making requires that the decision maker make a choice between two or more alternatives (note that doing nothing can be viewed as making a choice). The alternative selected results in real or imaginary consequences to the decision maker. Judgment is a closely related process in which a person rates or assigns values to attributes of the alternatives considered. For example, a person might judge both the safety and attractiveness of a car being considered for purchase. Obtaining an attractive car is a desirable consequence of the decision, while obtaining an unsafe car is an undesirable consequence. A rational decision maker seeks desirable consequences and attempts to avoid undesirable consequences.

The nature of decision making can vary greatly, depending on the decision context. Certain decisions, such as deciding where and what to eat for lunch, are routine and repeated often. Other choices, such as purchasing a house, choosing a spouse, or selecting a form of medical treatment for a serious disease, occur rarely, may involve much deliberation, and take place over a longer period. Decisions may also be required under severe time pressure and involve potentially catastrophic consequences, such as when a fire chief decides whether to send firefighters into a burning building. Previous choices may constrain or otherwise influence subsequent choices (e.g., a decision to enter the graduate school might constrain a future employment-related decision to particular job types and locations). The outcomes of choices may be uncertain and in certain instances are determined by the actions of potentially adverse parties, such as competing manufacturers of a similar product. Decisions may be made by a single person or by a group. Within a group, there may be conflicting opinions and differing degrees of power between individuals or factions. Decision makers may also vary greatly in their knowledge and degree of aversion to risk.

Conflict occurs when a single decision maker is not sure which choice should be selected or when there is lack of consensus within a group regarding the choice. Both for groups and single decision makers, conflict occurs, at the most fundamental level, because of uncertainty or conflicting objectives. Uncertainty can take many forms and is one of the primary reasons that decisions can be difficult. In ill-structured decisions, decision makers may not have identified the current condition, alternatives to choose between, or their consequences. Decision makers also may be unsure what their aspirations or objectives are or how to choose between alternatives. At least four reasons for conflict may exist after a decision has been structured. First, when alternatives have both undesirable and desirable consequences, decision makers may experience conflict due to conflicting objectives. For example, a decision maker considering the purchase of an air bag–equipped car may experience conflict because an air bag increases the cost but improves safety. Second, decision makers may be unsure of their reaction to a consequence. For example, people considering whether to enter a raffle where the prize is a sailboat may be unsure how much they want a sailboat. Third, decision makers may not know whether

a consequence will be sure to happen. Even worse, they may be unsure what the probability of the consequences is or may not have enough time to evaluate the situation carefully. They may also be uncertain about the reliability of their information. For example, it may be difficult to determine the truth of a salesperson's claim regarding the probability that a product will break down immediately after the warranty expires.

To resolve conflicts, decision makers must deal appropriately with uncertainty, conflicting objectives, or a lack of consensus. Conflict resolution therefore becomes a primary focus of decision theory. In the following section we present an integrative model of decision making that relates conflict resolution to the elements of decision making discussed above. This model considers specifically how decision making changes when different sources of conflict are present. It also matches methods of conflict resolution to particular sources of conflict and decision rules.

### 1.3 Integrative Model of Decision Making

Human decision making can be viewed as a stage of information processing that falls between perception and response execution (Welford, 1976). The integrative model of human decision making, presented in Figure 1, shows how the elements of decision making discussed above fit into this perspective. From this view, decision making is the process followed when a response to a perceived stimulus is chosen. The process followed depends on what decision strategy is applied and can vary greatly between decision contexts.[*] Decision strategies in Figure 1 correspond to different paths between situation assessment and executing an action. The particular decision strategy followed depends on both the decision context and on whether or not the decision maker experiences conflict.[†]

At least four, sometimes overlapping, categories of decision making can be distinguished. *Group decision making* occurs when multiple decision makers interact and is represented at the highest level of the model as a source of conflict that might be resolved through debate, bargaining, or voting. For example, members of a university faculty committee might debate and bargain before voting for the best candidate for a job opening.

*Dynamic decision making* occurs in a changing environment, in which the results of earlier decisions affect future decisions. The decisions made in such settings often make use of feedback and are multistage in nature. For example, a decision to take a medical test almost always requires a subsequent decision regarding what to do after receiving the test results. Dynamic decision

making is represented at the lowest level of the model by the presence of two feedback loops, which show how the action taken and its effects can feed forward to the assessment of a new decision or feed back to the reassessment of the current decision.

*Routine decision making* occurs when decision makers use knowledge and past experience to decide quickly what to do and is especially prevalent in dynamic decision-making contexts. Routine decision making is represented in Figure 1 as a single pattern-matching step or associative leap between situation assessment and executing an action. For example, a driver, after perceiving a stop sign, decides to stop. Similarly, the user of a word-processing system, after perceiving a misspelled word, decides to activate the spell checker. Since routine decisions are often made in dynamic task environments, routine decision making is discussed in this chapter as a subtopic of dynamic decision making.

*Conflict-driven decision making* occurs when various forms of conflict must be resolved before an alternative action can be chosen and often involves a complicated path between situation assessment and executing an action.[‡] Before executing an action, the decision maker experiences conflict, somehow resolves it, and then either recognizes the best action (conflict resolution might transform the decision to a routine one) or applies a decision rule. Applying the decision rule leads ideally to a choice which is then executed. Attempting to apply the decision rule may, however, cause additional conflicts, leading to more conflict resolution. For example, decision makers may realize that they need more information to apply a particular decision rule. In response, they might decide to use a different decision rule that requires less information. Along these lines, when choosing a home, a decision maker might decide to use a satisficing decision rule after seeing that hundreds of homes are listed in the classified ads of the local newspaper.

Potential sources of conflict, methods of conflict resolution, and the results of conflict resolution are listed at the top of Figure 1. Each source of conflict maps to a particular method of conflict resolution, which then provides a result necessary to apply a decision rule, as illustrated schematically in the figure.[§]

Accordingly, conflict occurs at the most fundamental level when the current condition, alternative actions, or their consequences have not been identified. At the next most fundamental level, conflict occurs when the decision maker is unsure how to compare the alternatives. In other words, the decision maker has not yet selected a decision rule. Given that the decision maker

---

[*] The notion that the best decision strategy varies between decision contexts is a fundamental assumption of the theory of contingent decision making (Payne et al., 1993), cognitive continuum theory (Hammond, 1980), and other approaches discussed later in the chapter.

[†] Conflict has been recognized as an important determinant of what people do in risky decision-making contexts (Janis and Mann, 1977). Janis and Mann focus on the stressful nature of conflict and on how affective reactions in stressful situations can affect decision strategies.

---

[‡] The distinction between routine and conflict-driven decision making made here is similar to Rasmussen's (1983) distinction between (1) routine skill or rule-based levels of control and (2) nonroutine knowledge-based levels of control in information-processing tasks.

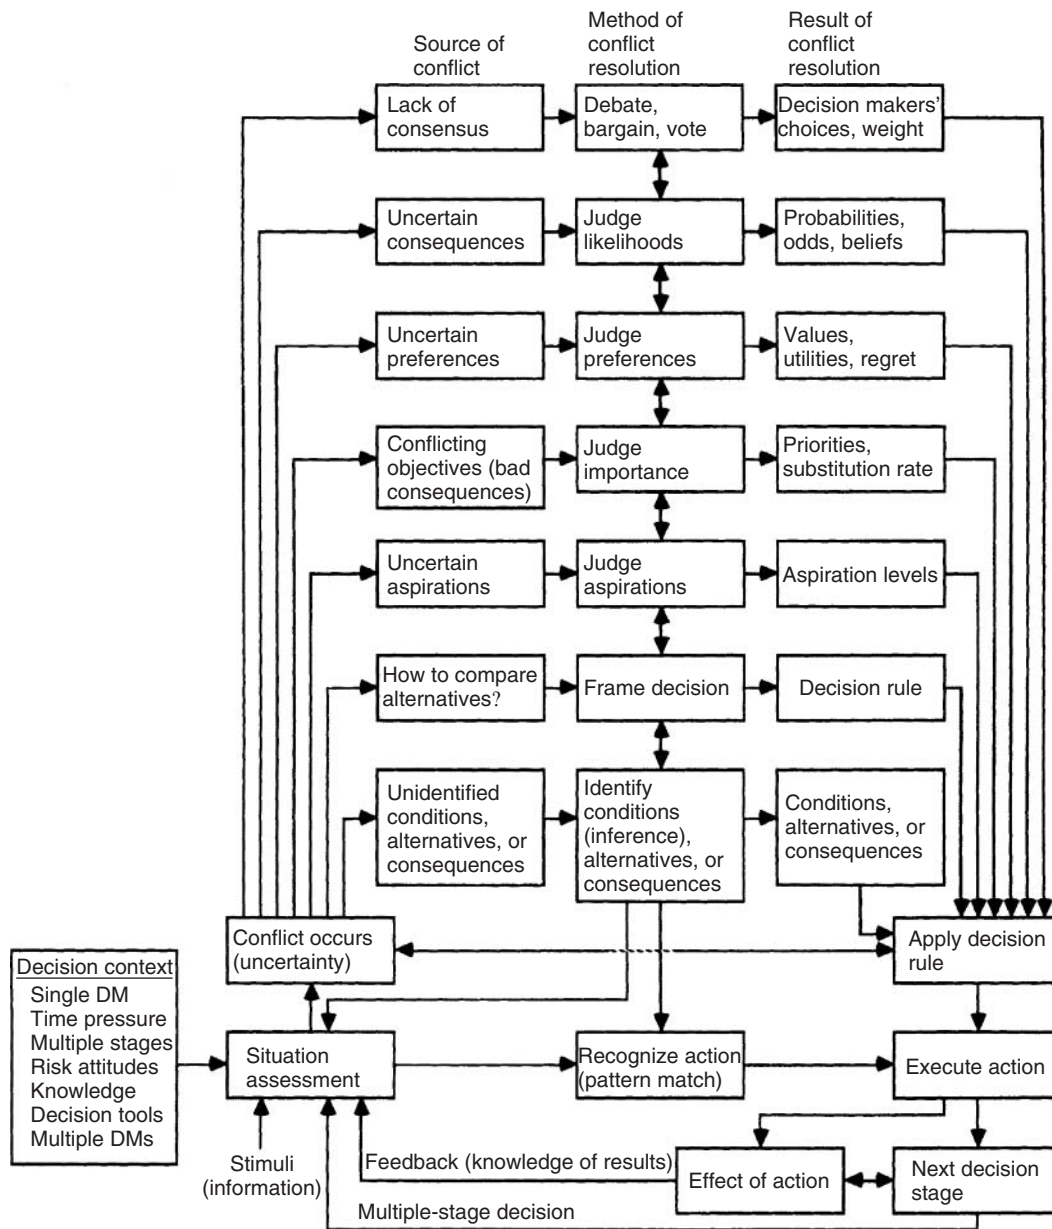
[§] Note that multiple sources of conflict are possible for a given decision context. An attempt to resolve one source of conflict may also make the decision maker aware of other conflicts that must first be resolved. For example, decision makers may realize they need to know what the alternatives are before they can determine their aspiration levels.


**Figure 1** Integrative model of human decision making (DM, decision maker).

has a decision rule, conflict can still occur if the needed inputs are not available. These sources of conflict and associated methods of conflict resolution are addressed briefly below in relation to the remainder of this chapter.

Identifying the current condition, alternative actions, and their consequences is an important part of decision making. This topic is emphasized in both naturalistic decision theory (Klein et al., 1993) and decision analysis[*] (Raiffa, 1968; Clemen, 1996). Decision trees, influence diagrams, and other tools for structuring decisions are covered in Section 4.1. In Section 2.2.1,

---

[*] Clemen (1996) includes a chapter on creativity and decision structuring. Some practitioners claim that structuring the decision is the greatest contribution of the decision analysis process.

we describe several descriptive models of human inference and discuss their limitations. Section 4.1 covers discussion group decision-making methods that may be useful at this decision-making stage.

When decision makers are unsure how to compare alternatives, they must consider what information is available and then frame a decision appropriately. The way the decision is framed then determines (1) which decision rules are appropriate, (2) what information is needed to make the decision using the rules given, and (3) the choices selected. As discussed in Section 2.2.3, there are reasons to believe that people apply different decision-making strategies in different decision contexts. We discuss the appropriateness of decision rules and how the particular rule used can affect choices. When the specific inputs needed by a decision rule are not available, the resulting conflict might be resolved by judging aspirations, importance, preference, or likelihood. It might also be resolved by choosing a different decision rule or strategy. As noted in Section 2.3, there is a prevalent tendency among decision makers in naturalistic settings to minimize analysis and the cognitive effort required. In group situations, conflict due to a lack of consensus among decision makers might be resolved through debate, bargaining, or voting (Section 3).

## 2  DECISION-MAKING MODELS

In this section, decision-making models are categorized into three types: normative (Section 2.1), behavioral (Section 2.2), and naturalistic (Section 2.3). Normative decision models date back to early application of economics and statistics to specify how to make optimal decisions (von Neumann and Morgenstern, 1947; Savage, 1954); thus, they focus heavily on the notion of rationality (Savage, 1954; von Winterfeldt and Edwards 1986). In contrast, behavioral decision models acknowledge the limitations of human decision makers: they are systematically biased and use heuristics to overcome cognitive limitations. In these models, decision makers are not rational but boundedly rational (Simon, 1955). Naturalistic decision models extend this perspective to understand how people actually make decisions and cognitively complex tasks in realistic demanding situations, which cannot be easily replicated in a laboratory setting.

## 2.1  Normative Models

Classical decision theory represents preference and choice problems in terms of four basic elements: (1) a set of potential actions ($A_i$) to choose between, (2) a set of events or world states ($E_j$), (3) a set of consequences ($C_{ij}$) obtained for each combination of action and event, and (4) a set of probabilities ($P_{ij}$) for each combination of action and event. For example, a decision maker might be deciding whether to wear a seat belt when traveling in an automobile. Wearing or not wearing a seat belt corresponds to two actions, $A_1$ and $A_2$. The expected consequence ($C_{ij}$) of either action depends on whether an accident occurs. Having or not having an accident corresponds to two events, $E_1$ and $E_2$. Wearing a seat belt reduces the expected consequences ($C_{11}$) of having an accident ($E_1$). As the probability of having an accident increases, use of a belt should therefore become more attractive.

Normative models are based on basic axioms (or what are felt to be self-evident assumptions) of rational choice. In the following discussion we first present some of the most basic axioms.

### 2.1.1  Axioms of Rational Choice

Numerous axioms have been proposed that are essential either for a particular model of choice or for the method of eliciting numbers used for a particular model (von Winterfeldt and Edwards, 1986). The best known set of axioms (Table 1) establishes the normative principle of *subjective expected utility* (SEU) as a basis for making decisions [see Savage (1954) and Luce and Raiffa (1957) for a more rigorous description of the axioms]. On an individual basis, these axioms are intuitively appealing (Stukey and Zeckhauser, 1978), but as discussed in Section 2.2.2, people's preferences can deviate significantly from the SEU model in ways that conflict with certain axioms. Consequently, there has been a movement toward developing less restrictive standards of normative decision making (Zey, 1992; Frisch and Clemen, 1994).

Frisch and Clemen (1994, p. 49) propose that "a good decision should (a) be based on the relevant consequences of the different options (*consequentialism*), (b) be based on an accurate assessment of the world

## Table 1  Basic Axioms of Subjective Expected Utility Theory

A. *Ordering/quantification of preference*. Preferences of decision makers between alternatives can be quantified and ordered using the relations:

> $>$, where $A > B$ means that $A$ is preferred to $B$

> $=$, where $A = B$ means that $A$ and $B$ are equivalent

> $\geq$, where $A \geq B$ means that $B$ is not preferred to $A$

B. *Transitivity of preference*. If $A_1 \geq A_2$ and $A_2 \geq A_3$, then $A_1 \geq A_3$.

C. *Quantification of judgment*. The relative likelihood of each possible consequence that might result from an alternative action can be specified.

D. *Comparison of alternatives*. If two alternatives yield the same consequences, the alternative yielding the greater chance of the preferred consequence is preferred.

E. *Substitution*. If $A_1 > A_2 > A_3$, the decision maker will be willing to accept a gamble [$p(A_1)$ and $(1 - p)(A_3)$] as a substitute for $A_2$ for some value of $p \geq 0$.

F. *Sure-thing principle*. If $A_1 \geq A_2$, then for all $p$, the gamble [$p(A_1)$ and $(1 - p)(A_3)$] $\geq$ [$p(A_2)$ and $(1 - p)(A_3)$].

and a consideration of all relevant consequences (*thorough structuring*), and (c) make tradeoffs of some form (*compensatory decision rule*)." Consequentialism and the need for thorough structuring are both assumed by all normative decision rules. Most normative rules are also compensatory. However, when people make routine habitual decisions, they often do not consider the consequences of their choices, as discussed in Section 2.3. In addition, because of cognitive limitations and the difficulty of obtaining information, it becomes unrealistic in many settings for the decision maker to consider all the options and possible consequences. To make decisions under such conditions, decision makers may limit the scope of the analysis by applying principles such as satisficing and other noncompensatory decision rules, which will be discussed in Section 2.2.3. They may also apply heuristics, based on their knowledge or experience, leading to performance that can approximate the results of applying compensatory decision rules (Section 2.2).

### 2.1.2 Dominance

Dominance is perhaps the most fundamental normative decision rule. *Dominance* is said to occur between two alternative actions, $A_i$ and $A_j$, when $A_i$ is at least as good as $A_j$ for all events $E$, and for at least one event $E_k$, $A_i$ is preferred to $A_j$. For example, one investment might yield a better return than another regardless of whether the stock market goes up or down. Dominance can also be described for the case where the consequences are multidimensional. This occurs when for all events $E$, the $k$th consequence associated with action $i$ ($C_{ik}$) and action $j$ ($C_{jk}$) satisfies the relation $C_{ik} \geq C_{jk}$ for all $k$ and for at least one consequence $C_{ik} > C_{jk}$. For example, a physician choosing between alternative treatments has an easy decision if one treatment is *both* cheaper and more effective for all patients.

Dominance is obviously a normative decision rule, since a dominated alternative can never be better than the alternative that dominates it. Dominance is also conceptually simple, but it can be difficult to detect when there are many alternatives to consider or many possible consequences. The use of tests for dominance by decision makers in naturalistic settings is discussed further in Section 2.3.

### 2.1.3 Maximizing Expected Value

From elementary probability theory, return is maximized by selecting the alternative with the greatest expected value. The expected value of an action $A_i$ is calculated by weighting the decision maker's preference $V(C_{ik})$ for its consequences $C_{ik}$ over all events $k$ by the probability $P_{ik}$ that the event will occur. The expected value of a given action $A_i$ is therefore

$$\text{EV}[A_i] = \sum_k P_{ik} V(C_{ik}) \qquad (1)$$

Monetary value is a common value function. For example, lives lost, units sold, or air quality might all be converted into monetary values. More generally,

however, value reflects preference, as illustrated by ordinary concepts such as the value of money or the attractiveness of a work setting. Given that the decision maker has large resources and is given repeated opportunities to make the choice, choices made on the basis of expected monetary value are intuitively justifiable. A large company might make nearly all of its decisions on the basis of expected monetary value. Insurance buying and many other rational forms of behavior cannot, however, be justified on the basis of expected monetary value. It has long been recognized that rational decision makers made choices not easily explained by expected monetary value (Bernoulli, 1738). Bernoulli cited the St. Petersburg paradox, in which the prize received in a lottery was $2^n$, $n$ being the number of times a flipped coin turned up heads before a tail was observed. The probability of $n$ flips before the first tail is observed is $0.5^n$. The expected value of this lottery becomes

$$\text{EV}[L] = \sum_k P_{ik} V(C_{ik}) = \sum_{n=0}^{\infty} 0.5^n 2^n \rightarrow \infty \qquad (2)$$

The interesting twist is that the expected value of the lottery above is infinite. Bernoulli's conclusion was that preference cannot be a linear function of monetary value since a rational decision maker would never pay more than a finite amount to play the lottery. Furthermore, the value of the lottery can vary between decision makers. According to utility theory, this variability, described in utility, reflects rational differences in preference between decision makers for uncertain consequences.

### 2.1.4 Subjective Expected Utility Theory

Expected utility theory extended expected value theory to describe better how people make uncertain economic choices (von Neumann and Morgenstern, 1947). In their approach, monetary values are first transformed into utilities using a utility function $u(x)$. The utilities of each outcome are then weighted by their probability of occurrence to obtain an expected utility. The SEU theory added the notion that uncertainty about outcomes could be represented with subjective probabilities (Savage, 1954). It was postulated that these subjective estimates could be combined with evidence using Bayes' rule to infer the probabilities of outcomes.[*] This group of assumptions corresponds to the Bayesian approach to statistics. Following this approach, the SEU of an alternative $A_i$, given subjective probabilities $S_{ik}$ and consequences $C_{ik}$ over events $E_k$, becomes

$$\text{SEU}[A_i] = \sum_k S_{ik} U(C_{ik}) \qquad (3)$$

Note the similarity between formulation (3) for SEU and equation (1) for expected value. The EV and SEU

---

[*] When no evidence is available concerning the likelihood of different events, it was postulated that each consequence should be assumed to be equally likely. The Laplace decision rule makes this assumption and then compares alternatives on the basis of expected value or utility.

are equivalent if the value function equals the utility function. Methods for eliciting value and utility functions differ in nature (Section 4.1). Preferences elicited for uncertain outcomes measure utility.[*] Preferences elicited for certain outcomes measure value. It has, accordingly, often been assumed that value functions differ from utility functions, but there are reasons to treat value and utility functions as equivalent (von Winterfeldt and Edwards, 1986). The latter authors claim that the differences between elicited value and utility functions are small and that "severe limitations constrain those relationships, and only a few possibilities exist, one of which is that they are the same."

When people are presented with choices that have uncertain outcomes, they react in different ways. In some situations, people find gambling to be pleasurable. In others, people will pay money to reduce uncertainty: for example, when people buy insurance. SEU theory distinguishes between risk-neutral, risk-averse, risk-seeking, and mixed forms of behavior. These different types of behavior are described by the shape of the utility function (Figure 2).

A risk-neutral decision maker will find the expected utility of a gamble to be the same as the utility of the gamble's expected value. That is, expected $u(\text{gamble}) = u(\text{gamble's expected value})$. For a risk-averse decision maker, expected $u(\text{gamble}) < u(\text{gamble's expected value})$; for a risk-seeking decision maker, expected $u(\text{gamble}) > u(\text{gamble's expected value})$. On any given point of a utility function, attitudes toward risk are described formally by the coefficient of risk aversion:

$$C_{\text{RA}} = \frac{u''(x)}{u'(x)} \qquad (4)$$

where $u'(x)$ and $u''(x)$ are, respectively, the first and second derivatives of $u(x)$ taken with respect to $x$. Note that when $u(x)$ is a linear function of $x$ [i.e., $u(x) = ax + b$], then $C_{\text{RA}} = 0$. For any point of the utility function, if $C_{\text{RA}} < 0$, the utility function depicts risk-averse behavior, and if $C_{\text{RA}} > 0$, the utility function depicts risk-seeking behavior. The coefficient of risk aversion therefore describes attitudes toward risk at each point of the utility function given that the utility function is continuous. SEU theory consequently provides a powerful tool for describing how people might react to uncertain or risky outcomes. However, some commonly observed preferences between risky alternatives cannot be explained by SEU. Section 2.2.2 focuses on experimental findings showing deviations from the predictions of SEU.

A major contribution of SEU is that it represents differing attitudes toward risk and provides a normative model of decision making under uncertainty. The prescriptions of SEU are also clear and testable. Consequently, SEU has played a major role in fields other than economics, both as a tool for improving human decision making and as a stepping stone for developing models

**Figure 2**  Utility functions for differing risk attitudes.

that describe how people make decisions when outcomes are uncertain. As discussed further in Section 2.2, much of this work has been done in psychology.

### 2.1.5  Multiattribute Utility Theory

Multiattribute utility theory (MAUT) (Keeney and Raiffa, 1976) extends SEU to the case where the decision maker has multiple objectives. The approach is equally applicable for describing utility and value functions. Following this approach, the utility (or value) of an alternative $A$, with multiple attributes $x$, is described with the multiattribute utility (or value) function $u(x_1, \ldots, x_n)$, where $u(x_1, \ldots, x_n)$ is some function $f(x_1, \ldots, x_n)$ of the attributes $x$. In the simplest case, MAUT describes the utility of an alternative as an additive function of the single-attribute utility functions $u_n(x_n)$. That is,

$$u(x_1, \ldots, x_n) = \sum_{i=1}^{n} k_i u_i(x_i) \qquad (5)$$

where the constants $k_n$ are used to weight each single-attribute utility function ($u_n$) in terms of its importance.[†] Assuming that an alternative has three attributes, $x$, $y$, and $z$, an additive utility function is $u(x, y, z) = k_x u_x(x) + k_y u_y(y) + k_z u_z(z)$. Along these lines, a community considering building a bridge across a river versus building a tunnel or continuing to use the existing ferry system might consider the attractiveness of each option in terms of the attributes of economic benefits, social benefits, and environmental benefits.

More complex multiattribute utility functions include multiplicative forms and functions that combine utility functions for subsets of two or more attributes (Keeney and Raiffa, 1976). An example of a simple multiplicative function would be $u(x, y) = u_x(x) u_y(y)$. A function

---

[*] Note that classical utility theory assumes that utilities are constant. Utilities may, of course, fluctuate. The random-utility model (Bock and Jones, 1968) allows such fluctuation.

[†] To develop the multiattribute utility function, the single-attribute utility functions ($u_n$) and the importance weights ($k_n$) are determined by assessing preferences between alternatives. Methods of doing so are discussed in Section 4.1.3.

that combines utility functions for subsets would be $u(x, y, z) = k_{xy} u_{xy}(x, y) + k_z u_z(z)$. The latter type of function becomes useful when utility independence is violated.

Utility independence is violated when the utility function for one attribute depends on the value of another attribute. Along these lines, when assessing $u_{xy}(x, y)$, it might be found that $u_x(x)$ depends on the value of $y$. For example, people's reaction to the level of crime in their own neighborhood might depend on the level of crime in a nearby suburb. In the latter case, it is probably better to measure $u_{xy}$ ($x$ is crime in one's own neighborhood and $y$ is crime in a nearby suburb) directly than to estimate it from the single-attribute functions. Assessment of utility and value functions is discussed in Section 4.1.

MAUT has been applied to a wide variety of problems (Clemen, 1996; Keeney and Raiffa, 1976; Saaty, 1990; Wallenius et al., 2008; von Winterfeldt and Edwards, 1986). An advantage of MAUT is that it helps structure complex decisions in a meaningful way. Alternative choices and their attributes often naturally divide into hierarchies. The MAUT approach encourages such divide-and-conquer strategies and, especially in its additive form, provides a straightforward means of recombining weights into a final ranking of alternatives. The MAUT approach is also a compensatory strategy that allows normative trade-offs between attributes in terms of their importance.

## 2.2 Behavioral Decision Models

As a normative ideal, classical decision theory has influenced the study of decision making in a major way. Much of the earlier work in behavioral decision theory compared human behavior to the prescriptions of classical decision theory (Edwards, 1954; Slovic et al., 1977; Einhorn and Hogarth, 1981). Numerous departures were found, including the influential finding that people use heuristics during judgment tasks (Tversky and Kahneman, 1974). On the basis of such research, psychologists have concluded that other approaches are needed to describe the process of human decision making. Descriptive models that relax assumptions of the normative models but retain much of their essence are now being evaluated in the field of judgment and decision theory (Stevenson et al., 1993). One of most exciting developments is that fast and frugal heuristics can perform very well even when compared to sophisticated optimization model (Gigerenzer, 2008).

The following discussion summarizes findings from this broad body of literature. The discussion begins by considering research on statistical estimation and inference. Attention then shifts to the topic of decision making under uncertainty and risk.

### 2.2.1 Statistical Estimation and Inference

The ability of people to perceive, learn, and draw inferences accurately from uncertain sources of information has been a topic of much research. In the following discussion we first consider briefly human abilities and limitations on such tasks. Attention then shifts to several heuristics that people may use to cope with their limitations and how their use can cause certain biases. In the next section, we then consider briefly the role of memory and selective processing of information from a similar perspective. Attention then shifts to mathematical models of human judgment that provide insight into how people judge probabilities, the biases that might occur, and how people learn to perform probability judgment tasks. In the final section, we summarize findings on debiasing human judgments.

***Human Abilities and Limitations*** Research conducted in the early 1960s tested the notion that people behave as "intuitive statisticians" who gather evidence and apply it in accordance with the Bayesian model of inference (Peterson and Beach, 1967). Much of the earlier work focused on how good people are at estimating statistical parameters such as means, variances, and proportions. Other studies have compared human inferences obtained from probabilistic evidence to the prescriptions of Bayes' rule.

A number of interesting results were obtained (Table 2). The research first shows that people can be fairly good at estimating means, variances, or proportions from sample data. Sedlmeier et al. (1998) point out that "there seems to be broad agreement with" (p. 754) the conclusion of Jonides and Jones (1992) that people can give answers that reflect the actual relative frequencies of many kinds of events with great fidelity. However, as discussed by von Winterfeldt and Edwards (1986), like other psychophysical measures, subjective probability estimates are noisy. Their accuracy will depend on how carefully they are elicited and on many other factors. Studies have shown that people are especially likely to have trouble estimating accurately the probability of unlikely events, such as nuclear plant explosions. For example, when people were asked to estimate the risk associated with the use of consumer products (Dorris and Tabrizi, 1978; Rethans, 1980) or various technologies (Lichtenstein et al., 1978), the estimates obtained were often weakly related to accident data. Weather forecasters are one of the few groups of people that have been documented as being able to estimate high and low probabilities accurately (Winkler and Murphy, 1973).

Part of the issue is that when events occur rarely, people will not be able to base their judgments on a representative sample of their own observations. Most of the information they receive about unlikely events will come from secondary sources, such as media reports, rather than from their own experience. This tendency might explain why risk estimates are often related more strongly to factors other than likelihood, such as catastrophic potential or familiarity (Lichtenstein et al., 1978; Slovic 1978, 1987; Lehto et al., 1994). Media reporting focuses on "newsworthy" events, which tend to be more catastrophic and unfamiliar. Consequently, judgments based on media reports might reflect the latter factors instead of likelihood. Weber (1994) provides additional evidence that subjective probabilities are related to factors other than likelihood and argues that people will overestimate the chance of a highly

positive outcome because of their desire to obtain it. Weber also argues that people will overestimate the chance of a highly undesirable outcome because of their fear of receiving it. Traditional methods of decision analysis separately elicit and then recombine subjective probabilities with utilities, as discussed earlier, and assume that subjective probabilities are independent of consequences. A finding of dependency therefore casts serious doubt on the normative validity of this commonly accepted approach.

When studies of human inference are considered, several other trends become apparent (Table 2). In particular, several significant deviations from the Bayesian model have been found:

1. Decision makers tend to be conservative in that they do not give as much weight to probabilistic evidence as does Bayes' rule (Edwards, 1968).

2. Decision makers do not consider base rates or prior probabilities adequately (Tversky and Kahneman, 1974).

3. Decision makers tend to ignore the reliability of the evidence (Tversky and Kahneman, 1974).

4. Decision makers tend to overestimate the probability of conjunctive events and underestimate the probability of disjunctive events (Bar-Hillel, 1973).

5. Decision makers tend to seek out confirming evidence rather than disconfirming evidence and place more emphasis on confirming evidence when it is available (Einhorn and Hogarth, 1978; Baron, 1985). The order in which the evidence is presented has an influence on human judgments (Hogarth and Einhorn, 1992).

6. Decision makers are overconfident in their predictions (Fischhoff et al. 1977), especially in hindsight (Fischhoff, 1982; Christensen-Szalanski and Willham, 1991).

7. Decision makers show a tendency to infer illusionary causal relations (Tversky and Kahneman, 1973).

A lively literature has developed regarding these deviations and their significance* (Evans, 1989; Caverni et al., 1990; Wickens, 1992; Klein et al., 1993; Doherty, 2003). From one perspective, these deviations demonstrate inadequacies of human reason and are a source of societal problems (Baron, 1998; and many others). From the opposite perspective, it has been held that the foregoing findings are more or less experimental artifacts that do not reflect the true complexity of the world (Cohen, 1993). A compelling argument for the latter point of view is given by Simon (1955, 1983). From this perspective, people do not use Bayes' rule to compute probabilities in their natural environments because it makes unrealistic assumptions about what is known or knowable. Simply put, the limitations of the human mind and time constraints make it nearly impossible for people to use principles such as Bayes' rule to make inferences in their natural environments. To compensate for their limitations, people use simple heuristics or decision rules that are adapted to particular environments. The use of such strategies does not mean that people will not be able to make accurate inferences, as emphasized by both Simon and researchers embracing the ecologica† (i.e., Hammond, 1996; Gigerenzer et al., 1999) and naturalistic (i.e., Klein et al., 1993) models of decision making. In fact, as discussed further in this section, the use of simple heuristics in rich environments can lead to inferences that are in many cases

more accurate than those made using Naïve Bayes, or linear regression (Gigerenzer et al., 1999).

There is an emerging body of literature that shows, on the one hand, that deviations from Bayes' rule can in fact be justified in certain cases from a normative view and, on the other hand, that these deviations may disappear when people are provided with richer information or problems in more natural contexts. For example, drivers performing a simulated passing task combined their own observations of the driving environment with imperfect information provided by a collision-warning system, as predicted by a distributed signal detection theoretic model of optimal team decision making (Lehto et al., 2000). Other researchers have pointed out that:

1. A tendency toward conservatism can be justified when evidence is not conditionally independent (Navon, 1979).

2. Subjects do use base-rate information and consider the reliability of evidence in slightly modified experimental settings (Birnbaum and Mellers, 1983; Koehler, 1996). In particular, providing natural frequencies instead of probabilities to subjects can improve performance greatly (Gigerenzer and Hoffrage, 1995; Krauss et al., 1999).

3. A tendency to seek out confirming evidence can offer practical advantages (Cohen, 1993) and may reflect cognitive failures, due to a lack of understanding of how to falsify hypotheses, rather than an entirely motivational basis (Klayman and Ha, 1987; Evans, 1989).

4. Subjects prefer stating subjective probabilities with vague verbal expressions rather than precise numerical values (Wallsten et al., 1993), demonstrating that they are not necessarily overconfident in their predictions.

5. There is evidence that the hindsight bias can be moderated by familiarity with both the task and the type of outcome information provided (Christensen-Szalanski and Willham, 1991).

Based on such results, numerous researchers have questioned the practical relevance of the large literature showing different types of biases. One reason that this literature may be misleading is that researchers overreport findings of bias (Evans, 1989; Cohen, 1993). A more significant concern is that studies showing bias are almost always conducted in artificial settings where people are provided information about an unfamiliar topic. Furthermore, the information is often given in a form that forces use of Bayes' rule or other form of abstract reasoning to get the correct answer. For example, consider the simple case where a person is asked to predict how likely it is that a woman has breast cancer given a positive mammogram (Martignon and Krauss, 2003). In the typical study looking for bias, the subject might be told to assume (1) the probability that a 40-year-old woman has breast cancer is 1%, (2) the probability of a positive mammogram given that a woman has cancer is 0.9, and (3) the probability of a positive mammogram given that a woman does not

---

* Doherty (2003) groups researchers on human judgment and decision making into two camps. The optimists focus on the success of imperfect human beings in a complex world. The pessimists focus on the deficiencies of human reasoning compared to normative models.

† As noted by Gigerenzer et al. (1999, p. 18), because of environmental challenges, "organisms must be able to make inferences that are fast, frugal, and accurate." Similarly, Hammond (1996) notes that a close correspondence between subjective beliefs and environmental states will provide an adaptive advantage.

have cancer is 0.1. Although the correct answer can be easily calculated using Bayes' rule, it is not at all surprising that people unfamiliar with probability theory have difficulty determining it. In the real world, it seems much more likely that a person would simply keep track of how many women receiving a mammogram actually had breast cancer. The probability that a woman has breast cancer, given a positive mammogram, is then determined by dividing the number of women receiving a mammogram who actually had breast cancer by the number of women receiving a mammogram. The latter calculation gives exactly the same answer as using Bayes' rule and is much easier to do.

The implications of the example above are obvious: First, people can duplicate the predictions of the Bayes rule by keeping track of the right relative frequencies. Second, if the right relative frequencies are known, accurate inferences can be made using very simple decision rules. Third, people will have trouble making accurate inferences if they do not know the right relative frequencies. Recent studies and reevaluations of older studies provide additional perspective. The finding that subjects are much better at integrating information when they are provided data in the form of natural frequencies instead of probabilities (Gigerenzer and Hoffrage, 1995; Krauss et al., 1999) is particularly interesting.

One conclusion that might be drawn from the latter work is that people are Bayesians after all if they are provided adequate information in appropriate representations (Martignon and Krauss, 2003). Other support for the proposition that people are not as bad at inference as it once seemed includes Dawes and Mulford's (1996) review of the literature supporting the overconfidence effect or bias, in which they conclude that the methods used to measure this effect are logically flawed and that the empirical support is inadequate to conclude that it really exists. Part of the issue is that much of the psychological research on the overconfidence effect "overrepresents those situations where cue-based inferences fail" (Juslin and Olsson, 1999). When people rate objects that are selected randomly from a natural environment, overconfidence is reduced. Koehler (1996) provides a similarly compelling reexamination of the base-rate fallacy. He concludes that the literature does not support the conventional wisdom that people routinely ignore base rates. To the contrary, he states that base rates are almost always used and that their degree of use depends on task structure and representation as well as their reliability compared to other sources of information.

Because such conflicting results can be obtained, depending on the setting in which human decision making is observed, researchers embracing the ecological (i.e., Hammond, 1996; Gigerenzer et al., 1999) and naturalistic (Klein et al., 1993; Klein, 1998) models of decision making strongly emphasize the need to conduct ecologically valid research in rich realistic decision environments.

***Heuristics and Biases*** Tversky and Kahneman (1973, 1974) made a key contribution to the field when they showed that many of the above-mentioned discrepancies between human estimates of probability and Bayes' rule could be explained by the use of three heuristics. The three heuristics they proposed were those of representativeness, availability, and anchoring and adjustment.

The *representativeness* heuristic holds that the probability of an item A belonging to some category B is judged by considering how representative A is of B. For example, a person is typically judged more likely to be a librarian than a farmer when described as "a meek and tidy soul who has a desire for order and structure and a passion for detail." Applications of this heuristic will often lead to good probability estimates but can lead to systematic biases. Tversky and Kahneman (1974) give several examples of such biases. In each case, representativeness influenced estimates more than other, more statistically oriented information. In the first study, subjects ignored base-rate information (given by the experimenter) about how likely a person was to be either a lawyer or an engineer. Their judgments seemed to be based entirely on how representative the description seemed to be of either occupation. Tversky and Kahneman (1973) found people overestimated conjunctive probabilities in a similar experiment. Here, after being told that "Linda is 31 years old, single, outspoken, and very bright," most subjects said it was more likely she was both a bank teller and active as a feminist than simply a bank teller. In a third study, most subjects felt that the probability of more than 60% male births on a given day was about the same for both large and small hospitals (Tversky and Kahneman, 1974). Apparently, the subjects felt that large and small hospitals were equally representative of the population.

Other behaviors explained in terms of representativeness by Tversky and Kahneman (1974) included gambler's fallacy, insensitivity to predictability, illusions of validity, and misconceptions of statistical regression to the mean. With regard to gambler's fallacy, they note that people may feel that long sequences of heads or tails when flipping coins are unrepresentative of normal behavior. After a sequence of heads, a tail therefore seems more representative. Insensitivity to predictability refers to a tendency for people to predict future performance without considering the reliability of the information on which they base the prediction. For example, a person might expect an investment to be profitable solely on the basis of a favorable description without considering whether the description has any predictive value. In other words, a good description is believed to be representative of high profits, even if it states nothing about profitability. The illusion of validity occurs when people use highly correlated evidence to make a conclusion. Despite the fact that the evidence is redundant, the presence of many representative pieces of evidence increases confidence greatly. Misconception of regression to the mean occurs when people react to unusual events and then infer a causal linkage when the process returns to normality on its own. For example, a manager might incorrectly conclude that punishment works after seeing that unusually poor performance improves to normal levels following punishment. The same manager might also conclude that rewards do not work

after seeing that unusually good performance drops after receiving a reward.

The *availability* heuristic holds that the probability of an event is determined by how easy it is to remember the event happening. Tversky and Kahneman state that perceived probabilities will therefore depend on familiarity, salience, effectiveness of memory search, and imaginability. The implication is that people will judge events as more likely when the events are familiar, highly salient (such as an airplane crash), or easily imaginable. Events will also be judged more likely if there is a simple way to search memory. For example, it is much easier to search for words in memory by the first letter rather than by the third letter. It is easy to see how each item above affecting the availability of information can influence judgments. Biases should increase when people lack experience or when their experiences are too focused.

The *anchoring-and-adjustment* heuristic holds that people start from an initial estimate and then adjust it to reach a final value. The point chosen initially has a major impact on the final value selected when adjustments are insufficient. Tversky and Kahneman (1974) refer to this source of bias as an anchoring effect. They show how this effect can explain under- and overestimates of disjunctive and conjunctive events. This happens if the subject starts with a probability estimate of a single event. The probability of a single event is, of course, less than that for the disjunctive event and greater than that for the conjunctive event. If adjustment is too small, under- and overestimates occur, respectively, for the disjunctive and conjunctive events. Tversky and Kahneman also discuss how anchoring and adjustment may cause biases in subjective probability distributions.

The notion of heuristics and biases has had a particularly formative influence on decision theory. A substantial recent body of work has emerged that focuses on applying research on heuristics and biases (Kahneman et al., 1982; Heath et al., 1994). Applications include medical judgment and decision making, affirmative action, education, personality assessment, legal decision making, mediation, and policy making. It seems clear that this approach is excellent for describing many general aspects of decision making in the real world. However, research on heuristics and biases has been criticized as being pretheoretical (Slovic et al., 1977) and, as pointed out earlier, has contributed to overselling of the view that people are biased. The latter point is interesting, as Tversky and Kahneman (1973) have claimed all along that using these heuristics can lead to good results. However, nearly all the research conducted in this framework has focused on when they might go wrong.

### Memory Effects and Selective Processing of Information

The heuristics-and-biases framework has been criticized by many researchers for its failure to adequately address more fundamental cognitive processes that might explain biases (Dougherty et al., 2003). This follows because the availability and representativeness heuristics can both be described in terms of more fundamental memory processes. For example, the availability heuristic proposes that the probability of

an event is determined by how easy it is to remember the event happening. Ease of recall, however, depends on many things, such as what is stored in memory, how it is represented, how well it is encoded, and how well a cue item matches the memory representation.

Dougherty et al. (2003) note that three aspects of memory can explain many of the findings on human judgment: (1) how information is stored or represented, (2) how information is retrieved, and (3) experience and domain knowledge. The first aspect pertains to what is actually stored when people experience events. The simplest models assume that people store a record of each instance of an experienced event and, in some cases, additional information such as the frequency of the event (Hasher and Zacks, 1984) or ecological cue validities (Brehmer and Joyce, 1988). More complex models assume that people store an abstract representation or summary of the event (Pennington and Hastie, 1988), in some cases at multiple levels of abstraction (Reyna and Brainerd, 1995). The way information is stored or represented can explain several of the observed findings on human judgment.

First, there is strong evidence that people are often excellent at storing frequency information[*] and the process by which this is done is fairly automatic (Hasher and Zacks, 1984; Gigerenzer et al., 1991). Gigerenzer et al. conclude that with repeated experience people should also be able to store ecological cue validities. The accuracy of these stored representations would, of course, depend on how large and representative the sample of encoded observations is. Such effects can be modeled with simple adding models that might include the effects of forgetting (or memory trace degradation) or other factors, such as selective sampling or the amount of attention devoted to the information at the time it is received. As pointed out by Dougherty et al. (2003) and many others, many of the biases in human judgment follow directly from considering how well the events are encoded in memory. In particular, except for certain sensory qualities which are encoded automatically, encoding quality is assumed to depend on attention. Consequently, some biases should reflect the tendency of highly salient stimuli to capture attention. Another completely different type of bias might reflect the fact that the person was exposed to an unrepresentative sample of events. Lumping these two very different biases together, as is done by the availability heuristic, is obviously debatable.

Other aspects of human memory mentioned by Dougherty et al. (2003) that can explain certain findings on human judgment include the level of abstraction of the stored representation and retrieval methods. One interesting observation is that people often find it preferable to reason with gist-based representations rather than verbatim descriptions of events (Reyna and Brainerd, 1995). When the gist does not contain adequate detail, the reasoning may lead to flawed conclusions. Some of the differences observed between highly skilled experts and novices might correspond to situations where

---

[*] This point directly confirms Tversky and Kahneman's (1973) original assumption that the availability heuristic should often result in good predictions.

experts have stored a large number of relevant instances and their solutions in memory, whereas novices have only gist-based representations. In such situations, novices will be forced to reason using the information provided. Experts, on the other hand, might be able to solve the problem with little or no reasoning, simply by retrieving the solution from memory. The latter situation would correspond to Klein's (1989, 1998) recognition-primed decision making. However, there is also reason to believe that people are more likely to develop abstract gist-type representations of events with experience (Reyna and Brainerd, 1995). This might explain the findings in some studies that people with less knowledge and experience sometimes outperform experts. A particularly interesting demonstration is given by Gigerenzer et al. (1999), who discuss a study where a simple recognition heuristic based on the collective recognition of the names of companies by 180 German laypeople resulted in a phenomenally high yield of 47% and outperformed the Dax 30 market index by 10%. It outperformed several mutual funds managed by professionals by an even greater margin.

Memory models and processes can also be used to explain primacy and recency effects in human judgment (Hogarth and Einhorn, 1992). Such effects seem similar to the well-known serial position effect.[*] Given that human judgment involves retrieval of information from memory, it seems reasonable that judgments would also show primacy and recency effects. Several mathematical models have been developed that show how the order in which evidence is presented to people might affect their judgments. For example, Hogarth and Einhorn (1992) present an anchoring and adjustment model of how people update beliefs that predicts both primacy and recency effects. The latter model holds that the degree of belief in a hypothesis after collecting $k$ pieces of evidence can be described as

$$S_k = S_{k-1} + w_k[s(x_k) - R] \tag{6}$$

where $S_k$ is the degree of belief after collecting $k$ pieces of evidence, $S_{k-1}$ is the anchor or prior belief, $w_k$ is the adjustment weight for the $k$th piece of evidence, $s(x_k)$ is the subjective evaluation of the $k$th piece of evidence, and $R$ is the reference point against which the $k$th piece of evidence is compared. In evaluation tasks, $R = 0$. This corresponds to the case where evidence is either for or against a hypothesis.[†] For estimation tasks, $R \neq 0$. The different values of $R$ result in an additive model for evaluation tasks and an averaging model for estimation tasks. Also, if the quantity $s(x_k) - R$ is evaluated for several pieces of evidence at a time, the model predicts primacy effects. If single pieces of

evidence are evaluated individually in a step-by-step sequence, recency effects become more likely.

Biases in human judgment, which in some but not all cases are memory related, can also be explained by models of how information is processed during task performance. Along these lines, Evans (1989) argues that factors which cause people to process information in a selective manner or attend to irrelevant information are the major cause of biases in human judgment. Evans's model of selective processing of information is consistent with other explanations of biases. Among such explanations, information overload has been cited as a reason for impaired decision making by consumers (Jacoby, 1977). The tendency of highly salient stimuli to capture attention during inference tasks has also been noted by several researchers (Nisbett and Ross, 1980; Payne, 1980). Nisbett and Ross suggest that vividness of information is determined by its emotional content, concreteness and imagability, and temporal and spatial proximity. As noted by Evans and many others, these factors have also been shown to affect the memorability of information. The conclusion is that biases due to salience can occur in at least two different ways: (1) People might focus on salient but irrelevant items while performing the task and (2) people might draw incorrect inferences when the contents of memory are biased due to salience effects during earlier task performance.

### Debiasing or Aiding Human Judgments

The notion that many biases (or deviations from normative models) in statistical estimation and inference can be explained has led researchers to consider the possibility of *debiasing* (a better term might be *improving*) human judgments (Keren, 1990). Part of the issue is that the heuristics people use often work very well. The nature of the heuristics also suggests some obvious generic strategies for improving decision making. One conclusion that follows directly from the earlier discussion is that biases related to the availability and representativeness heuristics might be reduced if people were provided better, more representative samples of information. Other strategies that follow directly from the earlier discussion include making ecologically valid cues more salient, providing both outcome and cognitive feedback, and helping people do analysis. These strategies can be implemented in training programs or guide the development of decision aids.[‡]

Emerging results from the field of naturalistic decision making support the conclusion that decision-making skills can be improved through training (Fallesen and Pounds, 2001; Pliske et al., 2001; Pliske and Klein, 2003). The use of computer-based training to develop task-specific decision-making skills is one very

---

[*] When people are asked to memorize lists of information, they almost always are able to remember items at the beginning or end of a list better than items in the middle of the list (Ebbinghaus, 1913). The improved ability for words at the start of the list is called the *primacy effect*. The improved ability for words at the end of the list is called the *recency effect*.

[†] It is easy to see that equation (6) approximates the log-odds form of Bayes' rule, where evidence for or against the hypothesis is combined additively.

[‡] These strategies seem to be especially applicable to the design of information displays and decision support systems. Chapter 42 addresses the issue of display design. Computer-based decision support is addressed in Section 4.2. These strategies also overlap with decision analysis. As discussed in Section 4.1, decision analysis focuses on the use of analytic methods to improve decision quality.

interesting development (Sniezek et al., 2002). Decision-making games (Pliske et al., 2001) and cognitive simulation (Satish and Streufert, 2002) are other approaches that have been applied successfully to improve decision-making skills. Other research shows that training in statistics reduces biases in judgment (Fong et al., 1986). In the latter study, people were significantly more likely to consider sample size after training.

These results supplement some of the findings discussed earlier, indicating that judgment biases can be moderated by familiarity with the task and the type of outcome information provided. Some of these results discussed earlier included evidence that providing feedback on the accuracy of weather forecasts may help weather forecasters (Winkler and Murphy, 1973), and research showing that cognitive feedback about cues and their relationship to the effects inferred leads to quicker learning than does feedback about outcomes (Balzer et al., 1989). Other studies have shown that simply asking people to write down reasons for and against their estimates of probabilities can improve calibration and reduce overconfidence (Koriat et al., 1980). This, of course, supports the conclusion that judgments will be less likely to be biased if people think carefully about their answers. Other research showed that subjects were less likely to be overconfident if they expressed subjective probabilities verbally instead of numerically (Zimmer, 1983; Wallsten et al., 1993). Conservatism, or the failure to modify probabilities adequately after obtaining evidence, was also reduced in Zimmer's study.

The results above support the conclusion that it might be possible to improve or aid human judgment. On the other hand, many biases, such as optimistic beliefs regarding health risks, have been difficult to modify (Weinstein and Klein, 1995). People show a tendency to seek out information that supports their personal views (Weinstein, 1979) and are quite resistant to information that contradicts strongly held beliefs (McGuire, 1966; Nisbett and Ross, 1980). Evans (1989) concludes that "pre-conceived notions are likely to prejudice the construction and evaluation of arguments." Other evidence shows that experts may have difficulty providing accurate estimates of subjective probabilities even when they receive feedback. For example, many efforts to reduce both overconfidence in probability estimates and the hindsight bias have been unsuccessful (Fischhoff, 1982). One problem is that people may not pay attention to feedback (Fischhoff and MacGregor, 1982). They also may attend only to feedback that supports their hypothesis, leading to poorer performance and at the same time greater confidence (Einhorn and Hogarth, 1978). Several efforts to reduce confirmation biases, the tendency to search for confirming rather than disconfirming evidence, through training have also been unsuccessful (Evans, 1989).[*]

---

[*] Engineers, designers, and other real-world decision makers will find it very debatable whether the confirmation bias is really a bias. Searching for disconfirming evidence obviously makes sense in hypothesis testing. That is, a single negative instance is enough to disprove a logical conjecture. In real-world settings, however, checking for evidence that supports a hypothesis can be very efficient.

The conclusion is that debiasing human judgments is difficult but not impossible. Some perspective can be obtained by considering that most studies showing biases have focused on statistical inference and generally involved people not particularly knowledgeable about statistics, who are not using decision aids such as computers or calculators. It naturally may be expected that people will perform poorly on such tasks, given their lack of training and forced reliance on mental calculations (von Winterfeldt and Edwards, 1986). The finding that people can improve their abilities on such tasks after training in statistics is particularly telling and also encouraging. Another encouraging finding is that biases are occasionally reduced when people process information verbally instead of numerically. This result might be expected given that most people are more comfortable with words than with numbers.

### 2.2.2 Preference and Choice

Much of the research on human preference and choice has focused on comparing observed preferences to the predictions of SEU theory (Goldstein and Hogarth, 1997). Early work examining SEU as a descriptive theory drew generally positive conclusions. However, it soon became apparent that people's preferences for risky or uncertain alternatives often violated basic axioms of SEU theory. The finding that people's preferences change when the outcomes are framed in terms of costs, as opposed to benefits, has been particularly influential. Several other common deviations from SEU have been observed. One potentially serious deviation is that preferences can be influenced by sunk costs or prior commitment to a particular alternative. Preferences change over time and may depend on which alternatives are being compared or even the order in which they are compared. The regret associated with making the "wrong" choice seems to play a major role when people compare alternatives. Accordingly, the satisfaction people derive from obtaining particular outcomes after making a decision is influenced by positive and negative expectations prior to making the decision. Other research on human preference and choice has shown that people choose between and apply different decision strategies depending on the cognitive effort required to apply a decision strategy successfully, the needed level of accuracy, and time pressure. Certain strategies are more likely than others to lead to choices consistent with those prescribed by SEU theory.

Alternative models, such as prospect theory and random-utility theory, were consequently developed to explain human preferences under risk or uncertainty.[†] The following discussion will first summarize some common violations of the axioms underlying SEU theory before moving on to framing effects and preference reversals. Attention will then shift to models of choice and preference. The latter discussion will begin with prospect theory before addressing other models of labile

---

[†] Singleton and Hovden (1987) and Yates (1992) are useful sources for the reader interested in additional details on risk perception, risk acceptability, and risk taking behavior. Section 2.3 is also relevant to this topic.

or conditional preferences. Decision-making strategies, and how people choose between them, are covered in Section 4.3.

***Violation of the Rationality Axioms*** Several studies have shown that people's preferences between uncertain alternatives can be inconsistent with the axioms underlying SEU theory. One fundamental violation of the assumptions is that preferences can be intransitive (Tversky, 1969; Budescu and Weiss, 1987). Also, as mentioned earlier, subjective probabilities may depend on the values of consequences (violating the independence axiom), and as discussed in the next section, the framing of a choice can affect preference. Another violation is given by the *Myers effect* (Myers et al., 1965), where preference reversals between high- (H) and low- (L) variance gambles can occur when the gambles are compared to a certain outcome, depending on whether the certain outcome is positive (H preferred to L) or negative (L preferred to H). The latter effect violates the assumption of independence because the ordering of the two gambles depends on the certain outcome.

Another commonly cited violation of SEU theory is that people show a tendency toward uncertainty avoidance, which can lead to behavior inconsistent with the "sure-thing" axiom. The Ellsberg and Allais paradoxes (Allais, 1953; Ellsberg, 1961) both involve violations of the sure-thing axiom (see Table 1) and seem to be caused by people's desire to avoid uncertainty. The *Allais paradox* is illustrated by the following set of gambles. In the first gamble, a person is asked to choose between gambles $A_1$ and $B_1$, where:

Gamble $A_1$ results in \$1 million for sure. Gamble $B_1$ results in \$2.5 million with a probability of 0.1, \$1 million with a probability of 0.89, and \$0 with a probability of 0.01.

In the second gamble, the person is asked to choose between gambles $A_2$ and $B_2$, where:

$A_2$ results in \$1 million with a probability of 0.11 and \$0 with a probability of 0.89. Gamble $B_2$ results in \$2.5 million with a probability of 0.1 and \$0 with a probability of 0.9.

Most people prefer gamble $A_1$ to $B_1$ and gamble $B_2$ to $A_2$. It is easy to see that this set of preferences violates expected utility theory. First, if $A_1 > B_1$, then $u(A_1) > u(B_1)$, meaning that $u(\$1 \text{ million}) > 0.1u(\$2.5 \text{ million}) + 0.89u(\$1 \text{ million}) + 0.01u(\$0)$. If a utility of 0 is assigned to receiving \$0 and a utility of 1 to receiving \$2.5 million, then $u(\$1 \text{ million}) > 1/11$. However, from the preference $A_2 > B_2$, it follows that $u(\$1 \text{ million}) < \$1/11$. Obviously, no utility function can satisfy this requirement of assigning a value both greater than and less than 1/11 to \$1 million.

Savage (1954) mentioned that the set of gambles above can be reframed in a way that shows that these preferences violate the sure-thing principle. After doing so, Savage found that his initial tendency toward choosing $A_1$ over $B_1$ and $A_2$ over $B_2$ disappeared. As noted by Stevenson et al. (1993), this example is one of the first cases cited of a preference reversal caused by reframing a decision, the topic discussed below.

***Framing of Decisions and Preference Reversals***
A substantial body of research has shown that people's preferences can shift dramatically depending on the way a decision is represented. The best known work on this topic was conducted by Tversky and Kahneman (1981), who showed that preferences between medical intervention strategies changed dramatically depending on whether the outcomes were posed as losses or gains. The following question, worded in terms of benefits, was presented to one set of subjects:

Imagine that the United States is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimate of the consequences of the programs are as follows:

If program A is adopted, 200 people will be saved.

If program B is adopted, there is a 1/3 probability that 600 people will be saved and a 2/3 probability that no people will be saved.

Which of the two programs would you favor?

The results showed that 72% of subjects preferred program A. The second set of subjects was given the same cover story but worded in terms of costs:

If program C is adopted, 400 people will die.

If program D is adopted, there is a 1/3 probability that nobody will die and a 2/3 probability that 600 people will die.

Which of the two programs would you favor?

The results now showed that 78% of subjects preferred program D. Since program D is equivalent to B and program A is equivalent to C, the preferences for the two groups of subjects were strongly reversed. Tversky and Kahneman concluded that this reversal illustrated a common pattern in which choices involving gains are risk averse and choices involving losses are risk seeking. The interesting result was that the way the outcomes were worded caused a shift in preference for identical alternatives. Tversky and Kahneman called this tendency the *reflection effect*. A body of literature has since developed showing that the framing of decisions can have practical effects for both individual decision makers (Kahneman et al., 1982; Heath et al., 1994) and group decisions (Paese et al., 1993). On the other hand, recent research shows that the reflection effects can be reversed by certain outcome wordings (Kuhberger, 1995); more important, Kuhberger provides evidence that the reflection effect observed in the classic experiments can be eliminated by fully describing the outcomes (i.e., referring to the paragraph above, a more complete description would state: "If program C is adopted, 400 people will die *and* 200 *will live*").

Other recent research has explored the theory that perceived risk and perceived attractiveness of risky outcomes are psychologically distinct constructs (Weber et al., 1992). In the latter study, it was concluded that perceived risk and attractiveness are "closely related but distinct phenomena." Related research has shown weak negative correlations between the perceived risk

and value of indulging in alcohol-related behavior for adolescent subjects (Lehto et al., 1994). The latter study also showed that the rated propensity to indulge in alcohol-related behavior was strongly correlated with perceived value ($R = 0.8$) but weakly correlated with perceived risk ($R = -0.15$). Both findings are consistent with the theory that perceived risk and attractiveness are distinct constructs, but the latter finding indicates that perceived attractiveness may be the better predictor of behavior. Lehto et al. conclude that intervention methods attempting to lower preferences for alcohol-related behavior should focus on lowering perceived value rather than on increasing perceived risk.

***Prospect Theory*** Prospect theory (Kahneman and Tversky, 1979) attempts to account for behavior not consistent with the SEU model by including the framing of decisions as a step in the judgment of preference between risky alternatives. Prospect theory assumes that decision makers tend to be risk averse with regard to gains and risk seeking with regard to losses. This leads to a value function that weights losses disproportionately. As such, the model is still equivalent to SEU, assuming a utility function expressing mixed risk aversion and risk seeking. Prospect theory, however, assumes that the decision maker's reference point can change. With shifts in the reference point, the same returns can be viewed as either gains or losses.[*] The latter feature of prospect theory, of course, is an attempt to account for the framing effect discussed above. Prospect theory also deviates significantly from SEU theory in the way in which probabilities are addressed. To describe human preferences more closely, perceived values are weighted by a function $\pi(p)$ instead of the true probability, $p$. Compared to the untransformed form of $p$, $\pi(p)$ overweights very low probabilities and underweights moderate and high probabilities. The function $\pi(p)$ is also generally assumed to be discontinuous and poorly defined for probability values close to 0 or 1.

Prospect theory assumes that the choice process involves an editing phase and an evaluation phase. The editing phase involves reformulation of the options to simplify subsequent evaluation and choice. Much of this editing process is concerned with determining an appropriate reference point in a step called *coding*. Other steps that may occur include the segregation of riskless components of the decision, combining probabilities for events with identical outcomes, simplification by rounding off probabilities and outcome measures, and search for dominance. In the evaluation phase, the perceived values are then weighed by the function $\pi(p)$. The alternative with the greatest weighed value is then selected. Several other modeling approaches that differentially weigh utilities in risky decision making have been proposed (Goldstein and Hogarth, 1997). As in prospect theory, such models often assume that

the subjective probabilities, or decision weights, are a function of outcome sign (i.e., positive, neutral, or negative), rank (i.e., first, second, etc.), or magnitude. Other models focus on display effects (i.e., single-stage vs. multistage arrangements) and distribution effects (i.e., two outcome lotteries vs. multiple-outcome lotteries). Prospect theory and other approaches also address how the value or utility of particular outcomes can change between decision contexts, as discussed below.

More recently, Hertwig et al. (2004) divided decision from description, where full description of probability of risky events is given, and decision from experience, where decision makers learn the probability from experiences. They reported that two different decisions can lead to dramatically different choice behavior. In the case of decisions from description, people make choices as if they overweight the probability of rare events, as described by prospect theory. In contrast, the case of decisions from experience lead choices as if they underweight the probability of rare events. This idea created interesting debate because some (e.g., Fox and Hadar, 2006) attributed the division to simply sampling error.

***Labile Preferences*** There is no doubt that human preferences often change after receiving some outcome. After losing money, an investor may become risk averse. In other cases, an investor may escalate her commitment to an alternative after an initial loss, even if better alternatives are available. From the most general perspective, any biological organism becomes satiated after satisfying a basic need, such as hunger. Preferences also change over time or between decision contexts. For example, a 30-year-old decision maker considering whether to put money into a retirement fund may currently have a very different utility function than at retirement. The latter case is consistent with SEU theory but obviously complicates analysis.

Economists and behavioral researchers have both focused on mathematically modeling choice processes to explain intransitive or inconsistent preference orderings of alternatives (Goldstein and Hogarth, 1997). Game theory provides interesting insight into this issue. From this perspective, preferences of the human decision maker are modeled as the collective decisions obtained by a group of internal agents, or selves, each of which is assumed to have distinct preferences (see Elster, 1986). Intransitive preferences and other violations of rationality on the part of the human decision maker then arise from interactions between competing selves.[†] Along these lines, Ainslie (1975) proposed that impulsive preference switches (often resulting in risky

---

[*] The notion of a reference point against which outcomes are compared has similarities to the notion of making decisions on the basis of regret (Bell, 1982). Regret, however, assumes comparison to the best outcome. The notion of different reference points is also related to the well-known trend that buying and selling prices of assets often differ for a decision maker (Raiffa, 1968).

---

[†] As discussed further in Section 4.3, group decisions, even though they are made by rational members, are subject to numerous violations of rationality. For example, consider the case where the decision maker has three selves that are, respectively, risk averse, risk neutral, and risk seeking. Assume that the decision maker is choosing between alternatives $A$, $B$, and $C$. Suppose that the risk-averse self rates the alternatives in the order $A$, $B$, $C$; the risk-neutral self rates them in the order $B$, $C$, $A$; and the risk-seeking self rates them in the order $C$, $A$, $B$. Also assume that the selves are equally powerful. Then two of the three agents always agree that $A > B$, $B > C$, and $C > A$. This ordering is, of course, nontransitive.

or unhealthy choices) arise as the outcome of a struggle between selves representing conflicting short- and long-term interests, respectively.

Another area of active research has focused on how experiencing outcomes can cause shifts in preference. One robust finding is that people tend to be more satisfied if an outcome exceeds their expectations and less satisfied if it does not (i.e., Feather, 1966; Connolly et al., 1997). Expectations therefore provide a reference point against which outcomes are compared. A related result found in marketing studies is that negative experiences often have a much larger influence on product preferences and future purchasing decisions than positive experiences (Baumeister et al., 2001; Oldenburger et al., 2007).

Other studies have shown that people in a wide variety of settings often consider sunk costs when deciding whether to escalate their commitment to an alternative by investing additional resources (Arkes and Blumer, 1985; Arkes and Hutzel, 2000). From the perspective of prospect theory, sunk costs cause people to frame their choice in terms of losses instead of gains, resulting in risk-taking behavior and consequently, escalating commitment. Other plausible explanations for escalating commitment include a desire to avoid waste or to avoid blame for an initially bad decision to invest in the first place. Interestingly, some recent evidence suggests that people may deescalate commitment in response to sunk costs (Heath, 1995). The latter effect is also contrary to classical economic theory, which holds that decisions should be based solely on marginal costs and benefits. Heath explains such effects in terms of mental accounting. Escalation is held to occur when a mental budget is not set or expenses are difficult to track. Deescalation is held to occur when people exceed their mental budget, even if the marginal benefits exceed the marginal costs.

Other approaches include value and utility as random variables within models of choice to explain intransitive or inconsistent preference orderings of alternatives. The random utility model (Iverson and Luce, 1998) describes the probability $P_{a,A}$ of choosing a given alternative $a$ from a set of options $A$ as

$$P_{a,A} = \text{Prob } (U_a \geq U_b, \text{ for all } b \text{ in } A) \qquad (7)$$

where $U_a$ is the uncertain utility of alternative $a$ and $U_b$ is the uncertain utility of alternative $b$. The most basic random utility models assign a utility to each alternative by sampling a single value from a known distribution. The sampled utility of each alternative then remains constant throughout the choice process. Basic random utility models can predict a variety of preference reversals and intransitive preferences for single- and multiple-attribute comparisons of alternatives (i.e., Tversky, 1972).

Sequential sampling models extend this approach by assuming that preferences can be based on more than one observation. Preferences for particular alternatives are accumulated over time by integrating or otherwise summing the sampled utilities. The utility of an alternative at a particular time is proportional to the latter sum. A choice is made when the summed preferences for a particular alternative exceed some threshold, which itself may vary over time or depend on situational factors (Busemeyer and Townsend, 1993; Wallsten, 1995). It is interesting to observe that sequential sampling models can explain speed–accuracy trade-offs in signal detection tasks (Stone, 1960) as well as shifts in preferences due to time pressure (Busemeyer and Townsend, 1993; Wallsten, 1995) if it is assumed that people adjust their threshold downward under time pressure. That is, under time pressure, people sample less information before making a choice. In the following section we explore further how and why decision strategies might change over time and between decision contexts.

### 2.2.3 Adaptive Decision Behavior

The main idea of adaptive decision behavior, or contingent decision behavior, is that an individual decision maker uses different strategies in different situations (Payne et al., 1993). These strategies also include some short-cuts or heuristics that reduce the complexity of the problem while increasing chances to select suboptimal choices. Various decision strategies have been identified (Bettman et al., 1998; Wright, 1975) and will be described next. In addition, these different strategies have trade-off relationships. In other words, some strategies are less cognitively burdensome but their accuracy is also low. Other strategies are more cognitively burdensome, but their accuracy could be higher. This relationship is discussed below.

***Decision Strategies*** According to the taxonomy of Wright (1975), decision strategies are organized along two dimensions: "data combination processes" and "choice rules." Data combination processes have two levels, compensatory and noncompensatory data integration. In compensatory data integration, a good value of one attribute compensates for a bad value of another attribute. In contrast, noncompensatory data integration could drop a choice with a bad value of an attribute, even if the choice or alternative has perfect values for the other attributes (Edwards and Fasolo, 2001). The other dimension, choice rule, also has two levels: "best" and "cutoff." The best-choice rule chooses the best option through heuristics (e.g., choosing an alternative that has the highest number of good features and the smallest number of bad features), whereas the cutoff rule merely eliminates available options based on a decision maker's threshold (e.g., eliminating alternatives that have bad aspects that do not meet criteria until only a few alternatives remain).

Table 3 outlines these strategies and heuristics along the two dimensions just described. The distinction among levels in the two dimensions will be clarified when each decision strategy is discussed. In Table 3, three heuristics (WADD, EQW, and VOTE) are categorized in both the best and cutoff rules since the calculated score through these heuristics can be used as a cutoff criterion. Payne et al. (1988) also introduced some combination of multiple strategies such as EBA+MCD, EBA+WADD, and EBA+EQW.

In applying a weighted adding strategy (WADD), the subjective importance ratings are associated with

**Table 3  Decision Heuristics**

| Choice Rule | Data Combination Process | |
|---|---|---|
| | Compensatory | Noncompensatory |
| Best | WADD | LEX |
| | EQW | LEXSEMI |
| | VOTE | MAXIMAX |
| | MCD | MINIMAX |
| Cutoff | WADD | SAT |
| | EQW | EBA |
| | VOTE | |

*Source*: Adapted from Wright (1975) and Bettman et al. (1998).
*Abbreviations*: Weighted adding (WADD), lexicographic (LEX), lexicographic semiorder (LEXSEMI), satisficing (SAT), elimination by aspects (EBA), equal weight (EQW), majority of confirming dimensions (MCD), feature voting (VOTE), maximize minimum (MINIMAX), and maximize maximum (MAXIMAX)

each attribute. These subjective ratings, or weights, are multiplied by the corresponding attribute value obtained by a particular alternative. The worth of any particular alternative, then, would be the sum of these products (i.e., assigned weight by attribute value), and the decision maker selects the alternative with the greatest value. Equal weight (EQW) is a special case of weighted adding. Since each attribute is considered equally important in this method, the value of each alternative is simply the sum of all its attribute values.

The strategy of feature voting (VOTE) is based on the number or frequency of occurrences of positive or negative features within an alternative. Here, the decision maker subjectively defines the positive and negative values for each attribute. The worth of the alternative is determined by the number of good votes (positive features) and bad votes (negative features). The decision maker may also disregard the number of bad votes or focus on minimizing the number of bad votes.

Paired comparisons are central to the strategy of majority of confirming dimensions (MCD). In this strategy, decision makers start by evaluating the first two alternatives. They then count the number of times each alternative has the higher score across all the attributes. The alternative with the higher count is then compared with the next alternative, and the process is repeated until all the alternatives have been considered. Finally, the alternative with the most "wins" is selected.

The lexicographic ordering principle (LEX) (Fishburn, 1974) considers the case where alternatives have multiple consequences or attributes. For example, a purchasing decision might be based on both the cost and performance of the product considered. The various consequences are first ordered in terms of their importance. Returning to the example above, performance might be considered more important than cost. The decision maker then compares each alternative sequentially, beginning with the most important consequence. If an alternative is found that is better than the others on the first consequence, it is selected immediately. If no alternative is best on the first dimension, the alternatives are compared for the next most important consequence.

This process continues until an alternative is selected or all the consequences have been considered without making a choice. The latter situation can happen only if the alternatives have the same consequences.

The lexicographic semiorder (LEXSEMI) method is a variation of LEX. In LEXSEMI, the condition of "equally good" is loosened by introducing the concept of "just-noticeable difference." For example, if car A is $20,000 and car B is $20,050 (but has better gas mileage), a car buyer using LEX will choose car A because car A is cheaper than car B. However, if another car buyer using LEXSEMI looks at gas mileage, which may be the second most important attribute, he may choose car B since $50 would become insignificant compared with future savings on gas costs.

The satisficing (SAT) method is a matter of selecting the first alternative that meets all the decision maker's requirements on the attributes. As such, decisions resulting from this technique depend on the order that the alternatives are presented. For example, a person considering the purchase of a car might stop looking once he or she has found an attractive deal, instead of comparing every model on the market. More formally, the comparison of alternatives stops once a choice is found that exceeds a minimum aspiration level $S_{ik}$ for each of its consequences $C_{ik}$ over the possible events $E_k$. Satisficing can be a normative decision rule when (1) the expected benefit of exceeding the aspiration level is small, (2) the cost of evaluating alternatives is high, or (3) the cost of finding new alternatives is high. More often, however, it is viewed as an alternative to maximizing decision rules. From this view, people cope with incomplete or uncertain information and their limited rationality by satisficing in many settings instead of optimizing (Simon, 1955, 1982).

Two similar noncompensatory decision strategies are minimize maximum loss (MINIMAX) and maximize maximum gains (MAXIMAX). A decision maker "applying MINIMAX compares the options on their worst attributes, rejecting one if another worst attributes is less offensive or if another has fewer worst attributes that are equally offensive. That is, the decision maker minimizes the maximum possible loss. MAXIMAX implies a decision maker compares options on their best attribute, choosing one over another if its best attribute is more desirable or if it possesses more best attributes of equal desirability" (Wright, 1975, p. 61).

Elimination by aspects (EBA) (Tversky, 1972) is a closely related sequential strategy of eliminating alternatives that do not meet selected criteria. EBA is similar to the LEX. It differs in that the consequences used to compare the alternatives are selected in random order, where the probability of selecting a consequence dimension is proportional to its importance. Often, the most important aspect (or attribute) is selected for inspection. If other alternatives have bad values for the attributes, they are eliminated from the candidates. For example, if one thinks that gas mileage is important, he can eliminate cars that have bad mileage, say less than 20 miles per gallon, from the pool of candidates.

Even though these strategies describe more accurately how people make decisions than the normative

approaches, they also have some problems. Some non-compensatory methods mistakenly eliminate the optimal alternative(s). For example, if a decision maker uses EBA, and if the optimal alternative has a bad value for a certain attribute, the optimal alternative can be eliminated from the pool of candidates due to this particular bad attribute even though the overall utility may be better than that of the remaining alternatives. Even compensatory strategies pose difficulties for those seeking to make the optimal choice. For example, if one uses MCD, the choice can vary depending on the order of comparisons, as the decision maker may eliminate a good alternative merely because it takes a "loss" in an early comparison and may have won several other comparisons with the remaining alternative.

***Effort-Accuracy Framework*** The theory of contingent decision making describes the trade-off situations in more detail (Payne et al., 1993). Payne and his colleagues measure the effort expended and accuracy resulting from the application of different strategies. They assume that performing each strategy has associated costs in the form of small information-processing tasks referred to as elementary information processes (EIPs). The number of EIPs for a decision strategy is assumed to be the measure of effort in making the decision. The accuracy of a strategy is measured in relative terms; "that is, the quality of the choice expected from a rule [strategy] is measured against the standard of accuracy provided by a normative model like the weighted additive rule [WADD]" (Payne et al., 1993, p. 93). (*Note*: Brackets have been added for terminology consistency.) As shown in Figure 3, use of the WADD method represents the most accurate, albeit most costly (in terms of effort), strategy to perform. In contrast, EBA is the most effortless strategy, but accuracy must often be sacrificed. Note that random choice is not considered here because it is not considered a method of decision making per se.

**Figure 3** Trade-off between relative accuracy and effort. (Adapted from Payne et al., 1993.)

The question then is how to help people make decisions more accurately and effortlessly. Todd and Benbasat (1991, 1993) conducted a series of empirical studies showing the effectiveness of computer-based decision aids. They showed that "when a more accurate normative strategy [WADD] is made less effortful to use, it is used" (Todd and Benbasat, 2000, p. 91). (*Note*: Brackets have been added for terminology consistency.) This decision aid helps decision makers perform more accurate decision strategies with less effort. Another interesting result of the same study is that although the decision aid also provided features to support noncompensatory strategies (EBA), the noncompensatory strategies were not significantly promoted. Todd and Benbasat argued that the noncompensatory strategies are only preferred when support for the compensatory strategies is low.

However, it should be noted that supporting a compensatory strategy is cumbersome. According to Edwards and Fasolo (2001), who reviewed representative Web-based decision aids, compensatory strategies have been sparingly employed by Web-based decision aids since interfaces supporting compensatory strategies are complicated and difficult to use. Thus, providing proper decision aids that assist target users requires some additional design effort to minimize the required efforts. Some creative solutions, probably using InfoVis techniques, will be required.

Another lesson from reviewing these results is that information overload plays an important role in selecting proper decision strategies. Under high information overload, noncompensatory strategies such as EBA appear to be more effective since they filter out unnecessary information. After filtering is over, compensatory strategies or relatively normative approaches appear to be more effective since more comprehensive comparisons among the alternatives are necessary.

### 2.2.4 Behavioral Economics

Behavioral economics is a subdiscipline of economics formulated as a backlash against neoclassical economics whose main tenet is strong reliance on rationality of human decision makers (Camerer and Loewenstein, 2004; Simon, 1987). In the middle of the twentieth century, it was shown that many axioms based on human rationality are often violated by decision models. As well as people are limited in their information processing (Simon, 1982), people care more about the fairness over self-interest (ultimatum game) (Thaler, 1988); people weight risky outcomes in a nonlinear fashion (the prospect theory) (Kahneman and Tversky, 1979); and people value a thing more after they possess it (endowment effect) (Thaler, 1980). Such evidence led many economists to reappreciate the values of psychology to model and predict decision-making behaviors, which led the growth of behavioral economics as a strong subdiscipline (Pesendorfer, 2006).

However, behavioral economics is neither a totally new idea nor a drastic change in the core idea of neoclassical economics. Human psychology was already well understood by Adam Smith, who is the father of

modern economics. His books include not only *The Wealth of Nations* but also *Theory of Moral Sentiments*, which is less known but has profound insights about human psychology. It is interesting to see how eloquently he described loss-aversion in his book, "We suffer more . . . when we fall from a better to a worse situation, than we ever enjoy when we rise from a worse to a better" (Smith, 1875, p. 331). In addition, it is difficult to say that behavioral economics changed the core idea of neoclassical economics. That is, maximizing expected value is still worthwhile as a core framework to help understand many economic behaviors. Behavioral economics instead provides more capability and external validity by adding additional parameters in traditional economic models and theories.

Some criticize behavioral economics as well. First, it has been claimed that behavioral economics did not provide a unified and elegant theory of rational agents. However, a lack of a unified model not only reflects the diversity and complexity of human decision making but also conversely demonstrates the incompleteness of traditional economic models based on rationality (Kahneman, 2003). Second, some doubt that findings in behavioral economics have significant influences on real-life situations, such as policy making (Brannon, 2008). However, recent publications for the general public (Ariely, 2008; Levitt and Dubner, 2005; Thaler and Sunstein, 2008) have demonstrated direct implications on policy making and economics. More specifically, behavioral economics has been used to understand behaviors in macroeconomics, saving, labor economics, and finance. For example, many people do not mind decreases in their real wage, considering inflation, as long as there is no decrease in their nominal wage, without considering inflation (Shafir et al., 1997). This behavioral pattern is called "the money illusion."

Theory in behavioral economics has been covered largely in this section, but several new directions of behavioral economics have been observed, such as understanding emotion, using the method of neuropsychology to better understand human behavior. These directions have not fully explored, but these could provide interesting new insights for us. More comprehensive review for behavioral economics and behavioral finance can be found elsewhere (Barberis and Thaler, 2003; Camerer et al., 2004; Glaser et al., 2004).

## 2.3 Naturalistic Decision Models

In a dynamic and realistic environment, actions taken by a decision maker are made sequentially in time. Taking actions can change the environment, resulting in a new set of decisions. The decisions might be made under time pressure and stress by groups or by single decision makers. This process might be performed on a routine basis or might involve severe conflict. For example, either a group of soldiers or an individual officer might routinely identify marked vehicles as friends or foes. When a vehicle has unknown or ambiguous marking, the decision changes to a conflict-driven process. Naturalistic decision theory has emerged as a new field that focuses on such decisions in real-world environments (Klein, 1998; Klein et al., 1993). The notion that most decisions are made in a routine, nonanalytical way is the driving force of this approach. Areas where such behavior seems prominent include juror decision making, troubleshooting of complex systems, medical diagnosis, management decisions, and numerous other examples.

For many years, it has been recognized that decision making in natural environments often differs greatly between decision contexts (Beach, 1993; Hammond, 1993). In addressing this topic, the researchers involved often question the relevance and validity of both classical decision theory and behavioral research not conducted in real-world settings (Cohen, 1993). Numerous naturalistic models have been proposed (Klein et al., 1993). These models assume that people rarely weigh alternatives and compare them in terms of expected value or utility. Each model is also descriptive rather than prescriptive. Perhaps the most general conclusion that can be drawn from this work is that people use different decision strategies, depending on their experience, the task, and the decision context. Several of the models also postulate that people choose between decision strategies by trading off effectiveness against the effort required.

In the following discussion we address several models of dynamic and naturalistic decision making: (1) levels of task performance (Rasmussen, 1983), (2) recognition-primed decisions (Klein, 1989), (3) dominance structuring (Montgomery, 1989), and (4) explanation-based decision making (Pennington and Hastie, 1988).

### 2.3.1 Levels of Task Performance

There is growing recognition that most decisions are made on a routine basis in which people simply follow past behavior patterns (Rasmussen, 1983; Svenson, 1990; Beach, 1993). Rasmussen (1983) follows this approach to distinguish among skill-based, rule-based, and knowledge-based levels of task performance. Lehto (1991) further considers judgment-based behavior as a fourth level of performance. Performance is said to be at either a skill-based or a rule-based level when tasks are routine in nature. *Skill-based performance* involves the smooth, automatic flow of actions without conscious decision points. As such, skill-based performance describes the decisions made by highly trained operators performing familiar tasks. *Rule-based performance* involves the conscious perception of environmental cues, which trigger the application of rules learned on the basis of experience. As such, rule-based performance corresponds closely to recognition-primed decisions (Klein, 1989). *Knowledge-based performance* is said to occur during learning or problem-solving activity during which people cognitively simulate the influence of various actions and develop plans for what to do. The *judgment-based level* of performance occurs when affective reactions of a decision maker cause a change in goals or priorities between goals (Janis and Mann, 1977; Etzioni, 1988; Lehto, 1991). Distinctive types of errors in decision making occur at each of the four levels (Reason, 1990; Lehto, 1991).

At the skill-based level, errors occur due to perceptual variability and when people fail to shift up

to rule-based or higher levels of performance. At the rule-based level, errors occur when people apply faulty rules or fail to shift up to a knowledge-based level in unusual situations where the rules they normally use are no longer appropriate. The use of faulty rules leads to an important distinction between running and taking risks. Along these lines, Wagenaar (1992) discusses several case studies in which people following risky forms of behavior do not seem to be consciously evaluating the risk. Drivers, in particular, seem habitually to take risks. Wagenaar explains such behavior in terms of faulty rules derived on the basis of benign experience. In other words, drivers get away with providing small safety margins most of the time and consequently learn to run risks on a routine basis. Drucker (1985) points out several cases where organizational decision makers have failed to recognize that the generic principles they used to apply were no longer appropriate, resulting in catastrophic consequences.

At the knowledge-based level, errors occur because of cognitive limitations or faulty mental models or when the testing of hypotheses causes unforeseen changes to systems. At judgment-based levels, errors (or violations) occur because of inappropriate affective reactions, such as anger or fear (Lehto, 1991). As noted by Isen (1993), there also is growing recognition that positive affect can influence decision making. For example, positive affect can promote the efficiency and thoroughness of decision making but may cause people to avoid negative materials. Positive affect also seems to encourage risk-averse preferences. Decision making itself can be anxiety provoking, resulting in violations of rationality (Janis and Mann, 1977).

A study involving drivers arrested for drinking and driving (McKnight et al., 1995) provides an interesting perspective on how the sequential nature of naturalistic decisions can lead people into traps. The study also shows how errors can occur at multiple levels of performance. In this example, decisions made well in advance of the final decision to drive while impaired played a major role in creating situations where drivers were almost certain to drive impaired. For example, the driver may have chosen to bring along friends and therefore have felt pressured to drive home because the friends were dependent on him or her. This initial failure by drivers to predict the future situation could be described as a failure to shift up from a rule-based level to a knowledge-based level of performance. In other words, the driver never stopped to think about what might happen if he or she drank too much. The final decision to drive, however, would correspond to an error (or violation) at the judgment-based level if the driver's choice was influenced by an affective reaction (perceived pressure) to the presence of friends wanting a ride.

### 2.3.2 Recognition-Primed Decision Making

Klein (1998, 2004) developed the theory of recognition-primed decision making on the basis of observations of firefighters and other professionals in their naturalistic environments. He found that up to 80% of the decisions made by firefighters involved some sort of situation recognition, where the decision makers simply followed a past behavior pattern once they recognized the situation.

The model he developed distinguishes between three basic conditions. In the simplest case, the decision maker recognizes the situation and takes the obvious action. A second case occurs when the decision maker consciously simulates the action to check whether it should work before taking it. In the third and most complex case, the action is found to be deficient during the mental simulation and is consequently rejected. An important point of the model is that decision makers do not begin by comparing all the options. Instead, they begin with options that seem feasible based on their experience. This tendency, of course, differs from the SEU approach but is comparable to applying the satisficing decision rule (Simon, 1955) discussed earlier.

Situation assessment is well recognized as an important element of decision making in naturalistic environments (Klein et al., 1993). Recent research by Klein and his colleagues has examined the possibility of enhancing situation awareness through training (Klein and Wolf, 1995). Klein and his colleagues have also applied methods of cognitive task analysis to naturalistic decision-making problems. In these efforts they have focused on identifying (1) critical decisions, (2) the elements of situation awareness, (3) critical cues indicating changes in situations, and (4) alternative courses of action (Klein, 1995). Accordingly, practitioners of naturalistic decision making tend to focus on process-tracing methods and behavioral protocols (Ericsson and Simon, 1984) to document the processes people follow when they make decisions.[*]

### 2.3.3 Dominance Structuring

Dominance structuring (Montgomery, 1989; Montgomery and Willen, 1999) holds that decision making in real contexts involves a sequence of four steps. The process begins with a preediting stage in which alternatives are screened from further analysis. The next step involves selecting a promising alternative from the set of alternatives that survive the initial screening. A test is then made to check whether the promising alternative dominates the other surviving alternations. If dominance is not found, the information regarding the alternatives is restructured in an attempt to force dominance. This process involves both the bolstering and deemphasizing of information in a way that eliminates disadvantages of the promising alternative.

Empirical support can be found for each of the four stages of the bolstering process (Montgomery and Willen, 1999). Consequently, this theory may have value as a description of how people make nonroutine decisions.

### 2.3.4 Explanation-Based Decision Making

Explanation-based decision making (Oskarsson et al., 2009; Pennington and Hastie, 1986, 1988) assumes that people begin their decision-making process by

---

[*] Goldstein and Hogarth (1997) describe a similar trend in judgment and decision-making research.

constructing a mental model that explains the facts they have received. While constructing this explanatory model, people are also assumed to be generating potential alternatives to choose between. The alternatives are then compared to the explanatory model rather than to the facts from which it was constructed.

Pennington and Hastie have applied this model to juror decision making and obtained experimental evidence that many of its assumptions seem to hold. They note that juror decision making requires consideration of a massive amount of data that is often presented in haphazard order over a long time period. Jurors seem to organize this information in terms of stories describing causation and intent. As part of this process, jurors are assumed to evaluate stories in terms of their uniqueness, plausibility, completeness, or consistency. To determine a verdict, jurors then judge the fit between choices provided by the trial judge and the various stories they use to organize the information. Jurors' certainty about their verdict is assumed to be influenced both by evaluation of stories and by the perceived goodness of fit between the stories and the verdict.

## 3 GROUP DECISION MAKING

Much research has been done over the past 25 years or so on decision making by groups and teams. Most of this work has focused on groups as opposed to teams. In a team it is assumed that the members are working toward a common goal and have some degree of interdependence, defined roles and responsibilities, and task-specific knowledge (Orasanu and Salas, 1993). Team performance is a major area of interest in the field of naturalistic decision theory (Klein et al., 1993; Klein, 1998), as discussed earlier. Group performance has traditionally been an area of study in the fields of organizational behavior and industrial psychology. Traditional decision theory has also devoted some attention to group decision making (Raiffa, 1968; Keeney and Raiffa, 1976). In the following discussion we first discuss briefly some of the ways that group decisions differ from those made by isolated decision makers who need to consider only their own preferences. That is, ethics and social norms play a much more prominent role when decisions are made by or within groups. Attention will then shift to group processes and how they affect group decisions. In the last section we address methods of supporting or improving group decision making.

### 3.1 Ethics and Social Norms

When decisions are made by or within groups, a number of issues arise that have not been touched on in the earlier portions of this chapter. To start, there is the complication that preferences may vary between members of a group. It often is impossible to maximize the preferences of all members of the group, meaning that trade-offs must be made and issues such as fairness must be addressed to obtain acceptable group decisions. Another complication is that the return to individual decision makers can depend on the actions of others.

Game theory[*] distinguishes two common variations of this situation. In competitive games, individuals are likely to take "self-centered" actions that maximize their own return but reduce returns to other members of the group. Behavior of group members in this situation may be well described by the minimax decision rule discussed in Section 2.2.3. In cooperative games, the members of the group take actions that maximize returns to the group as a whole.

Members of groups may choose cooperative solutions that are better for the group as a whole for many different reasons (Dawes et al., 1988). Groups may apply numerous forms of coercion to punish members who deviate from the cooperative solutions. Group members may apply decision strategies such as reciprocal altruism. They also might conform because of their social conscience, a need for self-esteem, or feelings of group identity. Fairness considerations can in some case explain preferences and choices that seem to be in conflict with economic self-interest (Bazerman, 1998). Changes in the status quo, such as increasing the price of bottled water immediately after a hurricane, may be viewed as unfair even if they are economically justifiable based on supply and demand. People are often willing to incur substantial costs to punish "unfair" opponents and reward their friends or allies. The notion that costs and benefits should be shared equally is one fairness-related heuristic that people use (Messick, 1991). Consistent results were found by Guth et al. (1982) in a simple bargaining game where player 1 proposes a split of a fixed amount of cash and player 2 either accepts the offer or rejects it. If player 2 rejects the offer, both players receive nothing. Classical economics predicts that player 2 will accept any positive amount (i.e., player 2 should always prefer something to nothing). Consequently, player 1 should offer player 2 a very small amount greater than zero. The results showed that contrary to predictions of classical economics, subjects tended to offer a substantial proportion of the cash (the average offer was 30%). Some of the subjects rejected positive offers. Others accepted offers of zero. Further research, summarized by Bolton and Chatterjee (1996), confirms these findings that people seem to care about whether they receive their fair share.

Ethics clearly plays an important role in decision making. Some choices are viewed by nearly everyone as being immoral or wrong (i.e., violations of the law, dishonesty, and numerous other behaviors that conflict with basic societal values or behavioral norms). Many corporations and other institutions formally specify codes of ethics prescribing values such as honesty, fairness, compliance with the law, reliability, considerance or sensitivity to cultural differences, courtesy, loyalty, respect for the environment, and avoiding waste. It is easy to visualize scenarios where it is in the best interest of a decision maker to choose economically undesirable options (at least in the short term) to comply with ethical codes. According to Kidder (1995), the "really tough choices...don't center on right versus

---

[*] Friedman (1990) provides an excellent introduction to game theory.

wrong. They involve right versus right." Kidder refers to four dilemmas of right versus right that he feels qualify as paradigms: (1) truth versus loyalty (i.e., whether to divulge information provided in confidence), (2) individual versus community, (3) short term versus long term, and (4) justice versus mercy. At least three principles, which in some cases provide conflicting solutions, have been proposed for resolving ethical dilemmas. These include (1) utilitarianism, selecting the option with the best overall consequences; (2) rule based, following a rule regardless of its current consequences (i.e., waiting for a stop light to turn green even if no cars are coming); and (3) fairness, doing what you would want others to do for you.

Numerous social dilemmas also occur in which the payoffs to each participant result in individual decision strategies harmful to the group as a whole. The tragedy of the commons (Hardin, 1968) is illustrative of social dilemmas in general. For example, as discussed in detail by Baron (1998), consider the crash of the east coast commercial fishing industry, brought about by overfishing. Baron suggests that individual fishers may reason that if they do not catch the fish, someone else will. Each fisher then attempts to catch as many fish as possible, even if this will cause the fish stocks to crash. Despite the fact that cooperative solutions, such as regulating the catch, are obviously better than the current situation, individual fishers continue to resist such solutions. Regulations are claimed to infringe on personal autonomy, to be unfair, or to be based on inadequate knowledge.

Similar examples include littering, wasteful use of natural resources, pollution, social free riding, and corporations expecting governments or affected consumers to pay for the cost of accidents (e.g., oil spill and subprime mortgage crisis). These behaviors can all be explained in terms of the choices faced by the offending individual decision maker (Schelling, 1978). Simply put, the individual decision maker enjoys the benefits of the offensive behavior, as small as they may be, but the costs are incurred by the entire group.

## 3.2 Group Processes

A large amount of research has focused on groups and their behavior. Accordingly, many models have been developed that describe how groups make decisions. A common observation is that groups tend to move through several phases as they go through the decision-making process (Ellis and Fisher, 1994). One of the more classic models (Tuckman, 1965) describes this process with four words: forming, storming, norming, and performing. *Forming* corresponds to initial orientation, *storming* to conflict, *norming* to developing group cohesion and expressing opinions, and *performing* to obtaining solutions. As implied by Tuckman's choice of terms, there is a continual interplay between socioemotive factors and rational, task-oriented behavior throughout the group decision-making process. Conflict, despite its negative connotations, is a normal, expected aspect of the group decision process and can in fact serve a positive role (Ellis and Fisher, 1994). In the following discussion we first address causes and effects of group conflict, then shift to conflict resolution.

### 3.2.1 Conflict

Whenever people or groups have different preferences, conflict can occur. As pointed out by Zander (1994), conflict between groups becomes more likely when groups have fuzzy or potentially antagonistic roles or when one group is disadvantaged (or perceives that it is not being treated fairly). A lack of conflict-settling procedures and separation or lack of contact between groups can also contribute to conflict. Conflict becomes especially likely during a crisis and often escalates when the issues are perceived to be important or after resistance or retaliation occurs. Polarization, loyalty to one's own group, lack of trust, and cultural and socioeconomic factors are often contributing factors to conflict and conflict escalation.

Ellis and Fisher (1994) distinguish between affective and substantive forms of conflict. *Affective conflict* corresponds to emotional clashes between individuals or groups; *substantive conflict* involves opposition at the intellectual level. Substantive conflict is especially likely to have positive effects on group decisions by promoting better understanding of the issues involved. Affective conflict can also improve group decisions by increasing interest, involvement, and motivation among group members and, in some cases, cohesiveness. On the other hand, affective conflict may cause significant ill-will, reduced cohesiveness, and withdrawal by some members from the group process. Baron (1998) provides an interesting discussion of violent conflict and how it is related to polarized beliefs, group loyalty, and other biases.

Defection and the formation of coalitions is a commonly observed effect of conflict, or power struggles, within groups. Coalitions often form when certain members of the group can gain by following a common course of action at the expense of the long-run objectives of the group as a whole. Rapidly changing coalitions between politicians and political parties are obviously a fact of life. Another typical example is when a subgroup of technical employees leaves a corporation to form their own small company, producing a product similar to one they had been working on. Coalitions, and their formation, have been examined from decision-analytic and game theory perspectives (Raiffa, 1982; Bolton and Chatterjee, 1996). These approaches make predictions regarding what coalitions will form, depending on whether the parties are cooperating or competing, which have been tested in a variety of experiments (Bolton and Chatterjee, 1996). These experiments have revealed that the formation of coalitions is influenced by expected payoffs, equity issues, and the ease of communication. However, Bazerman (1998) notes that the availability heuristic, overconfidence, and sunk cost effects are likely to explain how coalitions actually form in the real world.

### 3.2.2 Conflict Resolution

Groups resolve conflict in many different ways. Discussion and argument, voting, negotiation, arbitration, and other forms of third-party intervention are all methods of resolving disputes. Discussion and argument are clearly

the most common methods followed within groups to resolve conflict. Other methods of conflict resolution normally play a complementary rather than a primary role in the decision process. That is, the latter methods are relied on when groups fail to reach consensus after discussion and argument or they simply serve as the final step in the process.

Group discussion and argument are often viewed as constituting a less than rational process. Along these lines, Brashers et al. (1994) state that the literature suggests "that argument in groups is a social activity, constructed and maintained in interaction, and guided perhaps by different rules and norms than those that govern the practice of ideal or rational argument. Subgroups speaking with a single voice appear to be a significant force . . . . Displays of support, repetitive agreement, and persistence all appear to function as influence mechanisms in consort with, or perhaps in place of, the quality or rationality of the arguments offered." Brashers et al. also suggest that members of groups appear uncritical because their arguments tend to be consistent with social norms rather than the rules of logic: "[S]ocial rules such as: (a) submission to higher status individuals, (b) experts' opinions are accepted as facts on all matters, (c) the majority should be allowed to rule, (d) conflict and confrontation are to be avoided whenever possible."

A number of approaches for conflict management have been suggested that attempt to address many of the issues raised by Brashers et al. These approaches include seeking consensus rather than allowing decisions to be posed as win–lose propositions, encouraging and training group members to be supportive listeners, deemphasizing status, depersonalizing decision making, and using facilitators (Likert and Likert, 1976). Other approaches that have been proposed include directing discussion toward clarifying the issues, promoting an open and positive climate for discussion, facilitating face-saving communications, and promoting the development of common goals (Ellis and Fisher, 1994).

Conflicts can also be resolved through voting and negotiation, as discussed further in Section 3.3. Negotiation becomes especially appropriate when the people involved have competing goals and some form of compromise is required. A typical example would be a dispute over pay between a labor union and management. Strategic concerns play a major role in negotiation and bargaining (Schelling, 1960). Self-interest on the part of the involved parties is the driving force throughout a process involving threats and promises, proposals and counterproposals, and attempts to discern how the opposing party will respond. Threats and promises are a means of signaling what the response will be to actions taken by an opponent and consequently become rational elements of a decision strategy (Raiffa 1982). Establishing the credibility of signals sent to an opponent becomes important.

Methods of attaining credibility include establishing a reputation, the use of contracts, cutting off communication, burning bridges, leaving an outcome beyond control, moving in small steps, and using negotiating agents (Dixit and Nalebuff, 1991). Given the fundamentally adversarial nature of negotiation, conflict may

move from a substantive basis to an affective, highly emotional state. At this stage, arbitration and other forms of third-party intervention may become appropriate, due to a corresponding tendency for the negotiating parties to take extreme, inflexible positions.

## 3.3 Group Performance and Biases

The quality of the decisions made by groups in a variety of different settings has been seriously questioned. Part of the issue here is the phenomenon of *groupthink*, which has been blamed for several disastrous public policy decisions (Janis, 1972; Hart et al., 1997). Eight symptoms of groupthink cited by Janis and Mann (1977) are the illusion of invulnerability, rationalization (discounting of warnings and negative feedback), belief in the inherent morality of the group, stereotyping of outsiders, pressure on dissenters within the group, self-censorship, illusion of unanimity, and the presence of mindguards who shield the group from negative information. Janis and Mann proposed that the results of groupthink include failure to consider all the objectives and alternatives, failure to reexamine choices and rejected alternatives, incomplete or poor search for information, failure to adequately consider negative information, and failure to develop contingency plans. Groupthink is one of the most cited characteristics of how group decision processes can go wrong. Given the prominence of groupthink as an explanation of group behavior, it is somewhat surprising that only a few studies have evaluated this theory empirically. Empirical evaluation of the groupthink effect and the development of alternative modeling approaches continue to be active areas of research (Hart et al., 1997).

Other research has attempted to measure the quality of group decisions in the real world against rational, or normative, standards. Viscusi (1991) cites several examples of apparent regulatory complacency and regulatory excess in government safety standards in the United States. He also discusses a variety of inconsistencies in the amounts awarded in product liability cases. Baron (1998) provides a long list of what he views as errors in public decision making and their very serious effects on society. These examples include collective decisions resulting in the destruction of natural resources and overpopulation, strong opposition to useful products such as vaccines, violent conflict between groups, and overzealous regulations, such as the Delaney clause. He attributes these problems to commonly held, and at first glance innocuous, intuitions such as do no harm, nature knows best, and be loyal to your own group, the need for retribution (an eye for an eye), and a desire for fairness.

A significant amount of laboratory research is available that compares the performance of groups to that of individual decision makers (Davis, 1992; Kerr et al., 1996). Much of the early work showed that groups were better than individuals on some tasks. Later research indicated that group performance is less than the sum of its parts. Groups tend to be better than individuals on tasks where the solution is obvious once it is advocated by a single member of the group (Davis, 1992; Kerr et al., 1996). Another commonly cited finding is that groups tend to be more willing than individuals, to select

risky alternatives, but in some cases the opposite is true. One explanation is that group interactions cause people within the group to adopt more polarized opinions (Moscovici, 1976). Large groups seem especially likely to reach polarized, or extreme, conclusions (Isenberg, 1986). Groups also tend to overemphasize the common knowledge of members, at the expense of underemphasizing the unique knowledge certain members have (Stasser and Titus, 1985; Gruenfeld et al., 1996). A more recent finding indicates that groups were more rational than individuals when playing the ultimatum game (Bornstein and Yaniv, 1998).

Duffy (1993) notes that teams can be viewed as information processes and cites team biases and errors that can be related to information-processing limitations and the use of heuristics, such as framing. Topics such as mediation and negotiation, jury decision making, and public policy are now being evaluated from the latter perspective (Heath et al., 1994). Much of this research has focused on whether groups use the same types of heuristics and are subject to the same biases of individuals. This research has shown (1) framing effects and preference reversals (Paese et al., 1993), (2) overconfidence (Sniezek, 1992), (3) use of heuristics in negotiation (Bazerman and Neale, 1983), and (4) increased performance with cognitive feedback (Harmon and Rohrbaugh, 1990). One study indicated that biasing effects of the representativeness heuristic were greater for groups than for individuals (Argote et al., 1986). The conclusion is that group decisions may be better than those of individuals in some situations but are subject to many of the same problems.

## 3.4  Prescriptive Approaches

A wide variety of prescriptive approaches have been proposed for improving group decision making. The approaches address some of the foregoing issues, including the use of agendas and rules of order, idea-generating techniques such as brainstorming, nominal group and Delphi techniques, decision structuring, and methods of computer-mediated decision making. As noted by Ellis and Fisher (1994), there is conflicting evidence regarding the effectiveness of such approaches. On the negative side, prescriptive approaches might stifle creativity in some situations and can be sabotaged by dissenting members of groups. On the positive side, prescriptive approaches make the decision process more orderly and efficient, promote rational analysis and participation by all members of the group, and help ensure implementation of group decisions. In the following discussion we review briefly some of these tools for improving group decision making.

### 3.4.1  Agendas and Rules of Order

Agendas and rules of order are often essential to the orderly functioning of groups. As noted by Welch (1994), an agenda "conveys information about the structure of a meeting: time, place, persons involved, topics to be addressed, perhaps suggestions about background material or preparatory work." Agendas are especially important when the members of a group are loosely coupled or do not have common expectations. Without an agenda, group meetings are likely to dissolve into chaos (Welch, 1994). Rules of order, such as *Robert's Rules of Order* (Robert, 1990), play a similarly important role, by regulating the conduct of groups to ensure fair participation by all group members, including absentees. Rules of order also specify voting rules and means of determining consensus. Decision rules may require unanimity, plurality, or majority vote for an alternative.

Attaining consensus poses an advantage over voting, because voting encourages the development of coalitions, by posing the decision as a win–lose proposition (Ellis and Fisher, 1994). Members of the group who voted against an alternative are often unlikely to support it. Voting procedures can also play an important role (Davis, 1992).

### 3.4.2  Idea Generation Techniques

A variety of approaches have been developed for improving the creativity of groups in the early stages of decision making. Brainstorming is a popular technique for quickly generating ideas (Osborn, 1937). In this approach, a small group (of no more than 10 people) is given a problem to solve. The members are asked to generate as many ideas as possible. Members are told that no idea is too wild and are encouraged to build on the ideas submitted by others. No evaluation or criticism of the ideas is allowed until after the brainstorming session is finished. Buzz group analysis is a similar approach, more appropriate for large groups (Ellis and Fisher, 1994). Here, a large group is first divided into small groups of four to six members. Each small group goes through a brainstorming-like process to generate ideas. They then present their best ideas to the entire group for discussion. Other commonly applied idea-generating techniques include focus group analysis and group exercises intended to inspire creative thinking through role playing (Ellis and Fisher, 1994; Clemen, 1996).

The use of brainstorming and the other idea-generating methods mentioned above will normally provide a substantial amount of, in some cases, creative suggestions, especially when participants build on each other's ideas. However, personality factors and group dynamics can also lead to undesirable results. Simply put, some people are much more willing than others to participate in such exercises. Group discussions consequently tend to center around the ideas put forth by certain more forceful individuals. Group norms, such as deferring to participants with higher status and power, may also lead to undue emphasis on the opinions of certain members.

### 3.4.3  Nominal Group and Delphi Technique

Nominal group technique (NGT) and the Delphi technique attempt to alleviate some of the disadvantages of working in groups (Delbecq et al., 1975). The nominal group technique consists of asking each member of a group to write down and think about his or her ideas independently. A group moderator then asks each member to present one or more of his or her ideas. Once all

of the ideas have been posted, the moderator allows discussion to begin. After the discussion is finished, each participant rates or ranks the ideas presented. The subject ratings are then used to develop a score for each idea. Nominal group technique is intended to increase participation by group members and is based on the idea that people will be more comfortable presenting their ideas if they have a chance to think about them first (Delbecq et al., 1975).

The Delphi technique allows participants to comment anonymously, at their leisure, on proposals made by other group members. Normally, the participants do not know who proposed the ideas they are commenting on. The first step is to send an open-ended questionnaire to members of the group. The results are then used to generate a series of follow-up questionnaires in which more specific questions are asked. The anonymous nature of the Delphi process theoretically reduces the effect of participant status and power. Separating the participants also increases the chance that members will provide opinions "uncontaminated" by the opinions of others.

### 3.4.4 Structuring Group Decisions

As discussed earlier in this chapter, the field of decision analysis has devised several methods for organizing or structuring the decision-making process. The rational reflection model (Siebold, 1992) is a less formal, six-step procedure that serves a similar function. Group members are asked first to define and limit the problem by identifying goals, available resources, and procedural constraints. After defining and limiting the problem, the group is asked to analyze the problem, collect relevant information, and establish the criteria that a solution must meet. Potential solutions are then discussed in terms of the agreed-upon decision criteria. After further discussion, the group selects a solution and determines how it should be implemented. The focus of this approach is on forcing the group to confine its discussion to the issues that arise at each step in the decision-making process. As such, this method is similar to specifying an agenda.

Raiffa (1982) provides a somewhat more formal decision-analytic approach for structuring negotiations. The approach begins by assessing (1) the alternatives to a negotiated settlement, (2) the interests of the involved parties, and (3) the relative importance of each issue. This assessment allows the negotiators to think analytically about mutually acceptable solutions. In certain cases, a bargaining zone is available. For example, an employer may be willing to pay more than the minimum salary acceptable to a potential employee. In this case, the bargaining zone is the difference between the maximum salary the employer is willing to pay and the minimum salary a potential employee is willing to accept. The negotiator may also think about means of expanding the available resources to be divided, potential trading issues, or new options that satisfy the interests of the concerned parties.

Other methods for structuring group preferences are discussed in Keeney and Raiffa (1976). The development of group utility functions is one such approach.

A variety of computer-mediated methods for structuring group decisions are also available.

## 4 DECISION SUPPORT AND PROBLEM SOLVING

The preceding sections of this chapter have much to say about how to help decision makers make better decisions. To summarize that discussion briefly: (1) classical decision theory provides optimal prescriptions for how decisions should be made, (2) decision analysis provides a set of tools for structuring decisions and evaluating alternatives, and (3) studies of human judgment and decision making, in both laboratory settings and naturalistic environments, help identify the strengths and weaknesses of human decision makers. These topics directly mirror important elements of decision support. That is, decision support should have an objective (i.e., optimal or satisfactory choices, easier choices, more justifiable choices, etc.). Also, it must have a means (i.e., decision analysis or other method of decision support) and it must have a current state (i.e., decision quality, effort expended, knowledge, etc., of the supported decision makers). The effectiveness of decision support can then be defined in terms of how well the means move the current state toward the objective.

The focus of this section is on providing an overview of commonly used methods of computer-based decision support[*] for individuals, groups, and organizations. Throughout this discussion, an effort is made to address the objectives of each method of support and its effectiveness. Somewhat surprisingly, less information is available on the effectiveness of these approaches than might be expected given their prevalence (see also Yates et al., 2003), so the latter topic is not addressed in a lot of detail.

The discussion begins with a brief introduction to the field of decision analysis. Attention then shifts to the topics of decision support systems (DSSs), expert systems, and neural networks. These systems can be designed to support the intelligence, design, or choice phases of decision making (Simon, 1977). The intelligence phase involves scanning and searching the environment to identify problems or opportunities. The design phase entails formulating models for generating possible courses of action. The choice phase refers to finding an appropriate course of action for the problem

---

[*] Over the years, many different approaches have been developed for aiding or supporting decision makers (see von Winterfeldt and Edwards, 1986; Yates et al., 2003). Some of these approaches have already been covered earlier in this chapter and consequently are not addressed further in this section. In particular, decision analysis provides both tools and perspectives on how to structure a decision and evaluate alternatives. Decision analysis software is also available and commonly used. In fact, textbooks on decision analysis normally discuss the use of spreadsheets and other software; software may even be made available along with the textbook (e.g., see Clemen, 1996). Debiasing, discussed earlier in this chapter, is another technique for aiding or supporting decision makers.

or opportunity. Hence, the boundary between the design and choice phases is often unclear. Decision support systems and expert systems can be used to support all three phases of decision making, whereas neural networks tend to be better suited for design and choice phases. For example, DSSs can be designed to help with interpreting economic conditions, while expert systems can diagnose problems. Neural networks can learn a problem domain, after which they can serve as a powerful aid for decision making.

Attention then shifts to methods of supporting decisions by groups and organizations. The latter discussion first addresses the use by groups of DSSs and other tools similar to those used by individuals. In the sections that follow, we address approaches specifically designed for use by groups before briefly discussing the implications of problem-solving research for decision-making research.

## 4.1 Decision Analysis

The application of classical decision theory to improve human decision making is the goal of decision analysis (Howard, 1968, 1988; Raiffa, 1968; Keeney and Raiffa, 1976). Decision analysis requires inputs from decision makers, such as goals, preference and importance measures, and subjective probabilities. Elicitation techniques have consequently been developed that help decision makers provide these inputs. Particular focus has been placed on methods of quantifying preferences, trade-offs between conflicting objectives, and uncertainty (Raiffa, 1968; Keeney and Raiffa, 1976). As a first step in decision analysis, it is necessary to do some preliminary structuring of the decision, which then guides the elicitation process. The following discussion first presents methods of structuring decisions and then covers techniques for assessing subjective probabilities, utility functions, and preferences.

### 4.1.1 Structuring Decisions

The field of decision analysis has developed many useful frameworks for representing what is known about a decision (Howard, 1968; von Winterfeldt and Edwards, 1986; Clemen, 1996). In fact, these authors and others have stated that the process of structuring decisions is often the greatest contribution of going through the process of decision analysis. Among the many tools used, decision matrices and trees provide a convenient framework for comparing decisions on the basis of expected value or utility. Value trees provide a helpful method of structuring the sometimes complex relationships among objectives, attributes, goals, and values and are used extensively in multiattribute decision-making problems. Event trees, fault trees, inference trees, and influence diagrams are useful for describing probabilistic relationships between events and decisions. Each of these approaches is discussed briefly below.

***Decision Matrices and Trees***   Decision matrices are often used to represent single-stage decisions (Figure 4). The simplicity of decision matrices is their primary advantage. They also provide a very convenient

**Figure 4**   Decision matrix representation of a single-stage decision.

**Figure 5**   Decision tree representation of a single-stage decision.

format for applying the decision rules discussed in Section 2.1. Decision trees are also commonly used to represent single-stage decisions (Figure 5) and are particularly useful for describing multistage decisions (Raiffa, 1968). Note that in a multistage decision tree, the probabilities of later events are conditioned on the result of earlier events. This leads to the important insight that the results of earlier events provide information regarding future events.[*] Following this approach, decisions may be stated in conditional form. An optimal decision, for example, might be to do a market survey first, then market the product only if the survey is positive.

Analysis of a single- or multistage decision tree involves two basic steps, averaging out and folding back (Raiffa, 1968). These steps occur at chance and decision nodes, respectively.[†] *Averaging out* occurs when the expected value (or utility) at each chance node is calculated. In Figure 5 this corresponds to calculating the expected value of $A_1$ and $A_2$, respectively. *Folding back* refers to choosing the action with the greatest value expected at each decision node.

Decision trees thus provide a straightforward way of comparing alternatives in terms of expected value or SEU. However, their development requires significant simplification of most decisions and the provision of numbers, such as measures of preference and subjective probabilities, that decision makers may have difficulty determining. In certain contexts, decision makers struggling with this issue may find it helpful to develop value trees, event trees, or influence diagrams, as expanded on below.

---

[*] For example, the first event in a decision tree might be the result of a test. The test result then provides information useful in making the final decision.

[†] Note that the standard convention uses circles to denote chance nodes and squares to denote decision nodes (Raiffa, 1968).
**Figure 6**   Generic value tree.

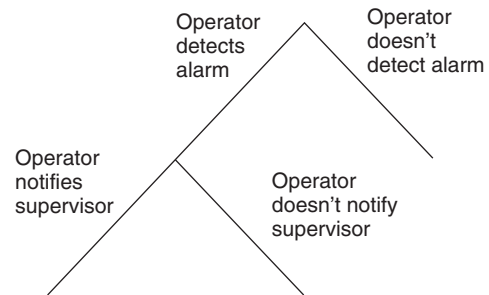
**Figure 7**   HRA event tree. (Adapted from Gertman and Blackman, 1994.)

***Value Trees***   Value trees hierarchically organize objectives, attributes, goals, and values (Figure 6). From this perspective, an objective corresponds to satisficing or maximizing a goal or set of goals. When there is more than one goal, the decision maker will have multiple objectives, which may differ in importance. Objectives and goals are both measured on a set of attributes. Attributes may provide (1) objective measures of a goal, such as when fatalities and injuries are used as a measure of highway safety; (2) subjective measures of a goal, such as when people are asked to rate the quality of life in the suburbs versus the city; or (3) proxy or indirect measures of a goal, such as when the quality of ambulance service is measured in terms of response time.

In generating objectives and attributes, it becomes important to consider their relevance, completeness, and independence. Desirable properties of attributes (Keeney and Raiffa, 1976) include:

1. *Completeness*: the extent to which the attributes measure whether an objective is met
2. *Operationality*: the degree to which the attributes are meaningful and feasible to measure
3. *Decomposability*: whether the whole is described by its parts
4. *Nonredundancy*: the fact that correlated attributes give misleading results
5. *Minimum size*: the fact that considering irrelevant attributes is expensive and may be misleading

Once a value tree has been generated, various methods can be used to assess preferences directly between the alternatives.

***Event Trees or Networks***   Event trees or networks show how a sequence of events can lead from primary events to one or more outcomes. Human reliability analysis (HRA) event trees are a classic example of this approach (Figure 7). If probabilities are attached to the primary events, it becomes possible to calculate the probability of outcomes, as illustrated in Section 4.1.2. This approach has been used in the field of risk assessment to estimate the reliability of human operators and other elements of complex systems (Gertman and Blackman, 1994).


Fault trees work backward from a single undesired event to its causes (Figure 8). Fault trees are commonly used in risk assessment to help infer the chance of an accident occurring (Hammer, 1993; Gertman and Blackman, 1994). Inference trees relate a set of hypotheses at the top level of the tree to evidence depicted at the lower levels. The latter approach has been used by expert systems such as Prospector (Duda et al., 1979). Prospector applies a Bayesian approach to infer the presence of a mineral deposit from uncertain evidence.

***Influence Diagrams and Cognitive Mapping***
Influence diagrams are often used in the early stages of a decision to show how events and actions are related. Their use in the early stages of a decision is referred to as *knowledge* (or *cognitive*) *mapping* (Howard, 1988). Links in an inference diagram depict causal and temporal relations between events and decision stages.[*] A link leading from event $A$ to event $B$ implies that the probability of obtaining event $B$ depends on whether event $A$ has occurred. A link leading from a decision to an event implies that the probability of the event depends on the choice made at that decision stage. A link leading from an event to a decision implies that the decision maker knows the outcome of the event at the time the decision is made.

One advantage of influence diagrams in comparison to decision trees is that influence diagrams show the relationships between events more explicitly. Consequently, influence diagrams are often used to represent complicated decisions where events interactively influence the outcomes. For example, the influence diagram in Figure 9 shows that the true state of the machine affects both the probability of the warning signal and the consequence of the operator's decision. This linkage would be hidden within a decision tree.[†] Influence

---

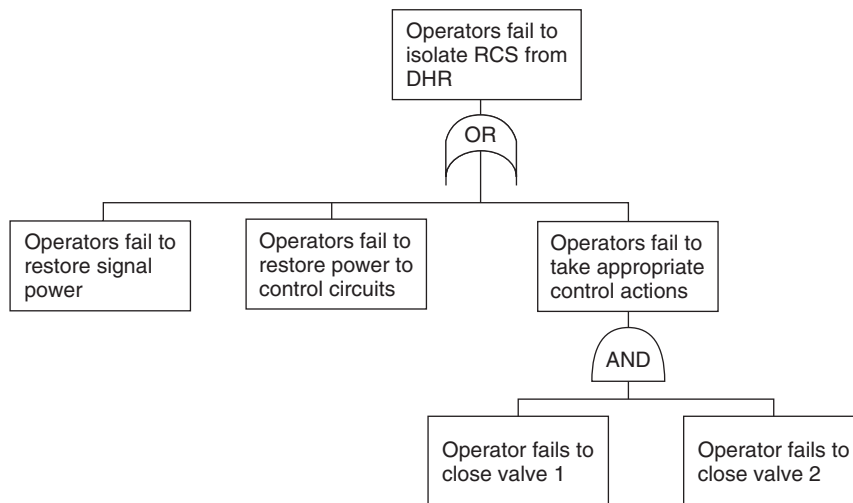
[*] As for decision trees, the convention for influence diagrams is to depict events with circles and decisions with squares.
[†] The conditional probabilities in a decision tree would reflect this linkage, but the structure of the tree itself does not show the linkage directly. Also, the decision tree would use the flipped probability tree using $P$(warning) at the first stage and $P$(machine down|warning) at the second stage. It seems more natural for operators to think about the problem in terms of $P$(machine down) and $P$(warning|machine down), which is the way the influence diagram in Figure 8 depicts the relationship.


**Figure 8** Fault tree for operators. (Adapted from Gertman and Blackman, 1994.)

**Figure 9** Influence diagram representation of a single-stage decision.

**Figure 10** Standard gamble used in the variable probability method of eliciting utility functions.

**Figure 11** Typical utility function.

diagrams have been used to structure medical decision-making problems (Holtzman, 1989) and are emphasized in modern texts on decision analysis (Clemen, 1996). Howard (1988) states that influence diagrams are the greatest advance he has seen in the communication, elicitation, and detailed representation of human knowledge. Part of the issue is that influence diagrams allow people who do not have deep knowledge of probability to describe complex conditional relationships with simple linkages between events. Once these linkages are defined, the decision becomes well defined and can be formally analyzed.

### 4.1.2 Utility Function Assessment

Standard methods for assessing utility functions (Raiffa, 1968) include (1) the variable probability method and (2) the certainty equivalent method. In the variable probability method, the decision maker is asked to give the value for the probability of winning at which they are indifferent between a gamble and a certain outcome (Figure 10). A utility function is then mapped out when the value of the certainty equivalent (CE) is changed over the range of outcomes. Returning to Figure 10, the value of $P$ at which the decision maker is indifferent

between the gamble and the certain loss of \$50 gives the value for $u(-\$50)$. In the utility function in Figure 11, the decision maker gave a value of about 0.5 in response to this question.

The certainty equivalent method uses lotteries in a similar way. The major change is that the probability of winning or losing the lottery is held constant while the amount won or lost is changed. In most cases the lottery provides an equal chance of winning and losing. The method begins by asking the decision maker to give a certainty equivalent for the original lottery ($CE_1$). The value chosen has a utility of 0.5. This follows since the utility of the best outcome is assigned a value of 1 and

the worst is given a utility of 0. The utility of the original gamble is therefore

$$u(\text{CE}_1) = pu(\text{best}) + (1-p)u(\text{worst})$$

$$= p(1) + (1-p)(0) = p = 0.5 \qquad (8)$$

The decision maker is then asked to give certainty equivalents for two new lotteries. Each uses the CE from the previous lottery as one of the potential prizes. The other prizes used in the two lotteries are the best and worst outcomes from the original lottery, respectively. The utility of the certainty equivalent $(\text{CE}_2)$ for the lottery using the best outcome and $\text{CE}_1$ is given by

$$u(\text{CE}_2) = pu(\text{best}) + (1-p)u(\text{CE}_1)$$

$$= p(1) + (1-p)(0.5) = 0.75 \qquad (9)$$

The utility of the certainty equivalent $(\text{CE}_3)$ given for the lottery using the worst outcome and $\text{CE}_1$ is given by

$$u(\text{CE}_3) = pu(\text{CE}_1) + (1-p)u(\text{worst})$$

$$= p(0.5) + (1-p)(0) = 0.25 \qquad (10)$$

This process is continued until the utility function is specified in sufficient detail. A problem with the certainty equivalent method is that errors are compounded as the analysis proceeds. This follows since the utility assigned in the first preference assessment [i.e., $u(\text{CE}_1)$] is used throughout the subsequent preference assessments. A second issue is that the CE method uses different ranges in the indifference lotteries, meaning that the CEs are compared against different reference values. This might create inconsistencies since, as discussed in Section 2.2, attitudes toward risk usually change depending on whether outcomes are viewed as gains or losses. The use of different reference points may, of course, cause the same outcome to be viewed as either a loss or a gain. Utilities may also vary over time. In Section 2.2.2, we discussed some of these issues further.

### 4.1.3 Preference Assessment

Methods for measuring strength of preference include indifference methods, direct assessment, and indirect measurement (Keeney and Raiffa, 1976; von Winterfeldt and Edwards, 1986). Indifference methods modify one of two sets of stimuli until subjects feel that they are indifferent between the two. Direct-assessment methods ask subjects to rate or otherwise assign numerical values to attributes, which are then used to obtain preferences for alternatives. Indirect-measurement techniques avoid decomposition and simply ask for preference orderings between alternatives. There has been some movement toward evaluating the effectiveness of particular methods for measuring preferences (Huber et al., 1993; Birnbaum et al., 1992). Each of these approaches are expanded upon below, and examples are given illustrating how they can be used.

***Indifference Methods***   Indifference methods are illustrated by the variable probability and certainty equivalent methods of eliciting utility functions presented in Section 2.1. There, indifference points were obtained by varying either probabilities or values of outcomes. Similar approaches have been applied to develop multiattribute utility or value functions. This approach involves four steps: (1) develop the single-attribute utility or value functions, (2) assume a functional form for the multiattribute function, (3) assess the indifference point between various multiattribute alternatives, and (4) calculate the substitution rate or relative importance of one attribute compared to the other. The single-attribute functions might be developed by indifference methods (i.e., the variable probability or certainty equivalent methods) or direct-assessment methods, as discussed later. Indifference points between multiattribute outcomes are obtained through an interactive process in which the values of attributes are increased or decreased systematically. Substitution rates are then obtained from the indifference points.

For example, consider the case for two alternative traffic safety policies, $A_1$ and $A_2$. Each policy has two attributes, $x =$ lives lost and $y =$ money spent. Assume that the decision maker is indifferent between $A_1$ and $A_2$, meaning the decision maker feels that $v(x_1, y_1) = v(20{,}000 \text{ deaths}; \$1 \text{ trillion})$ is equivalent to $v(x_2, y_2) = v(10{,}000 \text{ deaths}; \$1.5 \text{ trillion})$. For the sake of simplicity, assume an additive value function, where $v(x, y) = kv_x(x) + (1-k)v_y(y)$. Given this functional form, the indifference point $A_1 = A_2$ is used to derive the relation

$$(1-k)kv_x\,(20{,}000 \text{ deaths}) + kv_y\,(\$1 \times 10^{12})$$

$$= (1-k)v_x\,(10{,}000 \text{ deaths}) + kv_y\,(\$1.5 \times 10^{12}) \qquad (11)$$

This results in the substitution rate

$$\frac{k}{1-k} = \frac{v_x(20{,}000 \text{ deaths}) - v_x(10{,}000 \text{ deaths})}{v_y(\$1.5 \times 10^{12}) - v_y(\$1 \times 10^{12})} \qquad (12)$$

If $v_x = -x$ and $v_y = -y$, a value of approximately $2^{-5}$ is obtained for $k$. The procedure becomes somewhat more complex when nonadditive forms are assumed for the multiattribute function (Keeney and Raiffa, 1976).

***Direct-Assessment Methods***   Direct-assessment methods include curve-fitting and various numerical rating methods (von Winterfeldt and Edwards, 1986). Curve fitting is perhaps the simplest approach. Here, the decision maker first orders the various attributes and then simply draws a curve assigning values to them. For example, an expert might draw a curve relating levels of traffic noise (measured in decibels) to their level of annoyance (on a scale of $0-1$). Rating methods, as discussed earlier in reference to subjective probability assessment, include direct numerical measures on rating scales and relative ratings.

The analytic hierarchy process (AHP) provides one of the more implementable methods of this type (Saaty,

1990). In this approach, the decision is first structured as a value tree (Figure 6). Then each of the attributes is compared in terms of importance in a pairwise rating process. When entering the ratings, decision makers can enter numerical ratios (e.g., an attribute might be twice as important as another) or use the subjective verbal anchors mentioned earlier in reference to subjective probability assessment. The AHP program uses the ratings to calculate a normalized eigenvector assigning importance or preference weights to each attribute. Each alternative is then compared on the separate attributes. For example, two houses might first be compared in terms of cost and then be compared in terms of attractiveness. This results in another eigenvector describing how well each alternative satisfies each attribute. These two sets of eigenvectors are then combined into a single vector that orders alternatives in terms of preference. The subjective multiattribute rating technique (Smart) developed by Edwards (see von Winterfeldt and Edwards, 1986) provides a similar, easily implemented approach. Both techniques are computerized, making the assessment process relatively painless.

Direct-assessment approaches have been relied on extensively by product designers who would like to improve perceived product quality. For example, the automotive industry in the United States has for many years made extensive use of a structured approach for improving product quality called quality function deployment (QFD). QFD is defined as "converting the consumers' demands into quality characteristics and developing a design quality for the finished product by systematically deploying the relationships between the demands and the characteristics, starting with the quality of each functional component and extending the deployment to the quality of each part and process" (Akao, 2004, p. 5). The House of Quality in Figure 12 succinctly represents how QFD works though QFD is not a mere diagram, but more likely a quality improvement procedure. The matrix located at the center of Figure 12 combines the customer attributes (or consumers' demands) as rows and engineering characteristics as columns. By associating these two sets of attributes using a matrix, it is possible to identify which characteristics in a product should be improved in order to increase consumer satisfaction. On the top of the engineering characteristic, another diagonal matrix, which resembles a roof top of a house, shows the relationships between different engineering characteristics. Sometimes, two engineering characteristics can be improved together, but other times two engineering characteristics conflict (e.g., power vs. fuel efficiency of an automobile). Understanding the relationship between engineering characteristics could help informed decision making.

In order to capture the customer attributes (or consumers' needs), various methods have been used. First, the most important segment of users is usually defined, and analyzing existing customer databases and conducting a market survey using focus group, interview, and survey studies. As showing in Figure 12, consumers' needs are often described in their own words, such as "Easy to close from outside." These descriptions could be fuzzy, and fuzzy set theory could help quantify fuzziness, so that further quantitative analysis could be done (Lehto and Buck, 2007).

More recently, Web technologies have been used to efficiently collect customer ratings collectively, which is called collective filtering (e.g., Rashid et al., 2002; Schafer et al., 2001). These techniques have been actively applied to e-commerce websites, such as amazon.com and netflix.com.

***Indirect Measurement*** Indirect-measurement techniques avoid asking people to rate or rank directly the importance of factors that affect their preferences. Instead, subjects simply state or order their preferences for different alternatives. A variety of approaches can then be used to determine how individual factors influence preference.

Conjoint analysis provides one such approach for separating the effects of multiple factors when only their joint effects are known. Conjoint analysis is "a technique for measuring trade-offs for analyzing survey responses concerning preferences and intentions to buy, and it is a method for simulating how consumers might react to changes in current products or to new products introduced into an existing competitive array" (Green et al., 2001, p. S57). It has been successful in both academia and industry (Green et al., 2001) to understand preferences and intentions of consumers. For example, Marriott's Courtyard Hotels (Wind et al., 1989) and New York EZ-Pass system (Vavra et al., 1999) were designed using conjoint analysis approaches, both of which illustrated the utility of conjoint analysis.

There are different types of conjoint analysis. One of the simplest types is full-profile studies. In a full-profile study, profiles of a product (e.g., home) having relatively small number of attributes (four to five) are shown to a survey respondent, so that he or she can sort or rate the profiles based on attributes. The order or rating scores of profiles is used to investigate which attributes are more likely to influence the respondent's decision. Figure 13 shows examples of profiles.

Since each attribute could have multiple levels and profiles should cover all combinations comprehensively, even with a small number of attributes, the number of profiles that a respondent needs to compare with could be exponentially increased. For example, if each of five attributes has three levels, the number of profiles becomes 243 ($= 3^5$). This combinatorial nature restricts the number of attributes in full-profile studies. Common solutions to this problem are to use a partial set of profiles (Green and Krieger, 1990) or to ask a respondent what are more important attributes or which levels of attributes are more desired to decrease the number of profiles (Green and Krieger, 1987). More recent advances include adaptive conjoint analysis (Huber and Zwerina, 1996) and fast polyhedral adaptive conjoint estimation (Toubia et al., 2003), both of which cut down the number of questions in a conjoint analysis adaptively using respondent's responses. Related applications include the dichotomy-cut method, used to obtain decision rules for individuals and groups from ordinal rankings of multiattribute alternatives (Stanoulov, 1994).

However, in spite of its success and evolution of over three decades, conjoint analysis still has room

for improvement (Bradlow, 2005). Respondents may change their preference structure, but this aspect has not been systematically considered in many conjoint analysis studies. Conjoint analysis often burdens research participants by asking too many questions though various techniques (e.g., adaptive conjoint analysis and choice-based conjoint analysis) have been suggested to cut down the number of questions to be answered. Findings in behavioral research have not been fully reflected in conjoint analysis, yet. In other words, consumers actually use various heuristics and strategies to cut down the number of candidates (or profiles in the context of conjoint analysis), but many studies in conjoint analysis do not accommodate these aspects.

The *policy-capturing approach* used in social judgment theory (Hammond et al., 1975; Hammond, 1993) is another indirect approach for describing human judgments of both preferences and probability. The policy-capturing approach uses multivariate regression or similar techniques to relate preferences to attributes for one or more decision makers. The equations obtained correspond to policies followed by particular decision makers. An example equation might relate medical symptoms to a physician's diagnosis. It has been argued that the policy-capturing approach measures the influence of factors on human judgments more accurately than do decomposition methods. Captured weights might be more accurate because decision makers may have little insight into the factors that affect their judgments (Valenzi and Andrews, 1973). People may also weigh certain factors in ways that reflect social desirability rather than influence on their judgments (Brookhouse et al., 1986). For example, people comparing jobs might rate pay as being lower in importance than intellectual challenge, whereas their preferences between jobs might be predicted entirely by pay. Caution must also be taken when interpreting regression weights as indicating importance, since regression coefficients are influenced by correlations between factors, their variability, and their validity (Stevenson et al., 1993).

There has been some movement toward evaluating the effectiveness of particular methods for measuring preferences (Birnbaum et al., 1992; Huber et al., 1993). However, the validity of direct versus indirect assessment is one area of continuing controversy. One conclusion that might be drawn is that it is not clear that any of the quantitative methods described above have adequate descriptors, factors, and methods to account for the dynamic characteristics (e.g., emerging consumer knowledge and reactions between competing opinions) of complex issues, such as making decisions about energy sources and consumption patterns responding to climate change and environmental concerns.

## 4.2 Individual Decision Support

The concept of DSSs dates back to the early 1970s. It was first articulated by Little (1970) under the term *decision calculus* and by Scott-Morton (1977) under the term *management decision systems*. DSSs are interactive computer-based systems that help decision makers utilize *data* and *models* to solve unstructured or semistructured problems (Scott-Morton, 1977; Keen and Scott-Morton, 1978). Given the unstructured nature of these problems, the goal of such systems is to *support*, rather than replace, human decision making.

The three key components of a DSS are (1) a model base, (2) a database, and (3) a user interface. The model base comprises quantitative models (e.g., financial or statistical models) that provide the analysis capabilities of DSSs. The database manages and organizes the data in meaningful formats that can be extracted or queried. The user interface component manages the dialogue or interface between the DSS and the users. For example, visualization tools can be used to facilitate communication between the DSS and the users.

DSSs are generally classified into two types: model driven and data driven. *Model-driven DSSs* utilize a collection of mathematical and analytical models for the decision analysis. Examples include forecasting and planning models, optimization models, and sensitivity analysis models (i.e., for asking "what-if" questions). The analytical capabilities of such systems are powerful because they are based on strong theories or models. On the other hand, *data-driven DSSs* are capable of analyzing large quantities of data to extract useful information. The data may be derived from transaction-processing systems, enterprise systems, data warehouses, or Web

warehouses. Online analytical processing and data mining can be used to analyze the data. Multidimensional data analysis enables users to view the same data in different ways using multiple dimensions. The dimensions could be product, salesperson, price, region, and time period. *Data mining* refers to a variety of techniques that can be used to find hidden patterns and relationships in large databases and to infer rules from them to guide decision making and predict future behavior. Data mining can yield information on associations, sequences, classifications, clusters, and forecasts (Laudon and Laudon, 2003). *Associations* are occurrences linked to a single event (e.g., beer is purchased along with diapers); *sequences* are events linked over time (e.g., the purchase of a new oven after the purchase of a house). *Classifications* refer to recognizing patterns and rules to categorize an item or object into its predefined group (e.g., customers who are likely to default on loans); *clustering* refers to categorizing items or objects into groups that have yet been defined (e.g., identifying customers with similar preferences). Data mining can also be used for forecasting (e.g., projecting sales demand).

Despite the popularity of DSSs not a lot of data are available documenting that they improve decision making (Yates et al., 2003). It does seem logical that DSSs should play a useful role in reducing biases (see Section 2.2.2) and otherwise improving decision quality. This follows because a well-designed DSS will increase both the amount and quality of information available to the decision maker. A well-designed DSS will also make it easier to analyze the information with sophisticated modeling techniques. Ease of use is another important consideration. As discussed earlier, Payne et al. (1993) identify two factors influencing the selection of a decision strategy: (1) cognitive effort required of a strategy in making the decision and (2) the accuracy of the strategy in yielding a "good" decision. Todd and Benbasat (1991, 1992) found that DSS users adapted their strategy selection to the type of decision aids available in such a way as to reduce effort. In other words, effort minimization is a primary or more important consideration to DSS users than is the quality of decisions. More specifically, the role of effort may have a direct impact on DSS effectiveness and must be taken into account in the design of DSSs.

In a follow-up study, Todd and Benbasat (1999) studied the moderating effect of incentives and cognitive effort required to utilize a more effortful decision strategy that would lead to a better decision outcome (i.e., additive compensatory vs. elimination by aspects; the former strategy requires more effort but leads to a better outcome). Although the results show that the level of incentives has no effect on decision strategy, the additive compensatory (i.e., 'better') strategy was used more frequently when its level of support was increased from no or little support to moderate or high support. The increased support decreased the amount of effort needed to utilize the additive compensatory strategy, thus inducing a strategy change. When designing DSSs, effort minimization should be given considerable attention, as it can drive the choice of decision strategy, which in turn influences the decision accuracy.

### 4.2.1 Expert Systems

Expert systems are developed to capture knowledge for a very specific and limited domain of human expertise. Expert systems can provide the following benefits: cost reduction, increased output, improved quality, consistency of employee output, reduced downtime, captured scarce expertise, flexibility in providing services, easier operation of equipment, increased reliability, faster response, ability to work with incomplete and uncertain information, improved training, increased ability to solve complex problems, and better use of expert time.

Organizations routinely use expert systems to enhance the productivity and skill of human knowledge workers across a spectrum of business and professional domains. They are computer programs capable of performing specialized tasks based on an understanding of how human experts perform the same tasks. They typically operate in narrowly defined task domains. Despite the name *expert systems*, few of these systems are targeted at replacing their human counterparts; *most of them are designed to function as assistants or advisers to human decision makers*. Indeed, the most successful expert systems—those that actually address mission-critical business problems—are not "experts" as much as "advisors" (LaPlante, 1990).

An expert system is organized in such a way that the knowledge about the problem domain is separated from general problem-solving knowledge. The collection of domain knowledge is called the *knowledge base*, whereas the general problem-solving knowledge is called the *inference engine*. The knowledge base stores domain-specific knowledge in the form of facts and rules. The inference engine operates on the knowledge base by performing logical inferences and deducing new knowledge when it applies rules to facts. Expert systems are also capable of providing explanations to users.

Examples of expert systems include the Plan Power system used by the Financial Collaborative for financial planning (Sviokla, 1989), Digital's XCON for computer configurations (Sviokla, 1990), and Baroid's MUDMAN for drilling decisions (Sviokla, 1986). As pointed out by Yates et al. (2003), the large number of expert systems that are now in actual use suggests that expert systems are by far the most popular form of computer-based decision support. However, as for DSSs, not a lot of data are available showing that expert systems improve decision quality. Ease of use is probably one of the main reasons for their popularity. This follows, because the user of an expert system can take a relatively passive role in the problem-solving process. That is, the expert system asks a series of questions which the user simply answers if he or she can. The ability of most expert systems to answer questions and explain their reasoning can also help users understand what the system is doing and confirm the validity of the system's recommendations. Such give and take may make users more comfortable with an expert system than they are with models that make sophisticated mathematical calculations that are difficult to verify.

### 4.2.2 Neural Networks

Neural networks consist of hardware or software that is designed to emulate the processing patterns of the biological brain. There are eight components in a neural network (Rumelhart et al., 1986):

1. A set of *processing units*
2. A *state of activation*
3. An *output function* for each unit
4. A *pattern of connectivity* among units
5. A *propagation rule* for propagating patterns of activities through the network
6. An *activation rule* for combining inputs impinging on a unit with its current state
7. A *learning* (or training) rule to modify patterns of connectivity
8. An *environment* within which the system must operate

A neural network comprises many interconnected processing elements that operate in parallel. One key characteristic of neural networks is their ability to learn. There are two types of learning algorithms: supervised learning and unsupervised learning. In supervised learning, the desired outputs for each set of inputs are known. Hence, the neural network learns by adjusting its weights in such a way that it minimizes the difference between the desired and actual outputs. Examples of supervised learning algorithms are back-propagation and the Hopfield network. Unsupervised learning is similar to cluster analysis in that only input stimuli are available. The neural network self-organizes itself to produce clusters or categories. Examples of unsupervised learning algorithms are adaptive resonance theory and Kohenen self-organizing feature maps.

By applying a training set such as historical cases, learning algorithms can be used to teach a neural network to solve or analyze problems. The outputs or recommendations from the system can be used to support human decision making. For example, neural networks have been developed to predict customer responses to direct marketing (Cui and Wong, 2004), to forecast stock returns (Olson and Mossman, 2003; Sapena et al., 2003; Jasic and Wood, 2004), to assess product quality in the metallurgical industry (Zhou and Xu, 1999), and to support decision making on sales forecasting (Kuo and Xue, 1998).

### 4.2.3 Visual Analytics

As the amount and complexity of available information ever grows, selecting and understanding relevant information become more and more challenging. For example, in the financial market, a decision maker should not only deal with numerous market indices for stock prices, bonds, futures, and so on, but also understand nonnumerical information about market trends and business rumors. Since such information is constantly created, and their historical aspects are also important, it is very challenging to keep up with such information

deluge and make an informed decision. Information deluge is actually a universal problem in other domains: physics and astronomy, environmental monitoring, disaster and emergency management, security, software analytics, biology, medicine, health, and personal information management (Keim et al., 2008b).

In order to deal with massive, complex, and heterogeneous information, attempts to utilize the highest bandwidth human sensory channel, *vision*, have been made. Thus, "visual analytics" has been recently proposed as a separate research field. A commonly accepted definition of visual analytics is "the science of analytical reasoning facilitated by interactive visual interfaces" (Thomas and Cook, 2005, p. 4). More specifically, Keim et al. (2008a, p. 4) detailed the goal of visual analytics as follows:

- Synthesize information and derive insight from massive, dynamic, ambiguous, and often conflicting data.
- Detect the expected and discover the unexpected.
- Provide timely, defensible, and understandable assessments.
- Communicate assessment effectively for action.

Obviously, visual analytics is largely overlapped with many disciplines, such as information visualization, human factors, data mining and management, decision making, and statistical analysis, to name a few. Keim et al. (2008b) especially pointed out the crucial role of human factors to understand interaction, cognition, perception, collaboration, presentation, and dissemination issues in employing visual analytics.

There have been some early successes in this endeavor. Jigsaw (Stasko et al., 2008) and IN-SPIRE (http://in-spire.pnl.gov/) are visual analytics tools to support investigative analysis on text data, such as investigative reports for potential terrorists. VisAware (Livnat et al., 2005) was built to raise situation awareness in the context of network intrusion detection. Map of the Market (Wattenberg, 1999) and FinDEx (Keim et al., 2006) are visualization techniques to analyze the stock market and assets. Figure 14 shows a screen shot of Map of the Market, which shows increases and decreases of stock prices in color encoding and market capitalization in size encoding. It also supports details on demand through simple interaction (e.g., a user can drill down to a specific market segment by selecting a pop-up menu item).

In spite of these interesting and successful examples, researchers in visual analytics run into several challenges. Some of visual analytic tools utilize quite complex visualization techniques which may not be intuitively understood by non-visualization-savvy users. The lack of comprehensive guidelines on how to create intuitive visualization techniques has long been a problem. Evaluating visual analytic tools has also been challenging (Plaisant, 2004). Visual analytics tasks tend to require high-level expertise and are dynamic, complex, and uncertain. Hence, investigating the effectiveness of visual analytic tools is very time-consuming and ambiguous. These problems are being further aggravated
**Figure 14** Screen Shot of Map of the Market taken on July 15, 2010.

by an explosive growth of information. Though visual analytic approaches help users deal with larger data sets, the rapid growth in the volume of information is challenging to keep up. For a more comprehensive list of challenges, refer to Keim et al. (2008b), Thomas and Cook (2005), and Thomas and Kielman (2009).

### 4.2.4 Other Forms of Individual Decision Support

Other forms of individual decision support can be developed using fuzzy logic, intelligent agents, case-based reasoning, and genetic algorithms. *Fuzzy logic* refers to the use of membership functions to express imprecision and an approach to approximate reasoning in which the rules of inference are approximate rather than exact. Garavelli and Gorgoglione (1999) used fuzzy logic to design a DSS to improve its robustness under uncertainty, and Coma et al. (2004) developed a fuzzy DSS to support a design for assembly methodology. Collan and Liu (2003) combined fuzzy logic with agent technologies to develop a fuzzy agent–based DSS for capital budgeting. *Intelligent agents* use built-in or learned rules to make decisions. In a multiagent marketing DSS, the final solution is obtained through cooperative and competitive interactions among intelligent agents acting in a distributed mode (Aliev et al., 2000). Intelligent agents can also be used to provide real-time decision support on airport gate assignment (Lam et al., 2003). *Case-based reasoning*, which relies on past cases to derive at a decision, has been used by Lari (2003) to assist in making corrective and preventive actions for solving quality problems and by Belecheanu et al. (2003) to support decision making on new product development. *Genetic algorithms* are robust algorithms that can search through large spaces quickly by mimicking the Darwinian "survival of the fittest" law. They can be used to increase the effectiveness of simulation-based DSSs (Fazlollahi and Vahidov, 2001).

### 4.3 Group and Organizational Decision Support

Computer tools have been developed to assist in group and organizational decision making. Some of them implement the approaches discussed in Section 3. The spectrum of such tools ranges from traditional tools used in decision analysis, such as the analytic hierarchy process (Saaty, 1990; Basak and Saaty, 1993), to electronic meeting places or group DSSs (DeSanctis and Gallupe, 1987; Nunamaker et al., 1991), to negotiation support systems (Bui et al., 1990; Lim and Benbasat, 1993). We will discuss the use of individual decision support tools for group support, group DSSs, negotiation support systems, enterprise system support, and other forms of group and organizational support.

### 4.3.1 Using Individual Decision Support Tools for Group Support

Traditional single-user tools can be used to support groups in decision making. A survey by Satzinger and Olfman (1995) found that traditional single-user tools were perceived by groups to be more useful than group support tools. Sharda et al. (1988) assessed the effectiveness of a DSS for supporting business simulation games and found that groups with access to the DSS made significantly more effective decisions than their non-DSS counterparts. The DSS groups took more time to make their decisions than the non-DSS groups at the beginning of the experiment, but decision times converged in a later period. The DSS teams also exhibited a higher confidence level in their decisions than the non-DSS groups. Knowledge-based systems (or expert support systems) are effective in supporting group decision making, particularly so with novices than experts (Nah and Benbasat, 2004). Groups using the system also make better decisions than individuals provided with the same system (Nah et al., 1999). Hence, empirical findings have shown that traditional single-user tools can be effective in supporting group decision making.

### 4.3.2 Group Decision Support Systems

Group decision support systems (GDSSs) combine communication, computing, and decision support technologies to facilitate formulation and solution of unstructured problems by a group of people (DeSanctis and Gallupe, 1987). DeSanctis and Gallupe defined three levels of GDSS. Level 1 GDSSs provide technical features aimed at removing common communication barriers, such as large screens for instantaneous display of ideas, voting solicitation and compilation, anonymous input of ideas and preferences, and electronic message exchange among members. In other words, a level 1 GDSS is a communication medium only. Level 2 GDSSs provide decision modeling or group decision techniques aimed at reducing uncertainty and "noise" that occur in the group's decision process. These techniques include automated planning tools [e.g., project evaluation review technique (PERT), critical path method (CPM), Gantt], structured decision aids for the group process (e.g., automation of Delphi, nominal, or other idea-gathering and compilation techniques), and decision analytic aids for the task (e.g., statistical methods, social judgment models). Level 3 GDSSs are characterized by machine-induced group communication patterns and can include expert advice in the selecting and arranging of *rules* to be applied during a meeting. To date, there has been little research in level 3 GDSSs because of the difficulty and challenges in automating the process of group decision making.

GDSSs facilitate computer-mediated group decision making and provide several potential benefits (Brashers et al., 1994), including (1) enabling all participants to work simultaneously (e.g., they don't have to wait for their turn to speak, thus eliminating the need to compete for air time), (2) enabling participants to stay focused and be very productive in idea generation (i.e., eliminating production blocking caused by attending to others), (3) providing a more equal and potentially anonymous opportunity to be heard (i.e., reducing the negative effects caused by power distance), and (4) providing a more systematic and structured decision-making environment (i.e., facilitating a more linear

process and better control of the agenda). GDSSs also make it easier to control and manage conflict through the use of facilitators and convenient voting procedures.

The meta-analysis by Dennis et al. (1996) suggests that, in general, GDSSs improve decision quality, increase time to make decisions, and have no effect on participant satisfaction. They also found that larger groups provided with a GDSS had higher satisfaction and experienced greater improvement in performance than smaller groups with GSSs. The findings from McLeod's (1992) and Benbasat and Lim's (1993) meta-analyses show that GDSSs increase decision quality, time to reach decisions, and equality of participation but decrease consensus and satisfaction. To resolve inconsistencies in the GDSS literature (such as those relating to satisfaction), Dennis and his colleagues (Dennis et al., 2001; Dennis and Wixom, 2002) carried out further meta-analyses to test a fit–appropriation model and identify further moderators for these effects. The result shows that both fit (between GSS structures and task) and appropriation support (i.e., training, facilitation, and software restrictiveness) are necessary for GDSSs to yield an increased number of ideas generated, reduce the time taken for the task, and increase satisfaction of users (Dennis et al., 2001). The fit–appropriation profile is adapted from Zigurs and Buckland (1998).

Computer-supported collaborative systems provide features beyond GDSSs, such as project and calendar management, group authoring, audio and video conferencing, and group and organizational memory management. They facilitate collaborative work beyond simply decision making and are typically referred to as computer-supported collaborative work. These systems are particularly helpful for supporting group decision making in a distributed and asynchronous manner.

### 4.3.3 Negotiation Support Systems

Negotiation support systems (NSSs) are used to assist people in activities that are competitive or involve conflicts of interest. The need for negotiation can arise from differences in interest or in objectives or even from cognitive limitations. To understand and analyze a negotiation activity, eight elements must be taken into account (Holsapple et al., 1998): (1) the issue or matter of contention, (2) the set of participants involved, (3) participants' regions of acceptance, (4) participants' location (preference) within the region of acceptance, (5) strategies for negotiation (e.g., coalition), (6) participants' movements from one location to another, (7) rules of negotiation, and (8) assistance from an intervenor (e.g., mediator, arbitrator, or facilitator). NSSs should be designed with these eight components in mind by supporting these components.

The configuration of basic NSSs comprises two main components (Lim and Benbasat, 1993): (1) a DSS for each negotiating party and (2) an electronic linkage between these systems to enable electronic communication between the negotiators. Full-feature session-oriented NSSs should also offer group process structuring techniques, support for an intervenor, and documentation of the negotiation (Foroughi, 1998). Nego-Plan is an expert system shell that can be used

to represent negotiation issues and decompose negotiation goals to help analyze consequences of negotiation scenarios (Matwin et al., 1989; Holsapple and Whinston, 1996). A Web-based NSS called Inspire is used in teaching and training (Kersten and Noronha, 1999). Espinasse et al. (1997) developed a multiagent NSS architecture that can support a mediator in managing the negotiation process. To provide comprehensive negotiation support, NSSs should provide features of level 3 GDSSs, such as the ability to (1) perform analysis of conflict contingencies, (2) suggest appropriate process structuring formats or analytical models, (3) monitor the semantic content of electronic communications, (4) suggest settlements with high joint benefits, and (5) provide automatic mediation (Foroughi, 1998). In general, NSSs can support negotiation either by assisting participants or by serving as a participant (intervenor).

### 4.3.4 Enterprise Systems for Decision Support

Enterprise-wide support can be provided by enterprise systems (ESs) and executive support systems (ESSs) (Turban and Aronson, 2001). ESSs are designed to support top executives, whereas ESs can be designed to support top executives or to serve a wider community of users. ESSs are comprehensive support systems that go beyond flexible DSSs by providing communication capabilities, office automation tools, decision analysis support, advanced graphics and visualization capabilities, and access to external databases and information in order to facilitate business intelligence and environmental scanning. For example, intelligent agents can be used to assist in environmental scanning.

The ability to use ESs, also known as enterprise resource planning (ERP) systems, for decision support is made possible by data warehousing and online analytical processing. ESs integrate all the functions as well as the transaction processing and information needs of an organization. These systems can bring significant competitive advantage to organizations if they are integrated with supply chain management and customer relationship management systems, thus providing comprehensive information along the entire value chain to key decision makers and facilitating their planning and forecasting. Advanced planning and scheduling packages can be incorporated to help optimize production and ensure that the right materials are in the right warehouse at the right time to meet customers' demands (Turban and Aronson, 2001).

### 4.3.5 The Wisdom of Crowds

Surowiecki (2004) popularized the concept of the wisdom of crowds through his book *The Wisdom of Crowds: Why the Many Are Smarter Than the Few*, which argues that the aggregation of information or opinions of crowds could result in better decisions than those of expert individuals or groups. The example that Surowiecki used to open his book is Galton's surprising result at a weight-judging competition of a dressed ox at the annual show of the West of England Fat Stock and Poultry Exhibition (Galton, 1907). Galton analyzed the 787 collected votes for the competition and found

that the median of the votes was 1207 lb, which was just 9 lb off from the true value, 1198 lb, which showed the power of aggregated information. Similar evidence has been collected in many other cases, such as locating a lost submarine, predicting the winner in sports betting, and predicating the future in investigative organizations (Surowiecki, 2004).

However, simply collecting opinions of crowds does not guarantee a better decision. The wisdom of crowds breaks down in the following situations (Surowiecki, 2004): (1) when the crowd becomes homogeneous, crowds fail to collect information from diverse perspectives. (2) when an organization is too centralized or too divided, it fails to collect information from individual members who directly confront the situation, and the collected information cannot be communicated within the organization. (3) when individuals in the crowd imitate others' opinions or are emotionally influenced by others, only a few members in the crowd play as information collectors or decision makers. Thus, Surowiecki suggests that the wisdom of crowds functions properly when the crowd has the following characteristics: diversity of opinions, independence, decentralization, and a mechanism to aggregate information.

There have been efforts to construct functioning crowds more systematically. The prediction market (also known as information market, decision market, and event future) is a market to predict future events using a similar mechanism of the financial market (Wolfers and Zitzewitz, 2004). For example, a betting exchange, Tradesports.com, listed a security paying $100 if the head of the Defense Advanced Research Projects Agency (DARPA), Admiral John Poindexter, resigned by the end of August 2003. The price of the security reflected the possibility of the event, so it fluctuated as more information was collected. This prediction market provides a platform to collect information from individuals with proper incentives. Various studies also reported that these prediction markets are extremely accurate (Berg et al., 2008), and it has been actively applied to various areas, such as predicting influenza outbreaks (Holden, 2007).

### 4.3.6 Other Forms of Group and Organizational Decision Support

We have discussed how individual decision support tools, GDSSs, NSSs, ESSs, and ESs can facilitate and support group and organizational decision making. Other techniques drawn from the field of artificial intelligence, such as neural networks, expert systems, fuzzy logic, genetic algorithms, case-based reasoning, and intelligent agents, can also be used to enhance the decision support capabilities of these systems. It should also be noted that knowledge management practices can benefit groups and organizations by capitalizing on existing knowledge to create new knowledge, codifying existing knowledge in ways that are readily accessible to others, and facilitating knowledge sharing and distribution throughout an enterprise (Davenport and Prusak, 2000). Since knowledge is a key asset of organizations and is regarded as the only source of sustainable

competitive strength (Drucker, 1995), the use of technologies for knowledge management purposes is a high priority in most organizations. For example, knowledge repositories (e.g., intranets) can be created to facilitate knowledge sharing and distribution, focused knowledge environments (e.g., expert systems) can be developed to codify expert knowledge to support decision making, and knowledge work systems (e.g., computer-aided design, virtual reality simulation systems, and powerful investment workstations) can be used to facilitate knowledge creation. By making existing knowledge more available, these systems can help groups and organizations make more informed and better decisions.

### 4.4 Problem Solving

Though problem solving is so commonly used, defining it is not an easy task (Hunt, 1998). Problem solving can be "understood as the bridging of the gap between an initial state of affairs and a desired state where no predetermined operation or strategy is known to the individual" (Öllinger and Goel, 2010, p. 4), and most definitions of problem solving attempted so far include three core components: an initial state, a goal state, and paths between the two states (Mayer, 1983). The path is often unknown, so problem solving is largely an activity to search for the path. However, these descriptions and characterization do not clearly specify what problem solving is and is not. Problem solving deals with various topics, which include, but are not limited to, reading, writing, calculation, managerial problem solving, problem solving in electronics, game playing (e.g., chess), and problem solving for innovation and inventions (Sternberg and Frensch, 1991). Some problems are structured (e.g., Tower of Hanoi), but others are ill-structured (e.g., preparing good dinner for guests) (Reitman, 1964). Thus, we might need an even more inclusive definition of problem solving, as Anderson et al. (1985) suggested: any goal-directed sequence of cognitive operations.

As problem solving includes a wide spectrum of topics, clearly drawing the boundary between problem solving and decision making is almost meaningless. Though Simon et al. (1987) provided elegant separation of two fields of research (i.e., problem solving covers fixing agendas, settings goals, and designing actions while decision making covers evaluating and choosing), one can easily argue against the division. Virtually all decision-making activities could be problem solving since decision making is an activity from a state of not having a selection toward a state with a selection. Conversely, some activities of problem solving, choosing a path out of potential paths or generating alternatives, would be considered as activities of decision making. Thus, it would be more appropriate to see that decision making and problem solving are largely overlapped, and suggesting a theoretical distinction between problem solving and decision making may not be fruitful. Kepner and Tregoe (1976) even said that problem solving and decision making are often used interchangeably.

In spite of the fuzzy boundary between the two fields, decision making and problem solving have

distinctive lineages. While decision-making research has been largely led by economists, statisticians, and mathematicians until descriptive approaches become more prominent, problem solving has a relatively longer and distinctive history of research mainly done by psychologists (Simon et al., 1987). Due to this difference, researchers in problem solving introduced several interesting research methods.

An interesting and seminal contribution of research in problem solving in understanding human mind is the results of tight collaboration between psychologists and computer scientists. After seminal work done by Simon (1955), information-processing theory provided a foundation for this endeavor. The main contribution was the emphasis on detailed task analysis and the clear computation characterization of the problem space (Öllinger and Goel, 2010). Newell later published unified theory of cognition (UTC) (1994), which emphasized the importance of unified architecture that includes existing research results in psychology and cognitive science. UTC initiated the implementation and evolution of various cognitive architectures, such as SOAR (Laird et al., 1987), ACT-R (Anderson, 1993; Anderson and Lebiere, 1998), and EPIC (Meyer and Kieras, 1997a, 1997b). These cognitive architectures have expedited the research of problem solving and the human mind (Anderson and Douglass, 2001), and they are also applied to various areas (e.g., aviation, vehicle design, and human–computer interactions).

Another interesting approach is applying neuroimaging techniques, such as electroencephalography (EEG) and functional magnetic resonance imaging (fMRI), to physiologically understand how people solve problems, especially ill-structured problems and insight problems. As briefly discussed, there are problems that do not have complete information in each component of problem solving (e.g., preparing a good meal for dinner and understanding creativity), which is called an ill-structured problem (Reitman, 1964). Goel (1995) argued that ill-structured problem solving involves different phases of problem solving (i.e., problem scoping, preliminary solutions, refinement, and detailing of solutions) and showed, using brain imaging techniques, that different parts of the brain are associated with these different types of computations required for these phases (Goel and Morrison, 2005). Insight problem solving has also fascinated many cognitive scientists and psychologists because of its interesting nature. Insight problems are often solved through very few steps in a path, but identifying the path turns out to be very difficult. The compound remote association (CRA) problem is an example of insight problems: "Each of the three words in (a) can form a compound word or two-word phrase with the solution word. The solution word can come before or after any of the problem words: boot, summer, ground" (Bowden et al., 2005, p. 324). The answer to this problem is "camp." Bowden et al. (2005) provided a neurophysiological account of the A-ha! moment using fMRI and EEG data while people solve CRA problems. They revealed that a certain region of the brain, the anterior superior temporal gyrus (aSTG), was highly activated right before experiencing

an epiphany (Lehrer, 2008). Neuroimaging approaches enable problem-solving researchers to take a close look at brain activity to unveil some of complicated and hidden cognitive activities while solving problems.

Over time, research in problem solving and decision making has largely overlapped, and approaches successfully employed in one domain are quickly adopted by the other. For example, information-processing theory has been one of important paradigms to driving the development of decision theory in the last half century (Payne and Bettman, 2004). Cognitive architectures, such as ACT-R, have been employed to understand biases and heuristics used in decision making (e.g., Altmann and Burns, 2005; Belavkin, 2006; Dickison and Taatgen, 2007). Neuroimaging techniques have also been employed to understand decision-making tasks (e.g., Ernst et al., 2002; Trepel et al., 2005). The interaction between the two research communities is expected to accelerate as the boundary of research questions is widened.

## 5  SUMMARY AND CONCLUSIONS

Beach (1993) discusses four revolutions in behavioral decision theory. The first took place when it was recognized that the evaluation of alternatives is seldom extensive. It is illustrated by use of the satisficing rule (Simon, 1955) and heuristics (Tversky and Kahneman, 1974; Gigerenzer et al., 1999) rather than optimizing. The second occurred when it was recognized that people choose between strategies to make decisions. It is marked by the development of contingency theory (Beach, 1990) and cognitive continuum theory (Hammond, 1980). The third is currently occurring. It involves the realization that people rarely make choices and instead rely on pre-learned procedures. This perspective is illustrated by the levels-of-processing approach (Rasmussen, 1983) and recognition-primed decisions (Klein, 1989). The fourth is just beginning. It involves recognizing that decision-making research must abandon a single-minded focus on the economic view of decision making and include approaches drawn from relevant developments and research in cognitive psychology, organizational behavior, and systems theory.

The discussion within this chapter parallels this view of decision making. The integrative model presented at the beginning of the chapter shows how the various approaches fit together as a whole. Each path through the model is distinguished by specific sources of conflict, the methods of conflict resolution followed, and the types of decision rules used to analyze the results of conflict resolution processes. The different paths through the model correspond to fundamentally different ways of making decisions, ranging from routine situation assessment-driven decisions to satisficing, analysis of single- and multiattribute expected utility, and even obtaining consensus of multiple decision makers in group contexts. Numerous other strategies and potential methods of decision support discussed in this chapter are also described by particular paths through the model.

This chapter goes beyond simply describing methods of decision making by pointing out reasons that people and groups may have difficulty making good decisions. These include cognitive limitations, inadequacies of various heuristics used, biases and inadequate knowledge of decision makers, and task-related factors such as risk, time pressure, and stress. The discussion also provides insight into the effectiveness of approaches for improving human decision making. The models of selective attention point to the value of providing only truly relevant information to decision makers. Irrelevant information might be considered simply because it is there, especially if it is highly salient. Methods of highlighting or emphasizing relevant information are therefore warranted. The models of selective information also indicate that methods of helping decision makers cope with working memory limitations will be of value. There also is reason to believe that providing feedback to decision makers in dynamic decision-making situations will be useful. Cognitive rather than outcome feedback is indicated as being particularly helpful when decision makers are learning. Training decision makers also seems to offer potentially large benefits. One reason for this conclusion is that the studies of naturalistic decision making revealed that most decisions are made on a routine, nonanalytical basis.

Studies of debiasing also partially support the potential benefits of training and feedback. On the other hand, the many failures to debias expert decision makers imply that decision aids, methods of persuasion, and other approaches intended to improve decision making are no panacea. Part of the problem is that people tend to start with preconceived notions about what they should do and show a tendency to seek out and bolster confirming evidence. Consequently, people may become overconfident with experience and develop strongly held beliefs that are difficult to modify, even if they are hard to defend rationally.

## 1 INTRODUCTION

Mental workload and situation awareness (SA) have certainly been topics of great interest to, and ongoing debate among, practitioners and researchers in human factors and cognitive engineering. By most accounts, the concept of mental workload that first permeated the literature in the 1970s (Leplat and Welford, 1978; Moray, 1979) and the concept of SA that first came on the scene in the late 1980s (e.g., Endsley, 1995; Pew, 1994) have matured to the point of their widespread applications in domains that range from office work to medicine, transportation, and military operations, to mention just a few (e.g., Proctor and Vu, 2010). Although there remain skeptics who argue that the constructs of mental workload and SA are nothing more than folk models lacking scientific merit (Dekker and Woods, 2002; Dekker and Hollnagel, 2004), Parasuraman et al. (2008) forcefully countered this on two grounds: (a) the constructs of mental workload and SA are distinguishable from other cognitive constructs such as attention or memory and

(b) the distinction is based on a large scientific base of empirical studies and theoretical treatments of the constructs (see Gopher, 1994; Vidulich, 2003; Endsley, 2006; Tenny and Pew, 2006; Tsang and Vidulich, 2006; Durso et al., 2007; Durso and Alexander, 2010). While the work is far from complete, research on their theoretical underpinnings and methodological exactitude continues, albeit at a slower pace than when the concepts first emerged (Proctor and Vu, 2010). The goal of this chapter is to review the current developments in the understanding of the constructs of mental workload and SA and their applications in selected domains.

Human engineering seeks to understand and improve human interactions with machines to perform tasks. This goal can be especially difficult to achieve in dynamic complex systems that characterize much of modern work. A good example of the problem can be seen in considering the human operator's response to automation. Many complex tasks, such as those involved in monitoring and managing a process control plant

(Moray, 1997; Wickens and Hollands, 2000) or remotely controlling multiple uninhabited vehicles (Parasuraman et al., 2009), would not be possible without the assistance of automation. However, many researchers (e.g., Kessel and Wickens, 1982; Bainbridge, 1987; Moray, 1986; Wiener and Curry, 1980; Tsang and Vidulich, 1989; Adams et al., 1991; Prewett et al., 2010) have pointed out that automated assistance can come at a high price. Moray (1986) noted that, as computer automation did more, the operator would do less and therefore experience less mental workload (Moray, 1986, p. 40-5):

> Is there a price for the advantages? It could be said that the information processing demands become so alien to the operator that if called upon to reenter the control loop such reentry is no longer possible. . . . The system will be poorly understood and the operator will lack practice in exercising control, so the possibility of human error in emergencies will increase.

Naturally there is an issue of how well the requirements of using any machine match the capabilities of the human operators. Some mismatches should be easy for an observer to discern, especially physical mismatches. For example, Fitts and Jones (1947/1961a) found that 3% of "pilot errors" in a corpus of 460 were due to the pilot being physically unable to reach the required control. But, other mismatches may not be so obvious, especially mental mismatches. Fitts and Jones (1947/1961b) found that 18% of errors in reading and interpreting aircraft instruments were due to problems associated with integrating the information from multirevolution indicators (e.g., altitude displays with different pointers for one, tens, and hundreds of feet). An outside observer would not necessarily know by watching the pilot that such a misinterpretation had occurred.

Given the impossibility of seeing the mental processes of an operator performing a task, the need to know set off a myriad of research and applied activities to explore and use constructs like mental workload and SA to shed light on the effectiveness of the coupling of the human operator and the machine with which the operator interacts. Vidulich (2003) echoed the argument of other researchers that mental workload and SA had taken on the quality of metameasures that encapsulate the demand on and the quality of the mental processes involved (Hardiman et al., 1996; Selcon et al., 1996). These measures are particularly useful at times when more specific information is simply not available. Other times, they may actually be preferable and sufficient. For example, an interface that allows the task to be performed with a more comfortable level of mental workload and better SA would be preferable to one that did not. Recently, Parasuraman et al. (2008) advocated that mental workload and SA are among a small number of human cognition and performance constructs that have the highly useful properties of being both predictive of performance in complex human–machine systems and diagnostic of the operator's cognitive state. Consequently, measures of both mental workload and SA can provide insight to practitioners seeking to improve the performance of human–machine systems.

To appreciate the potential roles workload and SA might play in supporting system development, visions of two future systems in aviation will be considered. Fallows (2001a,b) presented an intriguing vision of the future of air travel. Noting the increasing bottlenecks and delays inherent in the existing airline industry, Fallows expected that a simple scaling up of the existing system with more planes and more runways at existing airports would not be a practical or economically viable approach to keep pace with the projected increases in air travel. Fallows envisaged that the increased reliability of aircraft mechanical systems combined with innovative research on cockpit interfaces will not only revitalize general aviation but also lead to the emergence of a much more extensive light-jet air taxi industry. Such a development would naturally lead to more pilots flying that lack the extensive training of current professional pilots. But Fallows, along with the Advanced General Aviation Transport Experiments (AGATE) consortium of the National Aeronautics and Space Administration (NASA), the Federal Aviation Administration (FAA), the general aviation industry and a number of universities expected that future general aviation cockpits will take advantage of advanced technologies such as those of highway-in-the-sky displays, synthetic vision systems, and decision-making aids to reduce the mental workload and increase the SA of the pilot in order to maintain an acceptable level of safety. Although the vision that light-jet air travel would be commonplace has not materialized to date, considerable innovation is being demonstrated and some noteworthy accomplishments have been achieved (Fallows 2008a,b,c).

On a much broader scale, NextGen is a transformational modernization plan for the National Airspace System aimed at meeting the demands of significant growth in air traffic projected through 2025 (Joint Planning and Development Office, 2007). Sweeping changes in equipage supported by advance technologies are anticipated to fundamentally change the roles and responsibilities of the pilots and air traffic controllers. Reduced flight time, delays, and fuel expenditures are all expected to profit from such changes. A number of researchers have identified mental workload and SA to be among the most critical human factors considerations in the planning and assessment of NextGen systems for shaping a safer and more effective airspace (e.g., Durso and Manning, 2008; Langan-Fox et al., 2009; Sheridan, 2009). However, these researchers also have expressed concerns about the limitations of extant measurement tools and encouraged continued mental workload and SA research.

Technological changes constantly bring about a practical need to know about their impact on the human operator and on the safe and effective operation of the human–machine system. There seems to be a consensus that the concepts of both mental workload and SA are vital for building safe and effective systems that best accommodate the human's cognitive strengths while supporting human frailty. There is also the growing recognition that the utility of one concept does not replace or diminish the utility of the other. In

fact, parallel studies of both are not only good for applied evaluations but could also help sharpen their respective definitions and stimulate new understanding (Endsley, 1993; Wickens, 2001; Vidulich, 2003; Parasuraman, et al., 2008; Durso and Alexander, 2010; Vidulich et al., 2010).

## 2 THEORETICAL UNDERPINNINGS OF MENTAL WORKLOAD AND SITUATION AWARENESS

In 1994, Pew stated that *situation awareness* had replaced *workload* as the buzzword of the 1990s. But can the concept of situation awareness replace that of mental workload? Hendy (1995) and Wickens (1995, 2001) argued that the two concepts are clearly distinct but are also intricately related to each other. This idea has seemed to have congealed in the workload and SA literature and in practice (e.g., Durso and Alexander, 2010). Although the two concepts are affected by many of the same human variables (such as limited processing capacity and the severe limit of working memory) and system variables (such as task demands, system constraints, and technological support), one concept does not supplant, but rather complements, the other. For example, Ma and Kaber (2005) used both workload and SA measures to assess the individual and combined impact of adaptive cruise control and cell phone use on a simulated car-driving task. They found that the two types of measures combined to create a more complete and compelling picture of the benefits and risks associated with the use of such technologies during automobile driving.

Figure 1 provides a conceptual sketch of the relationship between mental workload and SA and is not intended to be a complete representation of all the processes involved. There are two main components in this figure: the attention and mental workload loop and the memory and SA loop. The ensuing portrayal will make clear that mental workload and SA are intricately intertwined, as one affects and is affected by the other. Although convention would bias us in thinking that elements on top or on the left in the figure might have temporal precedence over those at the bottom or on the right, this is not necessarily the case with the dynamic interplay between workload and SA. For example, task demands could be initiated by an external task (such as the need to respond to an air traffic controller's request) as well as by an internal decision to engage in solving a nagging problem. Despite the seemingly discrete and linear depiction of the relations among the elements in the figure, the elements are actually thought of to be mutually interacting adaptively in response to both exogenous demands and endogenous states (e.g., Hockey, 1997, 2008; Kramer and Parasuraman, 2007).

### 2.1 Attention and Workload

Since the 1970s, much has been debated and written about the concept of mental workload (e.g., Welford, 1978; Moray, 1979; Gopher and Donchin, 1986; O'Donnell and Eggemeier, 1986; Adams et al., 1991; Huey and Wickens, 1993; Gopher, 1994; Kramer et al., 1996; Tsang and Wilson, 1997; Vidulich, 2003; Hockey, 2008; Durso and Alexander, 2010). Parasuraman et al. (2008) succinctly defined mental workload as "the relation between the function relating the mental resources demanded by a task and those resources available to be supplied by the human operator" (pp. 145–146). This supply-and-demand notion is portrayed by the attention–workload loop in Figure 1.

There are two main determinants of mental workload: exogenous task demands as specified by factors such as task difficulty, task priority, situational contingencies (represented by the World in Figure 1), and endogenous supply of attentional or processing resources to support information processing such as perceiving, updating memory, planning, decision making, and response processing. Further, this supply is modulated by individual differences such as one's skill set and expertise. The ultimate interest in measuring

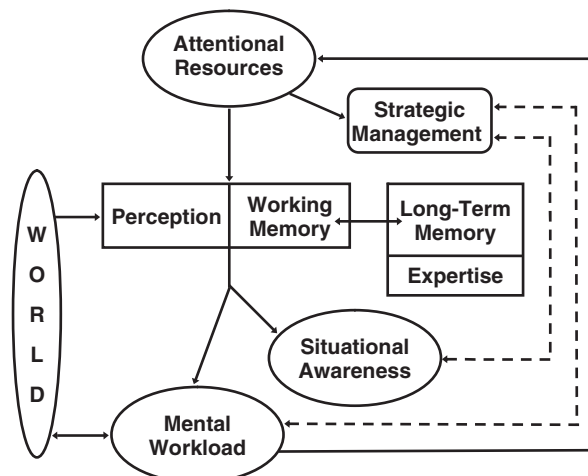

**Figure 1** Conceptual framework illustrating the relationship between mental workload and SA.

workload, of course, is how it might affect system performance represented via the feedback loop back to the world in Figure 1. Mental workload can be expressed in subjective experience, performance, and physiological manifestations. A host of assessment techniques now have been developed and are used in both laboratories and applied settings (see Kramer and Parasuraman, 2007; Gawron, 2008). A selected few will be described in Section 3 for illustrative purposes.

Although there are a number of theoretical accounts of attention, the one readily embraced and adopted in the workload literature is the energetics account (e.g., Hockey et al., 1986; Gopher, 1994; Wickens, 2001; Durso and Alexander, 2010). Central to the present discussion is the notion that attentional resources are demanded for task processing, but they are of limited supply. Performance improves monotonically with increasing investment of resources up to the limit of resource availability (Norman and Bobrow, 1975). An important implication of this relationship is that performance could be the basis of inference for the amount of resources used and remained. The latter, referred to as *spare capacity*, could serve as reserve fuel or energy for emergencies and unexpected added demands. Further, attentional resources are subject to voluntary and strategic allocation. According to Kahneman (1973), attention is allocated via a closed feedback loop with continuous monitoring of the efficacy of the allocation policy that is governed by enduring dispositions (of lasting importance, such as one's own name and well-learned rules), momentary intentions (pertinent to the task at hand), and evaluation of the performance (involving self-monitoring of the adequacy of performance in relation to task demands). Among the most convincing support for the limited, energetic, and allocatable property of attentional resources are the reciprocity effects in performance and certain neuroindices observed between time-shared tasks. As the demand or priority of one task changes, the increase in performance, P300 amplitude, or brain activity level in one task has been observed to be accompanied by a decrease in the corresponding measures in the other task (e.g., Gopher et al., 1982; Wickens et al., 1983; Kramer et al., 1987; Sirevaag et al., 1989; Fowler, 1994; Tsang et al., 1996; Parasuraman and Caggiano, 2002; Just, Carpenter, and Miyake, 2003; Tsang, 2007; Low et al., 2009). Because attention can be deployed flexibly, researchers advocate the need to examine the allocation policy in conjunction with the joint performance in a multitask situation in order to assess the workload and spare capacity involved (e.g., Gopher, 1994; Proctor and Vu, 2010).

By the late 1970s, the notion of Kahneman's undifferentiated or all-purpose attentional resource was challenged by a body of data that suggested multiple specialized resources for different types of processing (see Allport et al., 1972; Kinsbourne and Hicks, 1978; Navon and Gopher, 1979; Friedman and Polson, 1981; Wickens, 1984). Based on an expansive systematic review of the interference pattern in the dual-task data available at the time, Wickens (1980, 1987) proposed a multiple resource model. According to this model, attentional resources are defined along three dichotomous dimensions: (1) stages of processing with perceptual/central processing requiring resources different from those used for response processing, (2) processing codes with spatial processing requiring resources different from those used for verbal processing, and (3) input/output modalities with visual and auditory processing requiring different processing resources and manual and speech responses also requiring different processing resources. A recent revision of the model included a fourth dimension of visual channels, distinguishing between focal and ambient vision (Wickens, 2002, 2008a).

The energetic and specificity aspects of the attentional resources are receiving converging support from subjective (e.g., Tsang and Velazquez, 1996; Rubio et al., 2004), performance (e.g., Tsang et al., 1996; Wickens, 2002), and neurophysiological (e.g., Just et al., 2003; Parasuraman, 2003; Kramer and Parasuraman, 2007) measures. First, parametric manipulation of task demands as well as changes in task priorities have been found to produce systematic and graded changes in the level of subjective workload ratings, performances, and level of neuronal activation. Second, these measures have been found to be sensitive to the competition for specific resource demands. Further, increased neuronal activation associated with different types of processing (e.g., spatial processing and verbal processing) are found to be somewhat localized in different cortical regions. An important application of this model is its prediction of multiple-task performance that is common in many complex work environments (Wickens, 2008a). The higher the similarity in resource demands among the task components, the more severe the competition for similar resources, the less spare capacity, and the higher the level of workload that would result. The other side of the coin is that it would be less feasible to dynamically reallocate resources among task components that utilize highly dissimilar resources. Consequently, the characterization of the processing demand of a task will need to take into account both the intensity aspect (how much resources) and the structural aspect (which resources).

As mentioned above, the supply or availability of processing resources is subject to individual differences such as one's ability and skill level. Just et al. (2003) reviewed a set of behavioral and neurophysiological data that lend support to the notion that a higher level of skill or ability effectively constitutes a larger resource supply. For example, Parks et al. (1988) used a verbal fluency task that required subjects to generate as many words as possible that began with a given stimulus letter. Those with a higher verbal ability were found to exhibit a lower level of positron emission tomography (PET) measures of brain activity. Just et al. proposed that the difference between the more and less proficient subjects lay in the proportion of resources they needed to perform the task. In another study, Haier et al. (1992) found that weeks of practice in the spatial computer game Tetris led to improved performance and a reduced amount of PET-measured activity. Just et al. proposed that practice improved the subjects' procedural knowledge, and the newly acquired, more efficient procedures entailed a lower level of resource use. In practice, a reduced level

of resource requirement by one task would translate to increased spare resources for processing other tasks.

## 2.2 Memory and Situation Awareness

Like the concept of mental workload (and many other psychological concepts, such as intelligence), SA is difficult to define precisely (e.g., Durso and Gronlund, 1999). Pew (1994) defined a situation as "a set of environmental conditions and system states with which the participant is interacting that can be characterized uniquely by a set of information, knowledge and resource options" (p. 18). The most commonly referenced working definition for SA came from Endsley (1990, p. 1–3): SA is "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future." This definition connotes both perception of the now and present and connection with knowledge gained in the past. As Figure 1 denotes, SA is most closely linked to the perceptual and the working memory processes. Certainly, it is not sufficient just for the information relevant to the situation to be available; the information needs to be perceived by the operator, and perception entails far more than the detection of signals or changes. For pattern recognition, object categorization, and comprehension of meaning to occur, contact with knowledge is necessary. But knowledge stored in long-term memory (LTM) s accessible only through short-term or working memory. It is noteworthy that Baddeley (1990) introduced the term working memory to emphasize that short-term memory is far more than a temporary depository for information. Rather, it is an active, effortful process involved in maintaining information and is subject to capacity as well as attentional limits.

Adams et al. (1995) made a distinction between the process and product of SA: "*product* refers to the state of awareness with respect to information and knowledge, whereas *process* refers to the various perceptual and cognitive activities involved in constructing, updating, and revising the state of awareness" (p. 88). To elaborate, the product of SA is a distillation of the ongoing processing of the interchange between information perceived from the now and present (working memory) and knowledge and experience gained from the past (long-term memory). As will be made clear below, this distinction between the process and product of SA has important implications on the interaction of mental workload and SA and on the appropriate assessment techniques.

Just as, given the same objective task demand, mental workload could vary due to individual differences in resource supply as a result of skill and ability differences, given the same situation, SA could vary due to individual differences in knowledge and experience that is amassed in one's LTM. The extant view of the nature of expertise further expounds on the role of memory in determining the content and process of SA.

Expertise is mostly learned, acquired through many hours of deliberate practice (e.g., Glaser, 1987; Chi et al., 1988; Druckman and Bjork, 1991; Adams and Ericsson, 1992; Ericsson, 1996). A fundamental difference between novices and experts is the amount of acquired domain-specific knowledge (e.g., Charness and Tuffiash, 2008). For example, Chase and Ericsson (1982) and Staszewski (1988) reported three people who, after extensive practice, developed a digit span in the neighborhood of 100 numbers. Being avid runners, the subjects associated the random digits to running-related facts that already existed in their LTM (e.g., dates of the Boston Marathon). These subjects had a normal short-term memory span when the studies began and after practice demonstrated the normal span when materials other than digits were tested. Charness (1995) pointed out that such escapes from normal limits also have been observed in perceptual processing. For example, Reingold et al. (2001) found that when chess symbols (as opposed to letters designating chess pieces) were used, highly skilled players could make their decision in some cases without moving their eyes from the initial fixation point at the center of the display. In contrast, weaker players had to make direct fixations. When letter symbols instead of chess piece symbols were used, even the experts were forced to fixate on the pieces directly much more often. Charness pointed out that these observations show that experts can both accurately encode a situation and prepare an appropriate response much more quickly than their less skilled counterparts, but only in the domain of their expertise.

In addition to having acquired declarative knowledge (factual information), experts have a large body of procedural (how-to) knowledge. With practice, many procedural rules (productions) become concatenated into larger rules that can produce action sequences efficiently (Druckman and Bjork, 1991). Importantly, the expertise advantage goes beyond a quantitative difference. The organization of knowledge is fundamentally different between experts and novices. An expert's knowledge is highly organized and well structured, so that retrieving information is much facilitated. In a recent study, Meade et al. (2009) presented expert pilots, novice pilots, and nonpilots with aviation scenarios and had them recall the scenarios alone or in collaboration with a fellow participant at the same expertise level. Whereas the nonexperts were disrupted by collaboration, the experts benefited from it. The benefits were attributed to the expert's superior, highly organized, domain-specific knowledge and their ability to acknowledge and elaborate on contributions to the joint memory performance from others.

Ericsson and Kintsch (1995) further proposed that a long-term working memory (LTWM) emerges as expertise develops and is a defining feature of advanced skill (Ericsson and Delaney, 1998). Whereas working memory has severe capacity and temporal limits, LTWM is hypothesized to have a larger capacity that persists for a period of minutes (or even hours). With an organizational structure that already would have been built in LTM, even very briefly seen, seemingly random, incoming information might be organized similarly. Retrieval cues can then be devised and used to access information in LTM quickly. To illustrate, Ericsson and Kintsch (1995) described the medical diagnosis process that requires one to store numerous individual facts in

working memory. Medical experts were found to be better able to recall critical information at a higher conceptual level that subsumed specific facts and to produce more effective diagnosis. A very important function of LTWM appears to be providing working memory support for reasoning about and evaluating diagnostic alternatives (Norman et al., 1989; Patel and Groen, 1991). That is, expert problem solving is more than just quick retrieval of stored solutions to old problems. Expertise is also associated with effective application of a large amount of knowledge in reasoning to cope with novel problems (Charness, 1989; Horn and Masunaga, 2000).

Finally, experts show metacognitive capabilities that are not present in novices (Druckman and Bjork, 1991). These capabilities include knowing what one knows and does not know, planning ahead, efficiently apportioning one's time and attentional resources, and monitoring and editing one's efforts to solve a problem (Glaser, 1987). In short, experts' large body of organized knowledge enables them to readily see meaningful patterns, make inferences from partial information, constrain search, frame the problem, apprehend the situation, update perception of the current situation continuously, and anticipate future events, including eventual retrieval conditions (Glaser, 1987; Charness, 1995). Importantly, an accurate account of the current situation allows an experienced operator to rapidly retrieve the appropriate course of action directly from memory, enabling swift response execution.

## 2.3  Mental Workload and Situation Awareness

A number of researchers have emphasized that the concepts of mental workload and SA are intricately intertwined (e.g., Wickens, 2002; Vidulich, 2003; Wickens et al., 2008). In this section we attempt to sharpen their distinction and to examine their interactions more closely. Wickens (2001, p. 446) contrasts the two concepts in the following way: "Mental workload is fundamentally an *energetic* construct, in which the quantitative properties ('how much') are dominant over the qualitative properties ('what kind'), as the most important element. In contrast, situation awareness is fundamentally a *cognitive* concept, in which the critical issue is the operator's accuracy of ongoing understanding of the situation (i.e., a qualitative property)." In practice, one assesses the amount and type of workload and the quality (scope, depth, and accuracy) of the content of SA (Vidulich, 2003). Recently, Durso et al., (2007) and Durso and Sethumadhavan (2008) emphasized the need to assess the cognitive processes involved in attaining SA as well.

Both the level of workload and the quality of SA are shaped by exogenous and endogenous factors. Exogenous factors are inherent in the situation (e.g., task demands and situation complexity and uncertainty). Endogenous factors are inherent in a person's ability and skill. The same level of task demands could impose different levels of workload on the operator, depending on her ability or skill level. As discussed above, a high skill level is functionally equivalent to having a larger processing resource supply. A moderate crosswind could be a challenge for a student pilot trying to land a plane but a rather routine task for a seasoned pilot. An overly sensitive warning alarm could be exceedingly disruptive to assessment of the situation by a new operator but could safely be ignored by an experienced operator with intimate knowledge of the workings of the system. Although calibrating the exogenous demands is not always straightforward, their influence on workload is obvious. Less apparent is the endogenous influences on the interplay between the level of workload and the quality of SA.

To the extent that workload is caused, and SA supported, by many of the same cognitive processes, they are enabled by, and subject to the limits of, many of the same processes. The more demanding the task, the more complex the situation and the more "work" is required to get the job done and the situation assessed. By our definition, the higher the level of workload, the more attention is needed for task performance and the less is left for keeping abreast of the situation. The SA process could actually compete with task performance for the limited resource supply, and therefore a high level of workload could lead to poor SA. On the other hand, SA could be improved by working harder (e.g., more frequent sampling and updating of information). That is, a high-level workload is sometimes necessary to maintain a good SA. Thus, a high level of workload could be associated with either a low or high degree of SA (Endsley, 1993). But poor SA may or may not impose more workload. One could simply not be doing the work necessary to attain and maintain SA, and if one is not aware of the dire situation that one is in and takes no action to correct the situation, no additional work would be initiated. Although a low degree of SA is never desirable, an awareness of one's lack of SA could start a course of action that could increase the level of workload in the process of attaining or restoring SA. The ideal scenario is one where a high degree of SA would support more efficient use of resources and thereby produce a low level of workload. In short, mental workload and SA could support each other as well as compete with each other.

Strategic management is proposed to be needed for the balancing act of maintaining adequate SA without incurring excessive workload. Strategic management is also referred to as executive control and is a much discussed topic in the literature. One point of contention is what exactly constitutes executive control, since a host of higher level cognitive functions have been included under its rubric. The coordinating of multiple tasks (including the allocation of limited processing resources), planning, chunking or reorganizing information to increase the amount of materials that can be remembered, and the inhibiting of irrelevant information have all been labeled as part of executive control. As Figure 1 indicates, strategic management is skills based and is highly dependent on one's apprehension of the situation. For example, a beginner tennis player would be content to have made contact with the tennis ball and would not have the spare resources or the knowledge to ponder game strategies. After having mastered the basic strokes (which have become more automatic), however, the strategic component would take on more central importance. But strategic management is not attention free. Even though declarative and procedural knowledge

develops as expertise develops and are used to support performance, there are components in many complex performances that are never automatic. High-performing athletes, chess players, musicians, and command and control officers expend considerable effort to perform at the level that they display.

Recent neurophysiological evidence provides some support for the notion that executive control is a distinct construct and consumes processing resources. Just et al. (2003) pointed out that the executive system is identified primarily with the prefrontal cortex, which does not receive direct sensory input but has widespread connections with a number of cortical areas associated with various types of processing (e.g., spatial and verbal processing). A number of functional magnetic resonance imaging studies have shown a higher level of activation in the prefrontal cortex in (1) a problem-solving task that requires more planning than one that requires less (Baker et al., 1996), (2) a working memory task that requires more updating of a larger amount of information (Braver et al., 1997), and (3) dual-task performance (a semantic category judgment and a mental rotation task) versus single-task performance (D'Exposito et al., Zarahn, and Aguire, 1999). These results show that the activation in the prefrontal cortex varies systematically with task demands. Further, neuropsychological patients with lesions in the frontal lobe show impairments in planning and other higher level cognitive functions (Shallice, 1988).

Returning to Figure 1, strategic management competes directly with all the processes that generate mental workload for processing resources. But strategic management could optimize performance by planning and by smartly allocating the limited resources to the processes that need resources the most to meet system requirements. An efficacious strategic management would, of course, require high-quality SA. In a later section, we discuss potential human factors support (such as display support, automation aids, training) that would improve the potential of attaining this ideal scenario of a high level of SA without an exceedingly high level of workload.

## 3 METRICS OF MENTAL WORKLOAD AND SITUATION AWARENESS

There are three major categories of measures of mental workload and SA based on the nature of the data collected: performance, subjective ratings, and psychophysiological measures. There are several properties that should be considered when selecting measures of cognitive states or activities: sensitivity, diagnosticity, intrusiveness, validity, reliability, ease of use, and operator acceptance (e.g., Tsang and Wilson, 1997; Wickens and Hollands, 2000). In addition, Durso and Alexander (2010) and Tenny et al. (1992) caution that SA measures should be designed and selected based on whether the process or the product of SA is of interest. As outlined below, different measures have different strengths and weaknesses and a thoughtful combination of measures can lead to a more complete picture. Practitioners are encouraged to consult more in-depth coverage of the

metrics to develop a good understanding of the properties of the different measures such that the most appropriate choice(s) can be made (Gopher and Donchin, 1986; O'Donnell and Eggemeier, 1986; Lysaght et al., 1989; Vidulich et al., 1994a; Bryne, 1995; Wickens and Hollands, 2000; Vidulich, 2003; Salmon et al., 2006; Kramer and Parasuraman, 2007; Gawron, 2008).

### 3.1 Performance Measures

System designers are typically most concerned with system performance. Some might say that the workload or SA experienced by an operator can be important only if it affects system performance. Consequently, performance-based measures might be the most valuable to system designers. There are two main categories of performance-based workload measures: primary-task performance and secondary-task performance. SA assessment also has made use of primary-task performance. In addition, SA researchers have often employed recall-based memory probe performance and real-time performance. Although primary-task performance is the measure that is most strongly linked to the system designer's goal of optimizing system performance, Vidulich (2003) pointed out that the secondary-task method of workload assessment and the memory probe method of SA assessment are prototypical measures of the theoretical concepts behind workload and SA.

### 3.1.1 Primary-Task Performance

***Primary-Task Workload Assessment*** The primary-task method of workload assessment consists of monitoring the operator's performance of interest and noting what changes occur as task demands are varied. Some common measures are accuracy, response times, and signal detection performance. Some examples of more domain-specific measures are movement time for a specific computer mouse design, average brake time to traffic lights while texting, and deviation from a command altitude in a flight task. The primary-task methodology is grounded in the framework presented above. Since human operators have a finite capacity to deal with the task demand, as that task demand continues to increase, task performance would be expected to deteriorate as the task demand exceeds resource availability. For example, an automobile driver might have more difficulty maintaining a proper course as the weather becomes windy, and if the wind increases even more when the road is slippery, the driver may fail completely to keep the car in the proper lane.

It should be noted that mental workload is not the only factor that can influence operator performance (Gopher and Donchin, 1986; Wickens and Hollands, 2000). For example, direct performance measures often do not reflect variation in resource investment. One could incur a higher level of workload by trying harder to eschew performance deterioration as task demand increases. Alternatively, two individuals may produce the same level of performance but experience different levels of workload due to differences in skill or strategies used. They therefore would have different amount of spare capacity for other tasks. Of interest, Salvendy and his colleagues found that including a factor that

reflected a person's skill, attitude, and personality contributed significantly to the predictive value of their projective modeling technique (Bi and Salvendy, 1994; Xie and Salvendy, 2000a,b). In addition, performance could be limited by poor technological interface or by the poor quality of the data available. One does not have to try very hard to read in the dark to produce a poor comprehension score. Although the primary-task performance is, clearly, very important to system evaluators as a test of whether design goals have been achieved, primary-task performance by itself oftentimes does not provide an adequate metric of an operator's mental workload. First, primary-task performance may not be diagnostic of the source of workload. For example, a high error rate can be caused by many possible task or system factors. Second, in highly automated systems whereby the human operator takes on the monitoring and supervisory role rather than that of an active controller, directly observable performance measures may simply not be available.

***Primary-Task SA Assessment***   Despite the problems in using primary-task performance as a workload measure, it has become a common tool for assessing the impact of human–machine interface modifications intended to improve SA. For example, Vidulich (2000) found that it was common for researchers to propose an interface alteration that would improve SA and test it by determining if performance improved when the alteration was in place. The logic behind primary-task performance-based measures of SA is well illustrated by the Andre et al. (1991) study of aircraft cockpit display design. Andre et al. used the pilot's ability to recover from disorienting events as a direct measure of how well the attitude information provided by the cockpit supported the pilots' SA of current and future attitudes of the aircraft. Their results showed that, SA, as measured by flight performance and recovery from disorientation

events, was best maintained with a planar outside-in display among the alternatives studied.

### 3.1.2  Secondary-Task Measures of Workload

The secondary-task measure has been considered the prototypical measure of mental workload (e.g., Ogden et al., 1970; Gopher, 1994; Vidulich, 2003). A system evaluator would usually desire to assess primary-task performance even if it was not being interpreted as a mental workload indicator. In contrast, a secondary task is usually only incorporated in a system assessment for assessing mental workload. The secondary-task technique is considered to be a procedure that is optimally suited to reflect the commonly accepted concept of mental workload described above. Workload is often assessed to determine whether the human operator is working within a tolerable information-processing capacity while performing the required task. It follows logically that if there is unused capacity, the operator could perform another task. For example, it is expected that spare capacity would be very valuable in emergencies or when under stress (Wickens, 2001; Hockey et al., 2003).

With the secondary-task method, the operator is required to perform a second task concurrently with the primary task of interest. It is explained to the operators that the primary task is more important and the primary-task performance must be performed to the best of their ability whether or not it is performed with the secondary task. Operators are to use only their spare capacity to perform the secondary task. Since the primary and secondary tasks would compete for the limited processing resources, changes in the primary-task demand should result in changes in the secondary-task performance as more or less resources become available for the secondary task.

Figure 2*a* illustrates possible changes in the joint performance of the primary and secondary tasks within a

**Figure 2**  (*a*) Hypothetical performance operating characteristic (POC). Tasks A and B are two tasks that have been performed both independently and together. ST = level of single-task performance. The dashed and dotted lines illustrate possible joint performance when the two tasks are performed together. *X*, perfect time-sharing. (*b*) Hypothetical POC. The primary task was performed with two different interfaces. *Y* and *Z*, joint performances observed when the secondary task is performed with the two versions of the primary task.

performance operating characteristic (POC) representation. If the two tasks did not compete for any resources, perfect time-sharing could be observed. This is represented by the "X" on the figure, which would indicate that both tasks were performed at their respective single-task levels even when performed together. Such perfect time-sharing is rare but has been observed (e.g., Allport et al., 1972). The two performance lines in the figure, being much closer to the origin of the graph than the perfect time-sharing point, indicate substantial interference in dual-task conditions. The dashed line shows a perfect performance tradeoff pattern between the two tasks. As one task's performance improves, a comparable degradation is observed in the other. Performance tradeoffs of this sort would typically show up in dual-task studies that manipulate the relative priorities of the two tasks. The POC reflects the subject's allocation strategy for distributing attention between the time-shared tasks as the relative priorities of the two tasks varied. The dotted line shows the two task's joint performance being somewhat better than the perfect tradeoff case. This would be expected to occur if the two tasks required at least some different types of information-processing resources.

Figure 2b illustrates what can be expected in a situation in which the primary task's performance must be defended because of its priority or criticality. For example, as important as it is to communicate with air traffic control, the pilot's task to aviate has paramount priority. Suppose the primary-task performance ($x$ axis) of two possible interfaces, $Y$ and $Z$, is being evaluated. In this hypothetical example, the subjects have done a good job of following the priority instructions and are protecting their primary-task performance, maintaining it at a very high level—near that of the single task. Notice that the primary-task performance with both interfaces is equally high (points $Y$ and $Z$ on the POC). However, interface $Y$'s secondary-task performance is substantially better than interface $Z$'s secondary-task performance. This result would be interpreted as interface $Y$ inflicting less workload on the operator while performing the primary task than would interface $Z$.

An important consideration in the selection of a secondary task is the type of task demand of both the primary and secondary tasks. According to the logic of multiple-resource theory, secondary-task performance will be a sensitive workload measure of the primary-task demand only if the two tasks compete for the same processing resources. The greater the dissimilarity of the resource demands of the time-shared tasks, the lower the degree of the interference there would be between the two tasks. Although a low degree of interference usually translates to a higher level of performance (which of course is desirable), this is not compatible with the goal of workload assessment. A fundamental assumption of the secondary-task method is that the secondary task will compete with the primary task for limited processing resources. It is the degree of interference that is used for inferring the level of workload. Care must therefore be taken to assure that the secondary task selected demands resources similar to those of the primary task. Fortunately, many secondary tasks have been developed and calibrated for use in different evaluations, providing

a database (e.g., Gawron, 2008) for an evaluator to select the secondary tasks that would be most diagnostic of the primary task's resource demands.

The secondary-task measure also offers some practical advantages for workload assessment in comparison to primary-task performance assessment. The secondary-task measure can be assessed in environments where primary-task performance is difficult to obtain or is not available. This is often the case in many operational settings, such as automobiles, ships, and airplanes, that do not have performance-recording capability. Also, with highly automated systems in which the primary role of the operator is that of monitoring and supervising, little observable primary-task performance would be available for analysis. Finally, as noted above, primary-task measures may not be sensitive to very low workload levels because operators could increase their efforts to maintain a stable level of performance (e.g., O'Donnell and Eggemeier, 1986). Adding a secondary task will increase the overall task demand to a level that performance measures may be more sensitive.

One drawback of the secondary-task method is that the addition of an extraneous task to the operational environment may not only add to the workload but also fundamentally change the processing of the primary task. The resulting workload metric would then be nothing more than an experimental artifact. The *embedded secondary-task technique* was proposed to circumvent this difficulty (Shingledecker, 1984; Vidulich and Bortolussi, 1988). With this method, a naturally occurring part of the overall task is used as the secondary task. In some situations, such as piloting a jet fighter aircraft, task shedding is an accepted and taught strategy that is used when primary-task workload becomes excessive. Tasks that can be shed can perhaps serve as naturally lower priority embedded secondary tasks in a less intense workload evaluation situation. However, a naturally lower priority operational task may not always be available. Another drawback is that using the secondary-task method requires considerable background knowledge and experience to properly conduct a secondary-task evaluation and to interpret the results. For example, care must be taken to control for the operator's attention allocation strategy, so as to assure that the operator is treating the primary task as a high priority task (e.g., Damos, 1991). The use of secondary tasks may also entail additional software and hardware development.

Despite the challenges of using the secondary-task procedure, it is still used profitably for system assessment. For example, Ververs and Wickens (2000) used a set of secondary tasks to assess a simulated flight path following and taxiing performance with different sets of head-up display (HUD) symbology. One set of symbology presented a "tunnel in the sky" for the subjects to follow during landing approaches. The other display was a more traditional presentation of flight director information. The tunnel display reduced the subject's flight path error during landing. Subjects also responded more quickly and accurately to secondary-task airspeed changes and were more accurate at detecting intruders on the runway. However, the other display

was associated with faster detections of the runway intruder and quicker identification of the runway. The authors concluded that although the tunnel display produced a lower workload during the landing task, it also caused cognitive tunneling that reduced sensitivity to unexpected outside events. In a study of driving workload, Baldauf et al. (2009) successfully employed a time perception secondary task to distinguish between workload levels inflicted by driving tasks of differing levels of complexity. The length of produced time intervals increased with increasing driving complexity, as did the subjects' electrodermal activity and subjective workload ratings. In a study of office workload, Leyman et al. (2004) used a secondary task to assess the workload associated with simulated office tasks of varying complexity. The subjects in the experiment typed a practiced paragraph as the secondary task that was time-shared with a skilled-based random word memory task of varying list lengths, a more cognitively complex, rule-based geographical reasoning task, or the most cognitively complex, knowledge-based scheduling task. The secondary-task typing errors increased with increasing cognitive complexity. Further, the secondary-task results correlated with the perceived workload and validated the workload assessments of a new electromyographic (EMG) office workload measure. Leyman et al. proposed that this kind of information can be used to better organize work activities in office environments to increase productivity and reduce stress. In another study, Wästlund et al. (2008) used a reaction time secondary task to assess the benefits of better matching the text page layout to the computer screen size on reading comprehension and mental workload. The results indicated that the better layout reduced mental workload while maintaining reading comprehension level.

### 3.1.3 Memory Probe Measures of Situation Awareness

The first popular and standardized procedure for assessing SA was the memory probe technique. It can be considered the prototypical SA measurement tool. The memory probe technique attempts to assess at least part of the contents of memory at a specific time during task performance, so it assesses the product of SA. As represented by the Situation Awareness Global Assessment Technique (SAGAT, Endsley, 1988, 1990), the memory probe procedure consists of unexpectedly stopping the subject's task, blanking the displays, and asking the subject to answer questions to assess his or her knowledge of the current situation. The questions asked are typically drawn from a large set of questions that correspond to experimenter's assessment of the SA requirements for task performance. The subject's answers are compared to the true situation to determine the SAGAT score. Vidulich (2000) found this SAGAT-style approach with unpredictable measurement times and random selection of queries from large sets of possible questions to be generally sensitive to interface manipulations designed to affect SA. In contrast, as memory probes were made more specific or predictable, the sensitivity to interface manipulations appeared to be diminished. For example,

Vidulich et al. (1994b) used a memory probe procedure in which the memory probe, if it appeared, was at a predictable time and the same question was always used. This procedure failed to detect a beneficial effect of display augmentation to highlight targets in a simulated air-to-ground attack, even though there was a significant benefit in task performance (i.e., more targets destroyed) and a significant increase in SA ratings. In contrast, Vidulich et al. (1995) used a SAGAT-like approach with many different questions that were asked during unpredictable trial stoppages. In this case, the memory probe data showed a significant SA benefit of the presence of a tactical situation display.

In another study, Strater et al. (2001) examined U.S. Army platoon leaders in simulated Military Operations on Urbanized Terrain (MOUT) exercises. The platoon leaders varied from relatively inexperienced lieutenants to relatively experienced captains. SAGAT data were collected in a scenario that had the soldiers assaulting an enemy position and a scenario that involved defending a position. SAGAT probe questions were developed that could be used in either scenario. Results showed that the soldiers were more sensitive to different information depending on the scenario type. For example, the soldiers were more sensitive to the location of adjacent friendly forces in the assault scenario but they were more sensitive to the location of exposed friendly elements in the defend scenario. Consistent with the notion of a close link between SA and expertise described above, significant effects of soldier experience level were detected. Experienced soldiers were more sensitive to enemy locations and strength than were inexperienced soldiers. The authors suggested that the data collected from such experimentation could be used to improve training efficacy by identifying better information-seeking behaviors for the novices.

Although the memory probe procedure is attractive due to its assessing the information possessed by the subject at a specific moment in time, it does have practical constraints that limit its applicability. First, it can be highly intrusive to task performance when the task has to be stopped unexpectedly in order to query subject's knowledge of the current state. Although Endsley (1988) has demonstrated that the performance of a simulated air-to-air combat task in trials that included SAGAT stoppages did not significantly differ from trials that did not, the effect such stoppage could have on the cognitive processes involved was not clear. Second, there are assessment environments where such stoppages are impossible (e.g., actual airplane flight tests). Third, the number of questions required to provide an accurate picture of the operator's SA and that must be selected randomly and presented unpredictably can result in a large number of trials being needed.

### 3.1.4 Situation Awareness Real-Time Performance Assessment

Real-time performance has been used as a potential indicator of SA (Durso et al., 1995a; Pritchett and Hansman, 2000; Vidulich and McMillan, 2000). The logic is based on the assumption that if an operator is aware of task demands and opportunities, he will

react appropriately to them in a timely manner. This approach, if successful, would be unintrusive to task performance, diagnostic of operator success or failure, and potentially useful for guiding automated aiding. Since the continuous stream of operator performance is assessed, real-time performance could help shed light on the SA processes involved.

The Global Implicit Measure (GIM; Vidulich and McMillan, 2000) is an example of this approach. The GIM is based on the assumption that the operator of a human–machine system is attempting to accomplish known goals at various priority levels. Therefore, it is possible to consider the momentary progress toward accomplishing these goals as a performance-based measure of SA. Development of the GIM was an attempt to develop a real-time SA measurement that could effectively guide automated pilot aiding (Brickman et al., 1995, 1999; Vidulich, 1995; Shaw et al., 2004). In this approach, a detailed task analysis was used to link measurable behaviors to the accomplishment of mission goals. The goals would vary depending on the mission phase. For example, during a combat air patrol, a pilot might be instructed to maintain a specific altitude and to use a specific mode of the on-board radar, but during an intercept the optimal altitude might be defined in relation to the aircraft being intercepted, and a different radar mode might be appropriate. For each phase, these measurable behaviors that logically should affect goal accomplishment were identified and scored. The scoring was based on the contribution to goal accomplishment. The proportion of mission-specific goals being accomplished successfully according to the GIM algorithms indicated how well the pilot was accomplishing the goals of that mission phase. More important, the behavioral components scored as failing should identify the portions of the task that the pilot was either unaware of or unable to perform at the moment. Thus, GIM scores could potentially provide a real-time indication of the person's SA as reflected by the quality of task performance and a diagnosis of the problem if task performance deviated from the ideal, as specified by the GIM task analysis and scoring algorithms.

Vidulich and McMillan (2000) tested the GIM metric in a simulated air-to-air combat task using two cockpit designs that were known from previous evaluations to produce different levels of mission performance, mental workload, and perceived SA. The subjects were seven U.S. military pilots or weapons systems officers. The real-time GIM scores distinguished successfully between the two cockpits and the different phases of the mission. No attempt was made to guide adaptation on the basis of the GIM scores, but the results suggested that such an approach has promise.

### 3.1.5 Situation Present Assessment Method

Another assessment technique is the Situation Present Assessment Method (SPAM) developed by Durso and his colleagues (e.g., Durso et al., 1995a; Durso and Dattel, 2004). SPAM is especially interesting because it not only combines some of the beneficial features of performance-based SA assessment with aspects of

the memory probe approach but also incorporates a performance-based assessment of mental workload.

SPAM utilizes probe questions as a tool for assessing SA, but unlike the more typical memory probe procedures, SPAM does not remove the participant from the situation to force reliance on the contents of working memory. In SPAM the participant continues to engage in the task and, if unable to reply to the SPAM query based on the current contents of working memory, is able to search the situation to determine the answer. The experimenter then assesses not only the correctness of the participant's response but also the latency to generate the response. The idea behind using the latency as a SA measure is that, if the participant possesses good SA, then the reply will either be based on the current contents of working memory or the participant will know exactly where to search for the needed information; in either case, the response should be relatively quick. On the other hand, if the participant's SA is low, the search for the relevant information will probably be inefficient and relatively slow. SPAM has been demonstrated to be sensitive to expertise differences in Chess (Durso et al., 1995b), automation failures in air traffic control (ATC) simulations (Durso et al., 2001), and individual differences in ATC trainee potential (Durso et al., 1998). In these tests, the SPAM approach not only proved to be sensitive but was also generally unintrusive to primary-task performance.

In addition to the SA measurement provided by SPAM, the technique also incorporates a simple performance-based measure of mental workload. This is done by starting each SPAM query with a warning signal. The participant must acknowledge the signal before the SPAM query is presented. If the participant's momentary workload is high, then it is expected that more time will elapse between the warning cue and the acknowledgment.

Thus, the elegant combination of two latency-based measures into the SPAM technique allows simultaneous assessment of mental workload and SA. This makes the SPAM approach especially attractive for the study of participants' strategies for managing workload, performance, and SA (Durso and Alexander, 2010).

### 3.2 Subjective Measures

Subjective measures consist primarily of using techniques that usually require subjects to quantify their experience of workload or SA. Many researchers are suspicious of subjective data, perhaps as a holdover from the behaviorists' rejection of introspection as a unscientific research method (Watson, 1913). However, Annett (2002a,b) argued that subjective ratings are maligned unfairly. In an in-depth discussion of the issues, he contended that the lack of precision associated with subjective measures was expected to prohibit their use in setting design standards. However, he also concluded that subjective ratings could be useful for evaluating the mechanism underlying performance or for the comparative evaluation of competing interface designs. Such a comparative process is how subjective ratings of workload and SA are typically used.

Vidulich and Tsang (1987) and Tsang and Vidulich (1994) identified three variables that were useful for categorizing subjective rating techniques: dimensionality, evaluation style, and immediacy. *Dimensionality* refers to whether the metric required the subjects to rate their experiences along a single dimension or multiple dimensions. *Evaluation style* refers to whether the subjects were asked to provide an absolute rating of an experience or a relative rating comparing one experience to another. *Immediacy* distinguishes between subjective metrics that were designed to be used as soon as possible after the to-be-rated experience and those that were used at the end of a session or even at the end of an experiment. Although it is theoretically possible to create a subjective technique that combines any level of the three variables, in practice two basic combinations have dominated. The most common techniques combine multidimensionality, the absolute evaluation style, and immediacy. The typical alternative to the multidimensional–absolute–immediate approach are techniques that are usually unidimensional, use a relative comparison evaluation style, and are collected retrospectively rather than immediately.

### 3.2.1 Multidimensional Absolute Immediate Ratings

According to Tsang and Vidulich (1994), the subject's immediate assessment after trial completion should benefit from the freshest memory for the experience of performing the trial while minimizing the potential damaging effects of the operator second guessing her evaluation. The absolute scale design should also encourage the operator to consider the workload of each trial condition individually rather than relatively to other conditions. The multidimensional aspect supports diagnosticity because the subjects can be more precise in describing how experimental conditions influence their experience.

***Workload Ratings***  Although numerous scales have been developed, two popular multidimensional, absolute, and immediate rating scales are the National Aeronautics and Space Administration's Task Load Index (NASA-TLX) (Hart and Staveland, 1988) and the Subjective Workload Assessment Technique (SWAT) (Reid and Nygren, 1988). NASA-TLX is based on six subscales (i.e., mental demand, physical demand, temporal demand, performance, effort, and frustration level), and the ratings on the six scales are weighted according to the subject's evaluation of their relative importance. SWAT is based on three subscales (i.e., time load, mental effort load, and psychological stress load). The weighting of the three subscales is determined by the subject's rankings of the workload inflicted by each combination of the various levels of workload (1–3) in each of the three workload scales. A conjoint analysis is then conducted to produce a look-up table that translates the ordinal rankings to ratings with interval-scale properties. Both NASA-TLX and SWAT ultimately produce a workload rating from 0 to 100 for each trial rated.

NASA-TLX and SWAT have been compared to each other and to a number of other rating scales a number of times (e.g., Battiste and Bortolussi, 1988; Hill et al., 1992; Tsang and Vidulich, 1994; Rubio et al., 2004). In reviewing the comparisons, Rubio et al. (2004) noted that SWAT and NASA-TLX both offer diagnosticity, due to their multiple scales, and have generally demonstrated good concurrent validity with performance. Rubio et al. (2004) also pointed out that both techniques have demonstrated sensitivity to difficulty manipulations, although some researchers have found NASA-TLX to be slightly more sensitive, especially for low levels of workload (e.g., Battiste and Bortolussi, 1988; Hill et al., 1992). On the other hand, Dey and Mann (2010) compared several variants of both NASA-TLX and SWAT to each other in assessing an agricultural sprayer task and found a simplified version of the SWAT to be the most sensitive subjective scale overall.

NASA-TLX and SWAT have also been compared in terms of their ease of use. Each technique consists of two major parts: individual weighting of the subscales and ratings that operators provide after each trial that are then weighted and converted into a final workload score. For the immediate ratings, the SWAT scale requires the operator to choose one of three possible levels for each of the three subscales. The NASA-TLX scale requires the operator to provide a rating between 0 and 100 for each of the six subscales. This makes the SWAT ratings a little easier to collect, especially in a prolonged task, such as flying, while the task performance actually continues. On the other hand, NASA-TLX's paired comparison of the subscales to generate weightings for the subscale is much easier than SWAT's card-sorting procedure for both the subject to complete and the researcher to process. The NASA-TLX procedure only requires the subject to make 15 forced choices of importance between the individual subscales. The raw count of the number of times that each subscale was considered more important than another is then used to weigh the individual subscale ratings provided by the subject. In contrast, the SWAT card sort requires each subject to consider and sort 27 cards (each representing a possible combination of the level of workload for each subscale). Subsequently, specialized software is used to convert the card sort data into an overall workload scale.

Some researchers have investigated simpler methods of generating weights for SWAT. The simple sum of the ratings from the three SWAT subscales has been shown to exhibit the same pattern of findings as SWAT ratings using the original procedure (Biers and Maseline, 1987; Biers and McInerney, 1988; Luximon and Goonetilleke, 2001). Additionally, Luximon and Goonetilleke (2001) found that SWAT sensitivity could be improved by using a continuous scale rather than a three-level discrete scale. As with SWAT, the weighting procedure of NASA-TLX has undergone testing. Both Nygren (1991) and Hendy et al. (1993) have argued that whether the weighting procedure adds any value to NASA-TLX's effectiveness is still ambiguous (e.g., see also Wiebe et al., 2010). Further, according to Nygren (1991), the criterion validity of the measures is not completely clear.

Lee and Liu (2003) provide an example of the use of NASA-TLX to assessing the workload of 10 China Airline pilots flying a Boeing 747 aircraft in a high-fidelity 747 simulator. They found that the overall

NASA-TLX ratings discriminated successfully among four flight segments. As expected, takeoff, landing, and approach were all rated to incur higher workload than cruise. Lee and Liu also used the multidimensional scales of NASA-TLX to diagnose the causes of the higher workload. For example, they found that temporal demand was an important contributor to the takeoff and approach segments, but effort was a more important contributor to landing. The authors concluded that training programs should be designed to help the pilot cope with the specific expected stresses of different flight segments.

***SA Ratings*** Multidimensional, absolute, and immediate ratings have also been a popular approach for assessing SA. Probably the most commonly used subjective rating tool for SA has been the Situation Awareness Rating Technique (SART) developed by Taylor (1990). The SART technique characterizes SA as having three main dimensions: attentional demands (D), attentional supply (S), and understanding (U). The ratings on each of the three dimensions are combined into a single SART value according to a formula (Selcon et al., 1992): SA = U − (D −S). Inasmuch as SART contains ratings of attentional supply and demand, it can be seen to incorporate elements of mental workload in its evaluation but also provides additional distinct information. For example, Vidulich et al. (1995) reported that increased difficulty of a PC-based flight simulation increased the Demand scale on the SART but not the Supply or Understanding scales. Providing additional information increased the Understanding scale but not the Demand or Supply scales. In another study, a direct comparison of NASA-TLX and SART revealed that, although both were sensitive to task demand level, SART was also sensitive to the experience level of the 12 Royal Air Force pilot subjects (Selcon et al., 1991).

### 3.2.2 Unidimensional Relative Retrospective Judgments

The unidimensional relative retrospective judgment approach is based on the assumption that the operator who has experienced all of the task conditions is considered a subject matter expert with knowledge about the subjective experience of performing the various task conditions under consideration. This approach attempts to extract and quantify the operator's opinions about the experiences associated with task performance.

***Workload Judgments*** The use of unidimensional relative retrospective judgments was strongly supported by the work of Gopher and Braune (1984). Inspired by Stevens's (1957, 1966) psychophysical measurement theory, Gopher and Braune adapted it to the measurement of subjective workload. The procedure used one task as a reference task with an arbitrarily assigned workload value. All of the other tasks' subjective workload values were evaluated relative to that of the reference task. The resulting ratings were found to be highly sensitive in a number of studies (e.g., Tsang and Vidulich, 1994; Tsang and Shaner, 1998). In addition, high reliability of these ratings was revealed by split-half correlations of repeated ratings of the task conditions.

Another approach to collecting unidimensional relative retrospective judgments was developed by a mathematician, Thomas Saaty (1980). Saaty's *Analytic Hierarchy Process* (AHP) technique was developed to aid decision making. When applied to workload assessment, the AHP requires operators to perform all pairwise comparisons of all task conditions. These comparisons fill a dominance matrix, which is then solved to provide the ratings for each task condition. Saaty's AHP was originally designed to evaluate all dimensions relevant to a decision and then combine the multiple dimensions to support selection of one option in a decision-making task. However, Lidderdale (1987) demonstrated that a unidimensional version of the AHP could be an effective workload assessment tool and inspired further investigations using the tool. Vidulich and Tsang (1987) compared the AHP to NASA-TLX and a unidimensional absolute immediate rating of overall workload in assessing the workload of selected laboratory tasks. The AHP was found to be both more sensitive and more reliable than the other techniques. Vidulich (1989) compared several methods for converting dominance matrices to the final ratings and used the results to create the Subjective Workload Dominance (SWORD) technique. In one application, Toms et al. (1997) used SWORD to evaluate a prototype decision aid for landing an aircraft. The participating pilots performed landings with and without the decision aid in both low- and high-task-load conditions. Task load was varied by changing the information available to the pilots. Overall, the results showed that the decision aid improved landing performance while lowering mental workload.

Vidulich and Tsang performed a series of studies to examine the various approaches to subjective assessment. Although specific instruments were compared in these studies, the goal was not to determine which instrument was superior. Rather, the objective was to determine the assessment approach that can elicit the most and accurate workload information. Tsang and Vidulich (1994) found that the unidimensional relative retrospective SWORD technique with highly redundant pairwise comparisons was superior to a procedure using relative comparisons to a single reference task. Tsang and Velazquez (1996) found that, compared to an immediate absolute instrument, a relative retrospective psychophysical scaling was more sensitive to task demand manipulation and had higher concurrent validity with performance. They also found that a subjective multidimensional retrospective technique, the Workload Profile, provided diagnostic workload information that could be subjected to quantitative analysis. Rubio et al. (2004) confirmed the diagnostic power of the Workload Profile technique. They found the Workload Profile to be more diagnostic than either NASA-TLX or SWAT. Collectively, these studies suggested a relative retrospective approach advantage.

***SA Judgments*** Unidimensional relative retrospective judgments have also been applied to SA assessment. For example, the SWORD workload technique was adapted to measure SA (SA-SWORD; Vidulich and

Hughes, 1991). Vidulich and Hughes used SA-SWORD to evaluate the effect of data-linked information in an advanced fighter aircraft simulation. The technique demonstrated good sensitivity to the experimental manipulation and good reliability. Toms et al. (1997) used SA-SWORD to assess SA along with SWORD to measure workload. Their results showed that a decision aid's benefits to landing performance and mental workload were also associated with improved SA.

## 3.3 Physiological Measures

A host of physiological measures have been used to assess mental workload with the assumption that there are physiological correlates to mental work. The most common measures include cardiovascular (e.g., heart rate and heart rate variability), ocular (e.g., pupil dilation, eye movement measures), and measures of brain activity. The present review focuses on the brain measures because (1) it would seem that brain activity could most directly reflect mental work; (2) in line with our framework that hypothesizes both an intensity aspect and a structural aspect to mental work, many of the brain measures have been demonstrated to be sensitive to parametric manipulation of task demands and to be diagnostic with regard to the types of cognitive demands involved in certain task performance; and (3) there appears to be much potential for applications in the burgeoning field of neuroergonomics (Parasuraman and Rizzo, 2007). While the present review focuses on the brain measures, readers are urged to consult many fine and instructive reviews of nonbrain measures (e.g., Beatty, 1982; Stern et al., 1984; Wilson and Eggemeier, 1991; Jorna, 1992; Mulder, 1992; Backs and Boucsein, 2000; Kramer and Weber, 2000; McCarley and Kramer, 2007).

### 3.3.1 Electroencephalographic Measures

Electroencephalographic (EEG) measures are recorded from surface electrodes placed directly on the scalp and have been shown to be sensitive to momentary changes in task demands in laboratory studies (e.g., Glass, 1966), simulated environments (e.g., Fournier et al., 1999; Gevins and Smith, 2003), and operational settings (e.g., Wilson, 2002b). Spectral power in two major frequency bands of the EEG have been identified as being sensitive to workload manipulations: the alpha (7–14-Hz) and theta (4–7-Hz) bands. Spectral power in the alpha band that arises in widespread cortical areas is inversely related to the attentional resources allocated to the task, whereas theta power recorded over the frontal cortex increases with increased task difficulty and higher memory load (Parasuraman and Caggiano, 2002). Sterman and Mann (1995) reported a series of EEG studies conducted in simulated and operational military flights. A systematic decrease in power in the alpha band of the EEG activity was observed with a degraded control responsiveness of a T4 aircraft. A graded decrease in the alpha band power was also observed as U.S. Air Force pilots flew more difficult in-flight refueling missions in a B2 aircraft simulator. In another study, Brookings et al. (1996) had Air Force air traffic controllers perform computer-based

air traffic control simulation (TRACON). Task difficulty was manipulated by varying the traffic volume (number of aircraft to be handled), traffic complexity (arriving to departing flight ratios, pilot skill, and aircraft types), and time pressure. Brookings et al. found the alpha power to decrease with increases in traffic complexity and the theta power to increases with traffic volume. Recently, Dussault et al. (2005) compared EEG and heart-based physiological workload measures for sensitivity to the demands of a simulated flight task with both expert and nonexpert pilots. They found the heart-based measures to be insensitive to the different simulated flight segment, although expert pilots generally had a lower heart rate than nonexpert pilots. In contrast, the EEG measures showed both a lower level of activation for the expert pilots and distinguished between different flight segments. In a study using laboratory tasks, Berka et al. (2007) collected EEG measures via a wireless headset while subjects performed a battery of vigilance, spatial, verbal, and memory tasks. Using different algorithms, Berka et al. derived an EEG metric for task engagement (that tracks demands for sensory processing and attention resources) and one for mental workload (that tracks demands of executive control). The results showed that the EEG engagement metric reliably reflects demands for information gathering, visual processing, and allocation of attention whereas the EEG workload metric reflects demands for working memory, information integration, problem solving, and reasoning, Further, the EEG measures were found to correlate with subjective ratings and performance measures that included accuracy and reaction time.

Kramer and Parasuraman (2007) point out that, in addition to being able to provide a somewhat precise temporal index of changes in alertness and attention, an important advantage of EEG measures is that they can be recorded in the absence of discrete stimuli or responses, which make them particularly useful in situations in which an operator is monitoring slowly changing displays that requires minimal intervention. One drawback of the EEG measures is their sensitivity to numerous artifacts such as head and body movements that pose special difficulties for extralaboratory applications. While Kramer and Weber (2000) were concerned with the diagnosticity of the EEG measures, recent research such as those of Berka et al. (2007) has made some progress in using EEG measures to distinguish the different types of demands incurred. More in-depth discussion can be found in Gevins et al. (1995) and Pizzagalli (2007).

### 3.3.2 Event-Related Potentials

Evoked potentials are embedded in the EEG background and are responsive to discrete environmental events. There are several different positive and negative voltage peaks and troughs that occur 100–600 ms following stimulus presentation. The P300 component of the event-related potential (ERP) has been extensively studied as a mental workload measure (e.g., Gopher and Donchin, 1986; Parasuraman, 1990; Wickens, 1990; Kramer and Parasuraman, 2007). The P300 is often examined in a dual-task condition with either the oddball

paradigm or the irrelevant probe paradigm. In the *oddball paradigm*, the P300 is elicited by the subject keeping track of an infrequent signal (e.g., counting infrequent tones among frequent tones). One drawback of this paradigm is that the additional processing of the oddball and having to respond to it could inflate the true workload of interest artifactually. As an alternative, additional stimuli are presented, but subjects are not required to keep track of them in the *irrelevant probe paradigm*. But the irrelevant probe paradigm would work only if the irrelevant probes were presented in a channel that would be monitored anyway (Kramer and Weber, 2000)

With the oddball paradigm, the amplitude of the P300 has been found to decrease with increased task difficulty manipulated in a variety of laboratory tasks (e.g., Hoffman et al., 1985; Strayer and Kramer, 1990; Backs, 1997). Importantly, P300 is found to be selectively sensitive to perceptual and central processing demands. For example, Isreal et al. (1980) found that the amplitude of P300 elicited by a series of counted tones was not sensitive to manipulations of the response-related demand of the concurrent tracking task but was affected by manipulations of display perceptual load of the concurrent monitoring task. Many of the laboratory-based findings have been replicated in simulator studies. For example, Kramer et al. (1987) had student pilots fly an instrument flight plan in a single-engine aircraft simulator. The P300s elicited by the secondary tone-counting task decreased in amplitude with increasing turbulence and subsystem failures (see also Fowler, 1994). Using the irrelevant probe paradigm, Sirevaag et al. (1993) had senior helicopter pilots fly low-level, high-speed flight in a high-fidelity helicopter simulator. The P300 amplitude was found to increase with increased difficulty in the primary tracking task. In addition, the P300 amplitude elicited by the secondary irrelevant probes decreased with increased communication load.

A recent modeling effort further validates the usefulness of P300 as a real-time mental workload metric. Wu et al. (2008) presented a queuing network modeling approach that was demonstrated to be able to account for changes in the P300 amplitude and latency as task demands varied. The researchers proposed that the queuing network model could be a candidate tool for supporting adaptive automation because of its ability to assess mental workload in real time as well as to predict workload both in the temporal dimension (as reflected by the P300 latency) and the intensity dimension (as reflected by the P300 amplitude).

In short, ERP measures have been found to be sensitive to, and diagnostic of, changes in the perceptual and central processing task demands. Because of the sensitivity of ERP measures to the temporal aspects of neuronal activity, they may be a particularly good candidate tool for assessing workload dynamically. As with the EEG measures, ERP measures are subject to problems with motion artifacts and electrical noise. Another potential drawback is the possibility of artifactually augmenting the true workload of interest if the ERP measures are elicited from a secondary task. As with the performance measures, it would be ideal if a secondary

task naturally embedded in the test environment could be used. But because ERP signals are relatively small and ensemble averaging across many stimuli is necessary for meaningful interpretation, there are not always sufficient stimuli available from the embedded secondary task or the primary task. See Fabiani et al. (2007) and Kramer and Parasuraman (2007) for a more in-depth discussion.

### 3.3.3 Cerebral Blood Flow Measures

Cerebral blood flow measures are based on the principle that neuronal activity associated with mental processing could be assessed by measuring the blood flow responses of the brain (Kramer and Parasuraman, 2007). Three measures are considered here: positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and Transcranial Doppler Sonography (TCD). The PET and fMRI measures have been used to localize cortical regions associated with various cognitive processing (e.g., D'Exposito et al., 1999; Posner and DiGirolamo, 2000) and could provide diagnostic information with regard to the type of task demand incurred. Recent research has shown that all three measures are sensitive to systematic variations with parametric manipulation of task difficulty (Kramer and Parasuraman, 2007).

As an example, Corbetta et al. (1990) had subjects determine whether two stimuli presented in two frames separated by a blank display were the same or different. Between the two frames, the stimuli could vary in one of three dimensions: shape, color, and velocity. In the selective-attention condition, one of the dimensions would be designated as the relevant dimension, and zero, one, or two irrelevant dimensions could covary with the relevant dimension. In the divided-attention condition, any one of the dimensions could vary. The behavioral data (*d'*) indicated that the divided-attention condition was more difficult. In the selective-attention condition, increased blood flow as revealed by PET scans was observed in the region of the visual cortex known to be related to the processing of the relevant dimension designated. Corbetta et al. proposed that the increased neuronal activity in the specialized regions for the different dimensions was a result of top-down attentional control since the sensory information should be the same across selective- and divided-attention conditions.

Just et al. (2003) reviewed a series of PET studies and found lower brain metabolic rate to be associated with higher language proficiency (Parks et al., 1988) and increased practice with a spatial computer game (Haier et al., 1992). Just et al. interpreted these results to mean that high-ability, high-skill persons could process more efficiently, thereby requiring a smaller amount of their total amount of processing resources available. They effectively would have a larger supply of processing resources (for other processing). Just and Carpenter (1992) proposed that the computational work underlying thinking must be accompanied by resource utilization. In their 3CAPS (Capacity-Constrained Concurrent Activation-based Production System) model, a brain region is considered a resource pool. Computational activities are resource consuming in the sense that

they all operate by consuming an entity called activation. The intensity and volume of brain activation in a given cortical area are expected to increase in a graded fashion with increased computational load. Indeed, Just et al. (1996) found that with increasing sentence complexity the level of neuronal activation and the volume of neural tissue activated increased in four cortical areas associated with language processing (Wernicke's, Broca's, and their right-hemisphere homologues). With a spatial mental rotation task, Carpenter et al. (1999) found a monotonic increase in signal intensity and volume activation in the parietal region as a function of increased angular disparity between the two stimuli whose similarity was to be judged.

Reviewing the results from a number of studies that use an array of behavioral and neurophysiological measures (ERPs, PET, and fMRI), Just et al. (2003) came to a similar viewpoint adopted in the present chapter in that cognitive workload is hypothesized to be a function of resource consumption and availability. Several similarities between the 3CAPS model and Wickens's multiple-resource model are apparent. According to both models, (1) mental workload is a function of the supply and demand of processing resources, (2) resources can be modulated in a graded fashion, (3) specific resources are used for different types of cognitive processing (e.g., verbal and spatial task demands bring about activations in different cortical regions), and (4) supply or availability of resources can be modulated by individual differences in ability and skill or expertise.

The PET and fMRI studies described so far were all conducted in the laboratory. Although more studies conducted in the operational settings would certainly be desirable, the equipment required for their measurements makes it impractical. Notwithstanding, one simulated study on pilot performance can be presented. Pérès et al. (2000) had expert (with at least 3000 flight hours and flight instructor qualifications) and novice (with less than 50 flight hours) French Air Force pilots perform a continuous simulated flight control task at two speeds (100 and 200 knots) while fMRI measures were collected. The fMRI measures showed that neuronal activation was dominant in the right hemisphere, as would be expected for a visual spatial task. Further, novice pilots exhibited more intense and more extensive activation than expert pilots. In the high-speed condition, the expert pilots exhibited increased activation in the frontal and prefrontal cortical areas and reduced activity in visual and motor regions. This suggested that the expert pilots were better able to use their knowledge to focus their resources for the higher level functions in working memory, planning, attention, and decision making. In contrast, novice pilots' increased activation in the high-speed condition was more widespread and extended across the frontal, parietal, and occipital areas, suggesting that they were engaged in nonspecific perceptual processing. Interestingly, when the expert pilots were asked to track at an even higher speed (400 knots), their pattern of activation resembled that of the novice pilots tracking at 200 knots.

The TCD technique uses a transducer mounted on the subject's head that directs ultrasound waves toward an artery within the brain. The application of TCD in mental workload assessment is relatively recent. Still, a number of studies have shown systematic increase in blood flow in the middle cerebral arteries (MCAs) with increased task demands. For example, Serrati et al. (2000) observed increased blood flow with increased difficulty of a mental rotation task. Frauenfelder et al. (2004) observed increased blood flow with increased complexity of a planning task. Wilson et al. (2003) found that blood flow associated with performance of the Multi-Attribute Task Battery varied with task difficulty.

Notably, there is a paucity of physiological studies on SA included in this chapter. This is partly because, compared to the concept of mental workload, the concept of SA is relatively new (Pew, 1994; Wickens, 2001) and both its theoretical and methodological developments have not reached the level of maturity that the concept of mental workload has. It is also the case that the concept of SA is not associated with a specific process. Although complex performance generally entails multiple processes, it is often possible to identify many of the processes and hence the type of workload involved. In contrast, whereas SA is supported by many of the same processes, SA is an emergent property that has not been hypothesized to be associated with specific cortical regions or other physiological responses.

The neurophysiological measures discussed here have all demonstrated to show sensitivity to task demands. Some of them are able to provide a continuous measure for online assessment (e.g., EEG, ERP, TCD). Some could provide valuable diagnostic information with regard to the type of cognitive demands entailed (e.g., ERPs, PET, fMRI). Most of them are not cognitively intrusive, as in having to perform additional work in order to provide a measure. However, some are particularly vulnerable to interference from motion and electrical noise. The main drawback with many physiological measures is that they are equipment intensive and they require specialized expertise to collect, analyze, and interpret properly. This makes assessment of some of them (e.g., PET and fMRI) in the operational settings impractical. But it is not impossible. Even for the costly fMRI studies, attempts have been made to assess the mental workload of simulated flight performance (Pérès et al., 2000). One would expect that many of the physiological measures would become more feasible with the present rapid technological advances (e.g., see Gevins et al., 1995; Wilson, 2002a,b; Parasuraman, 2003; Kramer and Parasuraman, 2007). Readers are encouraged to consult additional sources for more technological details of the neurophysiological techniques (e.g., Kramer and Parasuraman, 2007; Tripp and Warm, 2007).

## 3.4 Multiple Measures of Workload and Situation Awareness

There are several facets to the undertaking of assessing workload and SA of a complex, dynamic human–machine system. First, there are a number of candidate measures to choose from, each with strengths and weaknesses. Measures that provide global information

about the mental workload of these tasks may fail to provide more specific information about the nature of the demand. Measures that could provide more diagnostic information may be intrusive or insensitive to other aspects of interest, and certain sensitive measures may be collected only under restrictive conditions. Still, many workload measures often associate. For example, many subjective measures have been found to correlate with performance (e.g., Tsang and Vidulich, 1994; Hockey et al., 2003; Rubio et al., 2004). Just et al. (2003) present a convincing account of how the associations among a number of behavioral and neurophysiological measures support the extant understanding of many cognitive concepts relevant to mental workload (see also Wickens, 1990; Fournier et al., 1999; Lee and Liu, 2003). Importantly, when the measures do not associate, they do not do so in haphazard ways. The association and dissociation patterns among measures should therefore be evaluated carefully rather than treated as unreliable randomness. Below we discuss in greater detail the dissociation between the subjective and performance workload measures and the relation between the workload and SA measures.

### 3.4.1  Dissociations among Workload Measures

When different types of workload measures suggest different trends for the same workload situation, the workload measures are said to *dissociate*. Given that mental workload is a multidimensional concept, and that various workload measures may be differentially sensitive to the different workload dimensions, some dissociations among workload measures are to be expected. Measures having qualities of general sensitivity (such as certain unidimensional subjective estimates) respond to a wide range of task manipulations but may not provide diagnostic information about the individual contributors to workload. Measures having selective sensitivity (such as secondary-task measures) respond only to specific manipulations. In fact, the nature of the dissociation should be particularly informative with regard to the characteristics of the workload incurred by the task under evaluation.

Several conditions for the dissociation of performance and subjective measures have been identified (Vidulich and Wickens, 1986; Vidulich, 1988; Yeh and Wickens, 1988):

1. Dissociation tends to occur under low-workload conditions (e.g., Eggemeier et al., 1982). Performance could already be optimal when the workload is low and thus would not change further with additional effort that would be reflected in the subjective measures.

2. Dissociation would occur when subjects are performing data-limited tasks (when performance is governed by the quality of the data rather than by the availability of resources). If subjects are already expending their maximum resources, increasing task demand would further degrade performance but would not affect the subjective ratings.

3. Greater effort would generally result in higher subjective ratings; however, greater effort could also improve performance (e.g., Vidulich and Wickens, 1986).

4. Subjective ratings are particularly sensitive to the number of tasks that subjects have to time-share. For example, performing an easy dual task (that results in good performance) tends to produce higher ratings than does performing a difficult single task (that results in poor performance) (e.g., Yeh and Wickens, 1988).

5. Performance measures are sensitive to the severity of the resource competition (or similarity of resource demand) between the time-shared tasks, but subjective measures are less so (Yeh and Wickens, 1988).

6. Given that subjects only have access to information available in their consciousness (Ericsson and Simon, 1993), subjective ratings are more sensitive to central processing demand (such as working memory demand) than to demands that are not represented well consciously, such as response execution processing demand. Dissociation would therefore tend to occur when the main task demands lie in response execution processing (Vidulich, 1988). McCoy et al. (1983) provided an excellent list of realistic examples of how performance and subjective ratings may dissociate in system evaluations and discussed how the dissociations can be interpreted in meaningful ways.

Hockey (1997) offers a more general conceptual account for the relations among performance, subjective, and physiological measures. Hockey proposes a compensatory control mechanism that allocates resources dynamically through an internal monitor very much like the one proposed by Kahneman (1973). Performance may be protected (as in primary-task performance) by strategic recruitment of further resources, at the risk of incurring increased subjective effort, physiological costs, or degraded secondary-task performance. Alternatively, performance goals may be lowered. Although performance may then be lower, no additional effort or physiological cost will be incurred. Hockey emphasizes that the efficacy of the control mechanism hinges on the accuracy of the perception of the situation. For example, Sperandio (1978) found air traffic controllers to switch strategy when the traffic load increased. Beyond a certain number of aircraft that the controllers handled, controllers would switch to a uniform strategy across aircraft as opposed to paying more individual attention to the various aircraft. Although this strategy should reduce the cognitive resources needed for dynamic planning, it would also probably produce less optimal scheduling. That is, the primary-task performance might have been preserved with the strategy switch, but some secondary goals would have suffered (Hockey, 1997).

A recent study by Horrey et al. (2009) further illustrates the importance of understanding the potential dissociations among workload measures. Drivers of

varying age and experience drove an instrumented vehicle on a closed-loop track while simultaneously performing an additional in-vehicle task. One of the in-vehicle tasks was a more engaging task that was game-like and involved back-and-forth information exchange with the experimenter. Another in-vehicle task was a running addition task presented at a fixed interval. Driving performance as well as the performance of both the in-vehicle tasks degraded in the dual-task condition from the single-task condition. Driving performance was degraded more with the more engaging task than with the addition task. However, neither subjective workload ratings nor subjective performance estimates differentiated the two conditions. These results suggested that the subjects were insufficiently sensitive to the competition for resources between driving and the more engaging task, posting important implications for road safety.

### 3.4.2 Relations of Workload and Situation Awareness Measures

Wickens (2001) pointed out that, due to the energetic properties of workload, many physiological and subjective rating measures are suited for capturing the quantitative aspects of workload. In contrast, physiological measures are likely to be poor candidates for assessing the quality or content of SA. Further, self-ratings of one's awareness are unlikely to be informative since one cannot be aware of what one is not aware. However, subjective SA ratings could still be useful if they are used for system evaluative purposes. As illustrated earlier, subjects often could indicate reliably which system design affords greater SA. Last, Wickens pointed out that explicit performance measures designed to examine what one is aware of (content of SA) have no parallel use for workload assessment. However, implicit performance measures such as those used to check for reaction to unexpected events can be used to assess both workload and SA.

As discussed earlier, the relationship between workload and SA is multifaceted. Although high SA and an acceptable level of workload are always desirable, workload and SA can correlate positively or negatively with each other, depending on a host of exogenous and endogenous factors. Three sample studies will be described to illustrate their potential relationships. Vidulich (2000) reviewed a set of studies that examined SA sensitivity to interface manipulations. Of the nine studies that manipulated the interface by providing additional information on the display, seven showed an increase in SA, four showed a concomitant reduction in workload, and three showed a concomitant increase in workload. In contrast, of another nine studies that manipulated the interface by reformatting the display, all nine showed an increase in SA, six showed a concomitant reduction in workload, and none showed an increase in workload. In short, although different patterns in the relationship between the workload and SA measures were observed, the various patterns were reasonably interpretable given the experimental manipulations. In another study, Alexander et al. (2000) examined the relationship between mental workload and SA in a simulated air-to-air combat task. Seven pilots flew simulated air intercepts against four bombers supported by two fighters. The main manipulations were two cockpit designs (the conventional cockpit with independent gauges and a virtually augmented cockpit designed by a subject matter expert) and four mission phases of various degrees of difficulty and complexity. A negative correlation between the workload and SA measures were observed for both the cockpit design and the mission complexity manipulations. The augmented cockpit improved SA and reduced workload, whereas increased mission complexity decreased SA and increased workload. Perry et al. (2008) performed an ambitious evaluation of the effects of increasing physical demands on the performance of a rule-based helicopter load planning task, a memory-probe SA measure, and NASA-TLX workload ratings. All measures were collected as subjects performed the task either standing, walking, or jogging on a treadmill. Although subjects were able to maintain performance on the cognitive helicopter loading task, increasing physical demands both decreased SA and increased workload ratings, showing the costs the physical demands were exacting from the subjects. The findings of these studies underscore the value of assessing both the mental workload and SA involved in any test and evaluation.

### 3.4.3 Need for Multiple Measures

There are several broad guiding principles that would be helpful in measures selection. Muckler and Seven (1992) held that "the distinction between 'objective' and 'subjective' measurement is neither meaningful nor useful in human performance studies" (p. 441). They contended that all measurements contain a subjective element as long as the human is part of the assessment. Not only is there subjectivity in the data obtained from the human subject, the human experimenter also imparts his or her subjectivity in the data collection, analysis, and interpretation. Thus, performance measures are not all objective, nor are subjective measures entirely subjective (see also, Annett, 2002a,b; Salvendy, 2002). Muckler and Seven advocated that the selection of a measure (or a set of measures) be guided by the information needs. Candidate measures can be evaluated by considering their relative strengths (such as diagnosticity) and weaknesses (such as intrusiveness). In addition, Kantowitz (1992) advocated using theory to select the measures. He made an analogy between theory and the blueprint of a building. Trying to interpret data without the guidance of a theory is like assembling bricks randomly when constructing a building. To elaborate, Kantowitz pointed out that an understanding of both the substantive theory of human information processing and the psychometric theory of the measurements is helpful. The former dictates what one should measure, and the latter suggests ways of measuring them. Another useful (if not required) strategy is to use multiple measures as much as feasible. As discussed above, even seemingly dissociated measures are informative (and sometimes especially so) if one is cognizant of the idiosyncratic properties of the different measures. In fact, Wickens (2001) pointed out that converging evidence from multiple measures

is needed to ensure an accurate assessment of the level of workload incurred and the quality of SA attained. This need is also reflected in the literature, that many, if not the majority, of the studies now do use multiple measures in their workload or SA assessment (e.g., Brookhuis and de Waard, 2010; Lehrer et al., 2010).

To emphasize the value of assessing multiple measures, Parasuraman (1990) reported a study that examined the effectiveness of safety monitoring devices in high-speed electric trains in Europe (Fruhstorfer et al., 1977). Drivers were required to perform a secondary task by responding to the occurrence of a target light in a cab within 2.5 s. If no response was made, a loud buzzer would be activated. If the buzzer was not responded to within an additional 2.5 s, the train's braking system was activated automatically. Over a number of train journeys, onset of the warning buzzer was rare, and the automatic brake was activated only once. However, the EEG spectra showed that the secondary-task performance could remain normal even when the drivers were transiently in stage 1 sleep.

## 4 DESIGN FOR MENTAL WORKLOAD AND SITUATION AWARENESS: INTEGRATED APPROACH TO OPTIMIZING SYSTEM PERFORMANCE

It is probably fair to say that after a decade of debate there is now a general agreement that mental workload and SA are distinct concepts and yet are intricately intertwined. Both can be affected by very many of the same exogenous and endogenous factors and have a significant impact on each other and on system performance. One implication is that fairly well understood psychological principles can be applied to both concepts. For example, in the framework presented above, both workload and SA are subject to attentional and memory limits, and both can be supported by expertise. There exists an established body of knowledge about the effects of these limits and the enabling power of expertise to allow fairly reliable performance predictions. But the fact that the two concepts are distinct also means that they each contribute uniquely to the functioning of a human–machine system. Below we review several research areas that could be exploited for developing support that would manage workload and SA cooperatively to optimize system performance.

### 4.1 Transportation

Although much of the early work in mental workload and SA was conducted in the aviation domain, recent developments in the light-jet air taxi and NextGen that we reported at the beginning of the chapter illustrates the continued need for workload and SA considerations in aviation system development and evaluation. This is also evident in the emerging field of uninhabited aerial vehicles (UAVs). Given the physical separation between the human operator and the actual system being controlled and the common practice of having a single operator controlling multiple UAVs simultaneously, the UAV operation is typically characterized by heavy reliance on automated systems and poses unique challenges for the

cognitive capabilities of the operator. Not surprisingly, mental workload and SA have figured prominently in UAV-related human factors discussions (e.g., Parasuraman etal., 2009; Prewett et al., 2010).

In ship control, Hockey et al. (2003) used a PC-based radar simulator to examine the cognitive demands of collision avoidance. Subjective workload ratings and secondary-task performance responded similarly to the relative demands of the different collision threats and traffic density, providing valuable information for design of collision avoidance systems. In a recent study, Gould et al. (2009) used a high-fidelity simulator to examine the effects of different navigation aids on high-speed ship navigation while fast patrol boat navigators underwent up to 60 h of sleep deprivation. The navigators were provided with either standard paper charts or a modern electronic chart display and information system (ECDIS). Performance, subjective, and physiological workload measures were collected. Interestingly, some of the workload metrics dissociated from each other and responded to the different experimental manipulations differently. Secondary-task performance was degraded by the sleep deprivation but unaffected by the chart manipulation. But despite improved ship-handling performance with the ECDIS, subjective ratings and heart rate variability indicated that it incurred more workload. Obviously, any single measure would have provided an incomplete picture of what was happening to the ship navigators in this experiment

If the public, special interests groups, and policymakers cannot be convinced of the potential danger of talking or texting on the cell phone while driving, it is not due to a lack of confirming experimental and epidemiological data. Collet et al. (2010a,b) compiled an extensive review of the phoning-while-driving literature. The experimental studies included an array of measures of primary-task measures such as lane-keeping performance in a simulated driving task, secondary-task reaction time to signal detection, subjective workload and SA ratings, and physiological measures. Disturbingly, dissociations between performance and subjective ratings were sometimes observed, suggesting that subjects failed to account for the added demands in the dual-task conditions (Horrey et al., 2009). Collet et al. concluded that concurrent use of cell phones while driving generally has a negative impact upon safety. However, they found that certain variables had larger effects than others. For, example, poor road conditions, demanding conversation content, youth, and inexperience all exacerbated the magnitude of interference between phoning and driving. Counterintuitively, hands-free phones offer no special benefits over hand-held phones. Just et al. (2008) explained that the deterioration in driving performance associated with phoning results from competition for central cognitive resources rather than for motor output. This assertion was further supported by their results from a dual-task study in which subjects drove a simulated car along curving roads while judging spoken sentences to be either true or false. The dual-task scenario degraded driving accuracy and fMRI data revealed that the parietal lobe activation associated with spatial processing decreased by 37% as compared

to the single-task scenario. These results showed that language comprehension (as would be required in a cell phone conversation) could draw mental resources away from driving even when it did not require holding or dialing a phone. Collet et al. (2010a) further pointed out that cell phone use is not the only driver distraction, given the proliferation of in-vehicle technologies, each device should be evaluated for potentially producing an unacceptable level of driver distraction.

In all three of the reviewed domains it can be seen that mental workload and SA considerations have strong potential contributions. The cognitive impacts of new technologies in emerging domains, such as UAVs, and even very familiar domains, such as driving, mandate that the human factors community develop and exploit a full battery of cognitive concepts and measurement tools to ensure maximum safety and effectiveness. Although considerable progress has been made in the areas of mental workload and SA theories and measurement over the years, there is still room for improvement. For example, the development of improved psychophysiological assessment tools would be a great boon for investigating mental workload and SA in the complex, real-world transportation environment.

## 4.2   Adaptive Automation

Automation is often introduced to alleviate the heavy demand on an operator or to augment system performance and to reduce error. Many modern complex systems simply cannot be operated by humans alone without some form of automation aids. However, it is now recognized that automation often redistributes, rather than reduces, the workload within a system (e.g., Wiener, 1988; Lee and Moray, 1994; Casner, 2009). Further, an increasing level of automation could distance the operator from the control system (e.g., Adams et al., 1991; Billings, 1997). The upshot of this is that, even if automation reduces mental workload successfully, it could reduce SA and diminish an operator's ability to recover from unusual events. The idea of adaptive automation was introduced as a means of achieving the delicate balance of a manageable workload level and an adequate SA level. This idea has been around for some time (e.g., Rouse, 1977, 1988) and is receiving much attention in recent research (e.g., Rothrock et al., 2002; Parasuraman and Bryne, 2003; Scerbo, 2007). Proponents of adaptive automation argue that static automation that entails predetermined fixed task allocation will not serve complex dynamic systems well. Workloads can change dynamically due to environmental and individual factors (e.g., skill level and effectiveness of strategies used). It has been proposed that a major environmental determinant of workload is rapid (Huey and Wickens, 1993) and unexpected (Hockey et al., 2003) changes in task load. So, ideally, more or fewer tasks should be delegated to automation dynamically. More automation would be introduced during moments of high workload, but as the level of workload eases, more tasks would be returned to the operator, thereby keeping the operator in the loop without overloading the person. The key issue is the development of an implementation algorithm that could efficaciously adapt the level of automation to the operator's state of workload and SA.

Parasuraman and Bryne (2003) described several adaptation techniques that rely on different inputs to trigger an increase or decrease in the extent of automation in the system. These techniques mostly use physiological or performance indices that afford fairly continual measures. One advantage of basing the adaptive automation algorithm on physiological measures is their noninvasive nature. A number of physiological measures have been evaluated for their potential to provide real-time assessment of workload. They include eye movement measures (Hilburn et al., 1997; McCarley and Kramer, 2007), heart rate variability (e.g., Jorna, 1999), EEG (e.g., Gevins et al., 1998; Prinzel et al., 2000; Gevins and Smith, 2003; Berka et al., 2007; Kohlmorgen, et al., 2007), ERP (Parasuraman, 1990; Kramer et al., 1996; Wu et al., 2008), and TCD (Tripp and Warm, 2007). While Coffey et al. (2010) concluded that the use of neurophysiological signals for direct system control is likely to be inherently limited by the information content and quality of the signals, they see greater promise in using these signals for real-time adaptive automation to aid operators at an appropriate level to keep workload manageable.

Although physiological-based measures are the dominant measures used in adaptive automation, recent studies have demonstrated the potential promise of subjective and performance measures as well. For example, Vidulich and McMillan (2000) propose that the Global Implicit Measure (GIM, described above) could be developed as a real-time SA measurement that could guide effective automated pilot aiding based on real-time scoring of both continuous and discrete tasks. In one performance study, Kaber and Riley (1999) used a secondary monitoring task along with a target acquisition task. Adaptive computer aiding based on secondary-task performance was found to enhance primary-task performance. In a more recent study, Kaber et al. (2006) again used a secondary monitory task and found the adaptive automation to be differentially effective in supporting SA performance of different information-processing tasks in a low-fidelity ATC-related simulation. Lower order functions such as information acquisition were found to benefit from the automation but not the higher functions such as information analysis. In a simulated reconnaissance mission that involved operators supervising multiple uninhabited air and ground vehicles, Parasuraman et al. (2009) used the changed detection performance as the trigger for adaptive automation. Beneficial effects on performance, workload, and SA were observed. Note that for the purpose of adaptive automation the performance measures used would need to afford fairly continual assessment, a property that not many performance-based measures possess. Also, as discussed above, for the secondary-task methodology to provide useful workload information, the time-shared tasks would need to be competing for some common resources, which of course could add to the workload, as Kaber et al. (2006) had observed.

Of note is that many studies now employ and find the use of multiple measures for deriving the automation algorithm to be superior to using a single measure

(e.g., Haarmann et al., 2009; Hockey et al., 2009; Ting et al., 2010).

## 4.3 Medicine

Another domain in which workload and SA assessment is making in-roads is in medicine, especially within the setting of surgical operations. The parallel between aviation and many branches of medicine is increasingly recognized. Both aviation and medicine make considerable use of advanced technology to meet the demands of their complex, dynamic, and safety-critical operations. To accomplish this, researchers in both aviation and medical human factors acknowledge the necessity to understand and optimize the mental workload and SA of the operators involved. For example, Leedal and Smith (2005) identified the workload construct as being applicable to the role of the anesthetist. In particular, they invoked a relationship between "spare capacity" as determined by workload metrics and a margin of safety in controlling the patient's physical state. They identified the potential use of workload metrics as a means for evaluating procedures and tools to ensure that there is adequate supply of spare capacity.

A number of recent studies have used various workload assessment techniques to evaluate the efficacy of medical instruments. For example, Spain and Bliss (2008) used the NASA-TLX subjective workload ratings for evaluating a novel sonification display for its potential utility in patient state monitoring during surgery. Sound parameters were examined for their ability to be informative without being distracting, or in other words to provide the needed information without consuming excess reserve capacity. Charabati et al. (2009) also used NASA-TLX ratings as a primary evaluation tool of a proposed novel integrated monitor of anesthesia (IMA) designed to integrate three essential data components for use by an anesthetist. Davis et al. (2009) used a secondary task for workload assessment of trainees in anesthesiology simulations. Their results clearly indicated an increased cognitive load as the trainees worked through the simulated emergencies. Davis et al. suggested that mental workload assessment should become a routine part of assessing training and equipment design to reduce the potential for future errors.

Perhaps due to the early recognition of the relevance of the SA concept to anesthesiology by Gaba and Lee (1990) and Gaba et al. (1995), workload and SA applications appear to be most prominent in this branch of medicine. Still, a recent review by Fioratou et al. (2010) on the application of the SA concept to anesthesiology found empirical research examining SA in anesthesia to be inadequate. In recognizing the utility of incorporating the consideration of SA in minimizing errors, Fioratou et al. (2010) called for more research and training on not only individual SA but also distributed SA among members of the surgical team. In other areas, Hazlehurst et al. (2007) found the SA construct to be very helpful in categorizing the communications among surgical teams during cardiac surgery. They argued that such work is important for understanding current practices and using them as a baseline for analyzing proposed procedural or equipment changes. In the emergency medical dispatch domain, Blandford

and Wong (2004) discussed the importance of the dispatchers having good SA for optimal ambulance control and the importance of understanding the task demands and the information needed for developing SA such that effective support could be provided.

Given all of these promising initial applications of mental workload and SA to understanding and improving medical human factors, it seems very likely that the use of these concepts in medicine will continue to increase for the foreseeable future.

## 4.4 Display Design

To the extent that excessive workload could reduce SA, any display that supports performance without incurring excessive workload would at least indirectly support SA as well (see, e.g., Previc, 2000). Wickens (1995) proposed that displays that do not overtax working memory and selective attention are particularly attractive because SA depends heavily on these processes. Wickens (1995, 2002, 2003) further discussed various display principles (e.g., proximity compatibility principle, visual momentum) that have been shown to support various types of performance (e.g., flight control as opposed to navigation) and display features (e.g., frame of reference) that would lend support to SA.

While display formats that facilitate information-processing support performance and thereby free up resources for SA maintenance, Wickens (2002, 2008b) shows that display formats could also affect the product (type) of SA. For example, a display with an egocentric frame of reference (an inside-out view with a fixed aircraft and a moving environment) provides better support for flight control, whereas an egocentric frame of reference (an outside-in view with a moving aircraft and fixed environment) provides better support for noticing hazards and general awareness of one's location. Wickens points out further that there are often trade-offs between alternative display formats. For example, whereas an integrated, ecological display generally provides better information about three-dimensional motion flow, a three-dimensional representation on a two-dimensional viewing surface tends to create ambiguity in locating objects in the environment. Such ambiguity is less of a problem in a two-dimensional display format. But it would take more than one two-dimensional display to present the same information in a three-dimensional display. It has been shown that it can be more cognitively demanding in trying to integrate information from two separate two-dimensional displays. The trade-off between promoting SA for objects in the environment and accomplishing other tasks at a lower workload level could only be resolved with regard to the specific goals or the priorities of competing goals of the system.

## 4.5 Training

Given the role that expertise plays in one's workload and SA, there is great potential in training to support SA and to permit tasks to be accomplished with less resources at a lower level of workload. The issue is: What does one train for? That expertise is based largely on a large body of domain-specific knowledge suggests that a thorough understanding of the workings of the

system would be helpful, particularly in nonroutine situations. Although expertise speeds up performance and experts generally perform at a high level under normal situations, their expertise is particularly useful in unexpected circumstances because of their ability to use their acquired knowledge to recognize and solve problems. Until there exist automated systems with total reliability that would never operate outside a perfectly orchestrated environment, the concern that operators trained on automated systems (which would be especially helpful for novices because of the presumed lower level of workload involved) might never acquire the needed knowledge and experience to build up their expertise is certainly a valid one. One possibility might be to provide some initial and refresher training in a nonautomated or less automated simulated system.

Although there exists in the literature a large body of training research that aims at accelerating the learning process and there is much evidence to support the advantages of not subjecting a trainee to an excessive level of workload, there are additional considerations when the goal is to build SA as well. First, it would be most useful to have some ideas about the knowledge structure that experts have so that the training program can build upon reinforcing this structure. After all, it is the structure and organization of information that support fast and accurate pattern recognition and information retrieval. Second, experts do not merely possess more knowledge, they are better at using it. This would suggest that training should extend to strategic training. Given the growing body of evidence to support that strategic task management (or executive control) is a higher level generalizable skill, much of the strategic training could be accomplished with low-cost low-physical-fidelity simulated systems such as a complex computer game (see Haier et al., 1992; Gopher, 1993). The strategic training can be at odds with the goal of keeping the level of workload down while the operators are in training. However, research has shown that the eventual benefits outweigh the initial cost in mental workload. As desirable as it is to train to develop automatic processing that is characterized as fast, accurate, and attention free, this training strategy may have only limited utility in training operators who have to function within a dynamic complex system. This is because there would be relatively few task components in these systems that would have an invariant stimulus–response mapping (a requirement for automatic processing to be developed and applied).

All five research areas underscore the interdependence of the concepts of workload and SA. The design of any efficacious technical support or training program would need to take into account the interplay of the two. Any evaluation of the effectiveness of these supports would need to assess both the operator's workload and SA in order to have a clear picture of their impact on system performance.

## 5   CONCLUSIONS

The years of research into mental workload and SA have been profitable. The research has developed a multitude of metric techniques, and although the results of different mental workload or SA assessment techniques sometimes show dissociations, they seem to fit within the theoretical constructs behind the measures. Workload is primarily a result of the limited attentional resources of humans, whereas SA is a cognitive phenomenon emerging from perception, memory, and expertise. The concepts of workload and SA have been studied extensively in the laboratory and have been transitioned successfully to real-world system evaluation. Indeed, workload and SA have been useful tools of system evaluators for years, and now they are providing vital guidance for shaping future automation, display, and training programs. In short, these concepts have been, and should continue to be, essential tools for human factors researchers and practitioners.

## 1  INTRODUCTION

The importance and influence of social context have been debated recurrently in attempts to define the ergonomics discipline. Wilson (2000, p. 560) defines *ergonomics* "as the theoretical and fundamental understanding of human behavior and performance in purposeful interacting socio-technical systems, and the application of that understanding to the design of *interactions* in the context of real settings." The International Ergonomics Association (IEA) defines ergonomics (or human factors) as the scientific discipline concerned with the understanding of *interactions* among humans and other elements of a system and the profession that applies theory, principles, data, and methods to design in order to optimize human well-being and overall system performance (IEA, 2000).

Ergonomics focuses on *interactive* behavior and the central role of human behavior in complex interacting systems. In this chapter we argue that these behaviors are deeply immersed in and cannot be separated from their social context.

When one examines the assumptions held by researchers and practitioners about the fundamentals of ergonomics, it is no surprise that the role of social

context remains a focus of discussion. Daniellou (2001) described some of these diverging tacit conceptualizations on *human nature, health*, and *work*, which reflect on distinct research models and practices and on different consequences to the public. He said that when referring to the *human nature* ergonomists may have in mind a biomechanical entity, an information-processing system, a subjective person with unique psychological traits, or a social creature member of groups that influence his or her behaviors and values. Similarly, the concept of *health* may be thought of as the absence of recognized pathologies, which would exclude any notion of discomfort, fatigue, or poverty, or could be defined in more comprehensive fashion as a general state of well-being (i.e., physical, mental, and social) or even interpreted as a process in a homeostatic state. Daniellou (2001) observed that, although many ergonomists today embrace a definition of *work* that includes both its physical and cognitive aspects, other important distinctions remain. Work is often considered as the task and work environment requirements, a specific quantifiable definition of what is demanded from all workers to accomplish a given target. Another perspective on work is given by examination of the workload from the perspective of each worker, a vantage point that

emphasizes the individual and collective strategies to manage the work situation in a dynamic fashion. Finally, some ergonomists focus on the ethical aspects of work, on its role on the shaping of individual and societal character. Daniellou reminded us of the challenge of producing work system models which are necessarily reductions of the actual world while ensuring that the reduction process does not eliminate the essential nature of the larger context.

Discussion of the role of social context in ergonomics can be possibly described within a continuum between two opposite perspectives. On one side there is a view of ergonomics as an applied science, a branch of engineering, a practice, even an art, which is deeply embedded in and influenced by a larger social context (Perrow, 1983; Oborne et al., 1993; Moray, 1994; Shackel, 1996; Badham, 2001). On the other side, we have authors who see ergonomics as applying the same standards of the natural and physical sciences and as a *science* is able to produce overarching laws and principles that are able to predict human performance. It is a laboratory-based discipline in which contextual factors have minimal influence (e.g., Meister, 2001). We maintain that the latter position poses significant limitations for the relevance of ergonomics as a practice because it severely limits its usefulness and impact in the real world.

Ergonomics is a discipline with a set of fundamentals derived from the scientific method application, but these cannot be isolated from a vital applied (situational) component. We understand that the development of ergonomics is strongly affected by the social environment, and its permanence as a workable modern discipline depends on its sensitivity to economic, legal, technological, and organizational contexts.

Ergonomics is an integral part of a social enterprise to optimize work systems by improving productivity, quality, safety, and working conditions. It contributes to the complete and uniform utilization of human and technical resources and to the reliability of production systems. It is central to the quest for better work conditions by reducing exposure to physical hazards and the occurrence of fatigue. Ergonomic efforts play a fundamental role in the maintenance of workforce health by reducing the prevalence of musculoskeletal disorders and controlling occupational stress. It answers to market needs of higher product value, useful product features, and increased sales appeal. Ergonomics is ultimately instrumental to the advance and welfare of individuals, organizations, and the broader society.

One could draw an analogy between the role of social forces in technological development and of these social forces in the evolution of the ergonomics discipline. Technological development has been seen as an important source of social change. In the traditional view, technology was considered to be the progressive application of science to solve immediate technical problems, and their release in the marketplace in turn had social impacts. In summary, "technological determinism" saw technology as a natural consequence of basic science progress and, in many circumstances, a cause of changes in society. Conversely, a more recent view

of technological development sees it as part of a social system with specific needs and structure and not driven exclusively by basic science (Hughes, 1991). The latter perspective is also germane to the development of ergonomics (technology), in which social demands and structure marked its evolution. For example, the introduction of an (ergonomic) technological improvement such as stirrups allowed horse riders to hold themselves steady and freed both hands for work or warfare (Pacey, 1991). From a deterministic view this innovation accounted for some of the success of nomadic groups in India and China in the thirteenth century and for the permanence of feudalism in Western Europe. From a systems perspective, on the other hand, this innovation can be conceived as part of a social system and one of the by-products of the critical reliance on horses by these nomadic groups, which later fit the needs of feudalism in Western Europe (White, 1962).

In the next section we examine the path of ergonomics to become an established discipline and how this course was shaped by social context.

## 2 HISTORICAL PERSPECTIVE

The development over time of the ergonomics discipline can be clearly traced to evolving societal needs. Ergonomics as a practice started at the moment the first human groups selected or shaped pieces of rock, wood, or bone to perform specific tasks necessary to their survival (Smith, 1965). Tools as extensions of their hands allowed these early human beings to act on their environment. Group survival relied on this ability, and the fit between hands and tools played an important role in the success of the human enterprise. The dawning of the discipline is therefore marked by our early ancestors' attempts to improve the fit between their hands and their rudimentary tools and to find shapes that increased efficiency, dexterity, and the capacity to perform their immediate tasks effectively.

The practice of ergonomics has been apparent as different civilizations across history used ergonomics methods in their projects. Historically, body motions have been a primary source of mechanical power, and its optimal utilization was paramount to the feasibility of many individual and collective projects. Handles, harnesses, and other fixtures that matched human anatomy and task requirements allowed the use of human power for innumerous endeavors. Tools and later simple machines were created and gradually improved by enhancing their fit to users' and tasks' characteristics (Smith, 1965).

Although human work was recognized as the source of economic growth, workplaces have always been plagued with risks for workers. The groundbreaking work of Ramazzinni (1700) pointed out the connections between work and the development of illnesses and injuries. In contrast to the medical practitioners of his time who focused exclusively on the patients' symptoms, Ramazzini argued for the analysis of work and its environment as well as the workers themselves and their clinical symptoms. In his observations he noted that some common (*musculoskeletal*) disorders seem to follow from prolonged, strenuous, and unnatural

physical motions and protracted stationary postures of the worker's body. Ramazzini's contributions to the development of modern ergonomics were enormous, in particular his argument for a systematic approach to work analysis.

Concomitantly with the increasing effectiveness of human work obtained through improved tools and machines, a growing specialization and intensification of work were also realized. The advent of the factory, a landmark in the advancement of production systems, was a social rather than a purely technical phenomenon. By housing a number of previously autonomous artisans under the same roof it was possible to obtain gains in productivity by dividing the work process into smaller, simpler tasks (Smith, 1776; Babbage, 1832). This process of narrowing down the types of tasks (and motions) performed by each worker while increasing the pace of the work activities had tremendous economic impact but was gradually associated with health and social welfare issues for the workforce. This became more noticeable with the beginning of the Industrial Revolution, when significant changes in technology and work organization occurred and larger portions of the population engaged in factory work.

Industrialization brought along an accelerated urbanization process and an increased access to manufactured goods. In the United States, in particular, this endeavor allowed for the tremendous growth in the supply and demand for capital and consumer goods. Some concern with the incidence of injuries and illnesses related to the industrialization process and its influence on the national economy (i.e., damage to national human resources) led to some early attempts to improve safety in factories in the nineteenth century (Owen, 1816).

During the Industrial Revolution almost exclusive attention was paid to production output increase. This *productivity enhancement* thrust crystallized in the work of Taylor (1912) and his *scientific management* approach. Taylor compiled and put in practice one of the first systematic methods for work analysis and design, focusing on improving efficiency. His approach emphasized the analysis of the work situation and the identification of the "one best way" to perform a task. This technique called for the fragmentation of the work into small, simple tasks that could be performed by most people. It required analysis and design of tasks, development of specialized tools, determination of lead times, establishment of work pace, specification of breaks, and work schedules.

This effort to better utilize technology and personnel had profound effects on the interactions between humans and their work. It could be argued that expansion of output through increased efficiency was socially preferable to long work hours (Stanney et al., 1997, 2001), but one should not lose sight of the fact that the higher economic gains could be derived from the former, which provided a more compelling justification for work intensification.

Taylor's work represented a crucial moment for the ergonomics discipline, although this development had a lopsided emphasis on the shop-floor efficiency aspects. Frank and Lillian Gilbreth (1917) further elaborated the

study of human motions (e.g., micromotions or Therbligs) and provided the basis for time-and-motion methods. Concurrently with the focus on the worker and workstation efficiency, the need to consider the larger organizational structure to optimize organizational output was also recognized. Published at almost the same time as Taylor's *The Principles of Scientific Management*, Fayol's *General and Industrial Management* (1916) defined the basics of work organization. Fayol's principles were in fact very complementary to Taylor's, as the latter focused on production aspects whereas the former addressed organizational issues.

Although preceded by Ransom Olds by almost 10 years, it is ultimately Henry Ford's assembly line that best epitomized this early twentieth-century work rationalization drive. In Ford's factories, tasks were narrowly defined, work cycles drastically shortened, and the pace of work accelerated. Time required per unit produced dropped from 13 to 1 h, and costs of production were sharply reduced, making the Ford Model T an affordable and highly popular product (Konz and Johnson, 2004). Despite the high hourly wage rates offered, about double the prevalent wage rate of the time, turnover at Ford's facilities was very high in its early years. Concern with the workers' health and well-being at this juncture was limited to preventing acute injury and some initial concern with fatigue (Gilbreth and Gilbreth, 1920).

The institution of ergonomics as a modern discipline has often been associated with the World War II period, when human–complex systems interactions revealed themselves as a serious vulnerability (Christensen, 1987; Sanders and McCormick, 1993; Chapanis, 1999). The operation of increasingly sophisticated military equipment was being compromised repeatedly by the lack of consideration to the human–machine interface (Chapanis, 1999). Endeavors to address these issues during World War II and in the early postwar period led to the development and utilization of applied anthropometrics, biomechanics, and the study of human perception in the context of display and control designs, among other issues. The ensuing Cold War and Space Race period from 1950 to 1980 provided a powerful impetus for rapid expansion of ergonomics in the defense and aerospace arenas, with a gradual transfer of that knowledge to civil applications.

Increasingly during the twentieth century, the scientific management approach became the dominant paradigm, with several nations reaping large economic benefits from its widespread adoption. In this period, ergonomics practice experienced a tremendous growth of its knowledge base at the task and human–machine interface levels. Over time, however, this *work rationalization* led to a prevalence of narrowly defined jobs, with typical cycle times reduced to a few seconds. Repetition rates soared, and work paces became very intense. This increased specialization also resulted in the need for large support staffs and in a general underutilization of abilities and skills of the workforce. In fact, many jobs became mostly devoid of any meaningful content, characterized by fast and endless repetition of a small number of motions and by overwhelming monotony. This "dehumanization" of work was associated with

low worker morale, increasing labor–management conflicts, as well as the growing problem of musculoskeletal disorders.

It has been argued that much of the success of the scientific management approach was due to its suitability to social conditions in the early twentieth century, when large masses of uneducated and economically deprived workers were available (Lawler, 1986). Decades of industrialization and economic development changed this reality significantly, creating a much more educated and sophisticated workforce dealing with a much more complex work environment. These workers had higher expectations for their work content and environment than Taylor's approach could provide. In addition, there was growing evidence that this rigid work organization was preventing the adoption and effective utilization of emerging technologies (Trist, 1981). Some researchers and practitioners started to realize that this mechanistic work organization provided little opportunity for workers to learn and to contribute to the improvement of organizational performance (McGregor, 1960; Argyris, 1964; Smith, 1965). One could infer that during that period a micro-optimization of work (i.e., at the task and workstation level) was actually going against broader systems performance since it underutilized technological and human resources, exposed the workforce to physical and psychological stressors, burdened national health systems, and ultimately jeopardized national economic development (Hendrick, 1991).

## 3 BRINGING SOCIAL CONTEXT TO THE FOREFRONT OF WORK SYSTEMS

The social consequences of managerial decisions in the workplace were addressed systematically for the first time by Lewin starting in the 1920s (Marrow, 1969). In his research he emphasized the human(e) aspects of management, the need to reconcile scientific thinking and democratic values, and the possibility of actual labor–management cooperation. He revolutionized management (consulting) practice by advocating an *intervention orientation* to work analysis. Lewin believed that work situations should be studied in ways that make participants ready and committed to act (Weisbord, 2004). He was concerned with how workers find meaning in their work. This search for meaning led him to argue for the use of ethnographic methods in the study of work. He was a pioneer in proposing worker involvement in the analysis and (re)design of work and in defining job satisfaction as a central outcome for work systems. Lewin laid the seeds for the concept of interactive systems and highlighted the need for strategies to reduce resistance to change in organizations. Lewin could rightly be named as a precursor of the study of psychosocial factors in the workplace.

Lewin's research set the ground for the development of macroergonomics decades later. In particular, Lewin's work was a forerunner to participatory ergonomics, as he defined workers as legitimate knowledge producers and agents of change. Lewin understood that workers could "learn how to learn" and had a genuine interest in improving working conditions and, by consequence, human–systems interactions. He saw work improvement not simply as a matter of shortening the workday but as one of increasing the human value of work (Weisbord, 2004).

Introduction of general systems theory by Bertalanffy (1950, 1968) and its subsequent application to several branches of science had profound implications for ergonomics theory and practice. The seminal work by researchers at the Tavistock Institute (Emery and Trist, 1960; Trist, 1981) and establishment of sociotechnical systems theory, especially, made clear the importance of the social context in work systems optimization.

The proponents of sociotechnical systems considered the consequences of organizational choices on technical, social, and environmental aspects. Their studies indicated that the prevailing work organization (i.e., scientific management) failed to fully utilize workers' skills and was associated with high absenteeism and turnover, low productivity, and poor worker morale (Emery and Trist, 1960). They saw Taylorism as creating an imbalance between the social and technical components of the work system and leading to diminishing returns on technical investments. Sociotechnical researchers advocated the reversal of what they saw as extreme job specialization, which often led to underutilized work crews and equipment and to high economic and social costs. They argued for organizational structures based on flexible, multiskilled workers (i.e., knowledgeable in multiple aspects of the work system) operating within self-regulated or semiautonomous groups.

According to sociotechnical principles, high performance of the technical component at the expense of the social component would lead to dehumanization of work, possibly to a situation where some segments of society would enjoy the economic benefits of work and another (larger) portion would bear its costs (i.e., work itself!). The opposite situation, where the social component becomes preponderant, would be equally troubling because it would lead to system output reduction, with negative effects on organizational and national economies. In summary, a total system output decline could be expected in both cases of suboptimization.

Sociotechnical systems (STSs) emphasized the match between social needs and technology, or, more specifically, improvement in the interaction between work systems' technical and social components. Sociotechnical systems focused on the choice of technologies suitable to the social and psychological needs of humans. The path to improved integration was pursued, with the maximization of worker well-being as its primary system optimization criteria. An alternative path to the same end was proposed decades later in the macroergonomic approach, which posited the quick and effective adoption of new technology as the crux of organizational survival and the primary optimization criteria (Hendrick, 1991, 1997). The macroergonomic approach urged organizations to implement job and organization designs that increased the chances of successful technology implementation by utilizing its human resources fully. Although providing different rationales, the two propositions had similar visions (i.e., effective and healthy work systems), achieved through analogous work organization designs.

A major contribution of sociotechnical systems to an understanding of work systems (organizations) was that they were intrinsically open systems which needed to exchange information, energy, or materials with their environment to survive (Bertalanffy, 1950). A second major contribution was the recognition of fast and unpredictable changes in the environmental contexts themselves. Emery and Trist (1965) describe four different types of causal texture, which refer to different possible dispositions of interconnected events producing conditions that call for very diverse organizational responses. The *placid, randomized environment* was characterized by relatively stable and randomly distributed *rewards and penalties*. This implied a strategy that was indistinguishable from tactics, where the entity or organization attempted to do its best in a purely local basis. These organizations survived adaptively and tended to remain small and independent in this environment. The *placid, clustered environment* implied some type of knowable (i.e., nonrandom) distribution of rewards and penalties. This environment justified the adoption of a strategy distinct from tactics and rewarded organizations that anticipated these clusters. Successful organizations in this context tended to expand and to become hierarchical. The *disturbed-reactive environment* indicated the existence of multiple organizations competing for the same resources and trying to move, in the long term, to the same place in the environment. Competitive advantage was the dominant strategy in this situation. Finally, *turbulent fields* were marked by accelerating changes, increasing uncertainty, and unpredictable connections of environmental components (Weisbord, 2004). In Emery and Trist's (1965) words: "The ground is in motion," which creates a situation of *relevant uncertainty*. This circumstance demanded the development of new forms of data collection, problem solving, and planning from the organization.

A significant offshoot of the sociotechnical theory was the *industrial democracy* movement, which had considerable influence in organizational and governmental policies and labor–management relations in several Scandinavian and Western European countries in the 1970s and 1980s. Industrial democracy proponents argued that workers should be entitled to a significant voice in decisions affecting the companies in which they worked (Gardell, 1982; Johnson and Johansson, 1991). The term has several connotations, but essentially it advocated union rights to representation on the boards of directors of large companies. It has also been used to describe various forms of consultation, employee involvement, and participation (Broedling, 1977).

A related concept, *codetermination*, achieved prominent status in Germany and Sweden in the 1970s, when legislation expanded the right of workers to participate in management decisions. Codetermination typically implied having an organization's board of directors with its composition of up to 50% of employee representatives. In the German experience, codetermination applied to both the plant and industry levels, and the proportion of worker representation in executive boards varied depending on the business size and type. Whereas industrial democracy urged increased workforce participation across the entire organization, codetermination was concerned primarily with worker influence at the top of the organization.

Sociotechnical theory deeply influenced another important societal and organizational initiative, the *quality of work life* (QWL) movement. The QWL concept has its roots in the somewhat widespread dissatisfaction with the organization of work in the late 1960s and early 1970s. Taylorism's inflexibility, extreme task specialization, and the resulting low morale were identified as the primary sources of these issues. A number of models of job and organization design attempting to improve utilization of worker initiative and to reduce job dissatisfaction were developed and put in practice, particularly in the Scandinavian countries. QWL initiatives called for organizational changes involving increased task variety and responsibility, making the case for increasing worker participation as a potent intrinsic motivator.

Of particular relevance was the experimental assembly plant established in 1989 by Volvo in Uddevalla, Sweden. The project was an attempt to apply sociotechnical principles to a mass production facility on a wide scale. In the context of a very tight job market, this initiative tried to make jobs and the work environment more attractive to workers by increasing autonomy and group cohesiveness and by recovering some of the meaning lost by extreme task fragmentation. Despite tremendous expectations from company, labor, and sociotechnical researchers, the plant was closed in 1993 because of inferior performance. Although some debate remains about the causes of the plant closure, one could infer that increased pressure for short-term financial returns, larger labor availability, globalization, and fierce international competition were primary contributing factors. Most of all, the end of the Uddevalla plant highlighted the difficulties of achieving acceptable compromises or, preferably, converging strategies between enhanced quality of work life and organizational competitiveness (Huzzard, 2003). The challenge of competitiveness remained an important one for the viability of QWL. In Huzzard's words (p. 93): "Despite the evidence that firms can reap considerable performance advantages through attempts at increasing the quality of working life through greater job enlargement, job enrichment, competence development and participation, there is also considerable evidence that some firms are actually eschewing such approaches in deference to short-run pressure for immediate results on the 'bottom-line' of the profit and loss account and rapid increases in stock market valuation."

The sociotechnical theory helped to consolidate the objectives of ergonomics by virtue of its *joint-optimization principle*, which established the possibility and the need for work systems to achieve concurrently high social and technical performance. In other words, it advocated that through a work organization focused on human physical and social needs (i.e., free of hazards, egalitarian, team based, semiautonomous) it would be possible to attain high productivity, quality, and reliability while reaching high levels of job satisfaction, organizational cohesiveness, and mental and physical well-being. The affinities between ergonomics and the

sociotechnical theory are quite evident, as the former is a keystone to the feasibility of joint optimization. In fact, contemporary ergonomics interventions are deeply influenced by sociotechnical theory calling for worker involvement, delegation of operational decisions, and a decentralized management structure (Cohen et al., 1997; Chengalur et al., 2004; Konz and Johnson, 2004).

The sociotechnical approach inspired a number of successful work systems performance improvement initiatives over recent decades. These initiatives often accentuated the need for decision-making decentralization and the enlargement of workers' understanding of the entire system and of the technical and economic effects of their actions on it. These approaches advocated jobs with increased amounts of variety, control, feedback, and opportunity for growth (Emery and Trist, 1960; Hackman and Oldham, 1980). Workers needed to recover their perception of the whole and to be encouraged to regulate their own affairs in collaboration with their peers and supervisors. These STS-inspired initiatives aimed at eliminating the inefficiencies and bottlenecks created by decades of scientific management practice, which shaped an inflexible and highly compartmentalized workforce.

Not all STS-inspired programs were equally successful, and many of them were withdrawn after some years. Proposals that relied heavily on worker participation but did not provide adequate support and guidance were found to be ineffective and stressful to workers. Fittingly, Kanter (1983) observed that many of the participatory management failures were caused by too much emphasis on *participation* and too little on *management*. Similarly, in some cases workers found themselves overwhelmed by excessive job variety. Studies have also shown that job control is not always sufficient to attenuate workload effects (Jackson, 1989). Finally, experiments with the concept of industrial democracy in Sweden, Norway, and Germany, where labor representatives participated in executive boards, produced little in the way of increasing rank-and-file workers' involvement and improving the social meaning of their jobs and did not result in competitive advantages in productivity or quality, at least not in the short term.

## 4 ERGONOMICS AND THE ORGANIZATION

In the 1980s a number of practitioners and researchers started to realize that some ergonomic solutions considered to be superior at the workstation level failed to produce relevant outcomes at the organizational level (Dray, 1985; Carlopio, 1986; Brown, 1990; Hendrick, 1991, 1997). These failures were attributed to a narrow scope of analysis typical of these ergonomics interventions, which neglected to consider the overall organizational structure (DeGreene, 1986). A new area within the ergonomics discipline was conceived, under the term *macroergonomics* (Hendrick, 1986). According to Hendrick (1991, 1997), macroergonomics emphasized the interface between organizational design and technology with the purpose of optimizing work systems performance. Hendrick saw macroergonomics as a top-down sociotechnical approach to the design of work

systems. Imada (1991) stated that this approach recognized that organizational, political, social, and psychological factors of work could have the same influence on the adoption of new concepts as the merits of the concepts themselves. Finally, Brown (1991) conceived macroergonomics as addressing the interaction between the organizational and psychosocial contexts of a work system with, and emphasis on, the fit between organizational design and technology. Effective absorption of technology is at the forefront of macroergonomic endeavors.

Although having many of its concepts derived from sociotechnical theory, macroergonomics diverged from the former in some significant aspects. Whereas macroergonomics was a top-down approach, sociotechnical systems embraced a bottom-up approach, where the workstation is the building block for organizational design. Macroergonomics saw macrolevel decisions as a prerequisite to microlevel decisions (Brown, 1991), in sharp contrast with the STS. The STS affirmed that joint optimization must first be constructed into the primary work system or it would not become a property of the organization as a whole (Trist, 1981).

Hendrick (1991) defined organizational design around three concepts: complexity, formalization, and centralization. *Complexity* referred to an organization's degree of internal differentiation and extent of use of integration and coordination mechanisms. Internal differentiation was further elaborated into horizontal differentiation, which referred to job specialization and departmentalization; vertical differentiation, which related to the number of hierarchical levels in the organization; and spatial dispersion. *Formalization* conveyed the reliance on written rules and procedures. *Centralization* referred to the degree of dispersion of decision-making authority. Although some given combinations of these structural elements seemed to be suitable to some types of organizations pursuing specific goals, a number of possible interactions may produce results that were difficult to predict.

Hendrick (1997) pointed out three work system design practices that characteristically undermined ergonomic efforts. The first problematic practice related to a situation where technology (hardware or software) was taken as a given and user considerations came as an afterthought. These were efforts that typically overlooked motivational and psychosocial aspects of users. The second practice was also related to the overriding attention to the technical component, where technical feasibility was the only criterion for function allocation. In this situation, optimization of the technical component forced the leftover functions on the social (human) element (DeGreene, 1986). In other words, users were forced to accommodate the remaining tasks, frequently resulting in work situations void of factors that produced satisfaction and identity. Finally, there was a failure to consider adequately the four elements (subsystems) of sociotechnical systems: personnel, technology, organizational structure, and the external environment.

Methods employed in macroergonomics were numerous and were typically embedded in a four-step analysis/assessment, design, implementation, and evaluation

(Brown, 1991). For a review of methods in macro-ergonomics, see Hendrick and Kleiner (2001) and Hendrick (2002).

# 5   PARTICIPATORY ERGONOMICS

As discussed previously, sociotechnical theory provided several arguments and examples supporting the benefits of worker participation, particularly through teamwork, as an effective work system design strategy. The germinal study, which gave the essential evidence for development of the sociotechnical field, was a work group experiment observed in the English mining industry during the 1950s. In this new form of work organization a set of relatively autonomous work groups performed a complete collection of tasks, interchanging roles and shifts and regulating their affairs with a minimum of supervision. This experience was considered a way of recovering group cohesion and self-regulation concomitantly with a higher level of mechanization (Trist, 1981). The group had the power to participate in decisions concerning work arrangements, and these changes resulted in increased cooperation between task groups, personal commitment from participants, reduction in absenteeism, and fewer accidents. From the sociotechnical perspective, participation permitted the ordering and utilization of worker-accumulated experience; it validated and legitimized this experiential knowledge.

Another strong defense of employee participation was made by Sashkin (1984, p. 11), arguing that "participatory management has positive effects on performance, productivity, and employee satisfaction because it fulfills three basic human needs: increased autonomy, increased meaningfulness, and decreased isolation." Perhaps the most original and polemic of the Sashkin's contributions to the subject was his statement that participation was an "ethical imperative." His reasoning was that basic human needs were met by participation, and denial of the process produced psychological and physical harm to the workers. Research on worker participation is extensive and started as early as the 1940s (Coch and French, 1948) and is punctuated by controversial and often ideological debate (Locke and Schweiger, 1979; Sashkin, 1984; Cotton et al., 1988; Leana et al., 1990). For an extensive review on participation and teamwork, refer to Medsker and Campion (2001) and Sainfort et al. (2001).

Aspects of employee participation and participatory ergonomics can be seen in total quality management (TQM) approaches. TQM relied on teamwork for problem solving and change implementation related to quality and production issues (Dean and Bowen, 1994). Over time, some of those teams also started to focus on working conditions. The term *participatory ergonomics* (PE) originated from discussions among Noro, Kogi, and Imada in the 1980s (Noro, 1999). It assumed that ergonomics was bounded by the degree to which people were involved in conducting its practice. According to Imada (1991), PE required users (the real beneficiaries of ergonomics) to be involved directly in developing and implementing ergonomics. Wilson (1995, p. 1071) defined PE as "the involvement of people in planning and controlling a significant amount of their own work activities, with sufficient knowledge and power to influence both processes and outcomes in order to achieve desirable goals." PE has been identified with the use of participative techniques in the analysis and implementation of ergonomics solutions (Wilson and Haines, 1997) and recognized as an approach to disseminate ergonomics knowledge throughout the organization (Noro, 1991).

Imada (1991) pointed out three major arguments in support of worker involvement in ergonomics. First, because ergonomics was an intuitive science, which in many cases simply organized knowledge that workers were already using, it could validate workers' accumulated experience. Second, people were more likely to support and adopt solutions for which they felt responsible. Involving users and workers in the ergonomic process had the potential to transform them into makers and supporters of the process rather than passive recipients. Finally, developing and implementing technology enabled workers to modify and correct problems continuously.

Participatory ergonomics saw end users' contributions as indispensable elements of its scientific methodology. It stressed the validity of simple tools and workers' experience in problem solution and denied that these characteristics resulted in nonscientific outcomes (Imada, 1991; Taveira and Hajnal, 1997). In most situations, it was believed that employees or end users were in the best position to identify the strengths and weaknesses of work situations. Their involvement in the analysis and redesign of their workplace could lead to better designs as well as to increase theirs and the company's knowledge of the process.

Participatory ergonomics was also conceived as an approach to enhance the human–work systems fit. Work environments have become highly complex, often beyond the capacity of individual workers. This mismatch between workers' capabilities and work systems requirements was shown to be an important factor in organizational failures (Weick, 1987; Reason, 1990, 1997; Reason and Hobbs, 2003). A possible strategy to address this imbalance was to pool workers' abilities through group teamwork, making them collectively more sophisticated (Imada, 1991). Other beneficial outcomes of PE included increased commitment to change (Lawler, 1986; Imada and Robertson, 1987), increased learning experiences (i.e., reduced training costs) and improved performance (Wilson and Grey Taylor, 1995), and increased job control and skills (Karasek and Theorell, 1990).

# 6   ERGONOMICS AND QUALITY IMPROVEMENT EFFORTS

A growing amount of attention among ergonomics scholars and practitioners concerns whether and how ergonomics is affected by organizational transformations. In particular, the integration of ergonomics and quality management programs has been discussed extensively (Drury, 1997, 1999; Eklund, 1997, 1999; Axelsson et al., 1999; Taveira et al., 2003). It seems clear, at

least in principle, that the two are related and interact in a variety of applications, such as inspection, process control, safety, and environmental design (e.g., Drury, 1978; Eklund, 1995; Rahimi, 1995; Stuebbe and Houshmand, 1995; Warrack and Sinha, 1999; Axelsson, 2000). There is some consensus that the form of this relationship is one in which "good ergonomics" (e.g., appropriate workstation, job, and organization design) leads to improved human performance and reduced risk of injury, which in turn leads to improved product and process quality. Eklund (1995), for example, found that the odds of having quality deficiencies among ergonomically demanding tasks at a Swedish car assembly plant were 2.95 times more likely than for other tasks.

TQM practice seems to enlarge the employees' role by increasing their control over their activities and by providing them with information and skills and the opportunity to apply them. On the other hand, this positive evaluation of TQM is not shared unanimously. Some believe that TQM is essentially a new package for the old Taylorism, with the difference that *work rationalization* is being made by the employees themselves (Parker and Slaughter, 1994). Lawler et al. (1992), commenting on work simplification in the context of TQM, noticed that even though this emphasis seems to work at cross purposes with job enrichment, most TQM concepts have not referred methodically to the issue of how jobs should be designed. Lawler and his colleagues proposed that work process simplification can otherwise occur concurrently with the creation of jobs that have motivating characteristics (i.e., meaning, autonomy, feedback, etc.).

Implementation by the manufacturing industry of flexible production systems (e.g., just-in-time, lean manufacturing) has created a renewed demand for ergonomics. Flexible production systems are based on the assumption that regarding workers as repetitive mechanical devices will not provide any competitive advantage and that only skilled and motivated workers are able to add value to production. This approach embraced the concept of continuous improvement, although without totally rejecting Taylor's *one best way* (Reeves and Bednar, 1994). These systems saw line workers as capable of performing most functions better than specialists, allowing for a lean organization stripped of most personnel redundancies. These systems required that each step of the fabrication process be conducted perfectly every time, thus reducing the need for buffer stocks while also producing a higher quality end product.

Information technology has been connected to changes in internal organization because it facilitates the work of multidisciplinary teams whose members work together from the start of a job to its completion. Information systems make it efficient to push decision making down in the organization—to the teams that perform an organization's work. Efficient operations in the modern workplace call for a more equal distribution of knowledge, authority, and responsibility.

Social context, along with characteristics of the production process (i.e., type of industry), has a central role in the production philosophy embraced by organizations.

The choice of a particular production philosophy has in turn a substantial impact on the work organization, technology, human resources practices and policies, organizational efficiency, and the general quality of work life. Eklund and Berggren (2001) identified four generic production philosophies: Taylorism, sociotechnical systems, flexible production systems, and modern craft.

Most organizations use some mix of these approaches and rarely does one find an organization strictly employing a specific philosophy. Taylorism, Fordism, or scientific management is characterized by high levels of standardization, job and equipment specialization, close control over worker activities, machine-paced work, and short cycle times. This production philosophy allowed for tremendous efficiency gains but produced poor work conditions, marked by fatigue, monotony, and poor utilization of workers capabilities. The second approach, sociotechnical systems (STS), addressed some of the Taylorism shortcomings by expanding job content in terms of its variety and meaningfulness, by reducing the rigidity of the production flow by adopting alternative production layouts and using buffers, and by transferring some decision-making power to workers. Although lessening some of the ergonomics issues associated with Taylorism, STS did not effectively address some of workload-related issues, had difficulty in maintaining high levels of output, and the use of buffers came at the cost of additional work in process. Flexible production systems were associated with the quality movement discussed above and were characterized by flexible equipment with quick setup times, a multiskilled workforce able to perform a variety of tasks, teamwork, and continuous improvement. Finally, modern craft was typically limited to large, specialized capital equipment production involving highly skilled workers and high-precision tools in very long work cycles. In many respects it was very representative of pre–Industrial Revolution work organization.

## 7 SOCIALLY CENTERED DESIGN

As defined by Stanney et al. (1997, p. 638), socially centered design was an approach concerned with system design variables that "reflect socially constructed and maintained world views which both drive and constrain how people can and will react to and interact with a system or its elements." It is a strategy aimed at filling the gap between system-centered approaches and user-centered approaches to job and organization design. In other words, it was conceived of as a bridge between a macro- and a microorientation to ergonomics.

Although conceding that the macroergonomic approach attempted to alleviate some of the issues associated with widespread adoption of scientific management, these authors argued that it did not sufficiently address group and intergroup interactions. In fact, the authors tend to group Taylorism and macroergonomics at one end of the technical versus social spectrum, as both consider the worker or user as a resource to be optimized (Stanney et al., 1997). User-centered design was positioned at the other end of the spectrum, as it regarded the users' abilities, limitations, and preferences as the

key design objectives (i.e., enabling user control as the primary goal). User-centered methodologies emphasized human error avoidance but generally ignored the social context of work by focusing instead on the individual and his or her workstation.

Socially centered design focuses on real-time interactions among people in the context of their work practices. In the Lewin tradition, the use of naturalistic methods was advocated to identify informal skills employed in the work process. It was assumed that the identification of these "unofficial" organizational and social factors added value to system design (Grudin, 1990). It saw workers' roles and responsibilities as characterized dynamically by ever-changing local interactions. Similarly, the concept of optimization was local and contingent, being defined by the system context. Socially centered design looked at artifacts (i.e., objects and systems) as solutions to problems. Considering that these problems were situated in a social context, one could expect that different groups in different situations may use the same artifacts in dissimilar ways. It led to the conclusion that artifacts must be examined from both a physical and a social perspective.

The methodologies for data acquisition advocated by this approach focused on group processes related to artifact use. These methods took into consideration the influence of the social work environment on system design effectiveness. Socially centered design saw everyday work interactions as relevant to effective system design and these factors must be extracted through contextual inquiries (Stanney et al., 1997). The most common techniques included group studies and ethnographic studies (Jirotka and Goguen, 1994). These methods were time and resource consuming, and transference of acquired knowledge to other situations required further refinement since these were locally generated explanations.

So far we have examined some of the critical aspects of the social foundations of ergonomics. The views described were rooted primarily in the seminal work of Kurt Lewin and of researchers at the Tavistock Institute, particularly Eric Trist and Fred Emery. Next we review approaches that, although related to the same tradition, put a stronger emphasis on how the social environment affects workers' mental and physical health.

## 8   PSYCHOSOCIAL FOUNDATIONS

For more than a century, medical practitioners have known that social, psychological, and stress factors influence the course of recovery from disease. During World Wars I and II, much attention was placed on how social, physical, and psychological stress affected soldier, sailor, and pilot performance, motivation, and health. Then, beginning in the 1950s and continuing until today, much attention has been paid to the relationship between job stress and employee ill health (Caplan et al., 1975; Cooper and Marshall, 1976; Smith, 1987a; National Institute for Occupational Safety and Health (NIOSH), 1992; Smith et al., 1992; Kalimo et al., 1997; Kivimaki and Lindstron, 2006). What has emerged is an understanding that "psychosocial"

attributes of the environment can influence human behavior, motivation, performance, and health and psychosocial factors have implications for human factors design considerations. Several conceptualizations have been proposed over the years to explain the human factors aspects of psychosocial factors and ways to deal with them. Next we will discuss some foundational considerations for social influences on human factors.

## 9   JOB STRESS AND THE PSYCHOSOCIAL ENVIRONMENT

Selye (1956) defined stress as a biological process created by social influences. The environment (physical and psychosocial) produces stressors that lead to adaptive bodily reactions by mobilizing energy, disease fighting, and survival responses. The individual's reactions to the environment are automatic survival responses (autonomic nervous system) and can be mediated by cognitive processes that are built on social learning. In Selye's concept, an organism undergoes three stages leading to illness. In the first, the state of *alarm*, the body mobilizes biological defenses to resist the assault of an environmental demand. This stage is characterized by high levels of hormone production, energy release, muscle tension, and increased heart rate. In the second stage, *adaptation*, the body's biological processes return to normal, as it seems that the environmental threat has been defeated successfully. In this second stage, the body is taking compensatory actions to maintain its homeostatic balance. These compensatory actions often carry a heavy physiological cost, which ultimately leads to the third stage. In the third and final phase, *exhaustion*, the physiological integrity of the organism is in danger. In this stage several biological systems begin to fail from the overwork of trying to adapt. These biological system failures can result in serious illness or death.

Much research has demonstrated that, when stress occurs, there are changes in body chemistry that may increase the risk of illness. Changes in body chemistry include higher blood pressure, increases in corticosteroids and peripheral neurotransmitters in the blood, increased muscle tension, and increased immune system responses (Selye, 1956; Levi, 1972; Frankenhaeuser and Gardell, 1976; Frankenhaeuser, 1986; Karasek et al., 1988; Shirom et al, 2008; Hansson et al., 2008; Asberg et al., 2009). Selye's pioneering research defined the importance of environmental stressors and the medical consequences of stress on the immune system, the gastrointestinal system, and the adrenal glands. However, Selye emphasized the physiological consequences of stress and paid little attention to the psychological aspects of the process or the psychological outcomes of stress.

Lazarus (1974, 1977, 1993, 1998, 1999, 2001) proposed that physiological changes caused by stressors came from a need for action resulting from emotions in response to the stressors (environment). The quality and intensity of the emotional reactions that lead to physiological changes depend on cognitive appraisal of the "threat" posed by the environment to personal security and safety. From Lazarus's perspective the

threat appraisal process determined the quality and intensity of the emotional reaction and defined coping activities that affected the emotional reactions. The extent of the emotional reaction influenced the number of physiological reactions.

Levi (1972) tied together the psychological and physiological aspects of stress. He recognized the importance of psychological factors as primary determinants of the stress sources (perception of stressors). He proposed a model that linked psychosocial stimuli with disease. In this model any psychosocial stimulus, that is, any event that takes place in the social environment, can act as a stressor. In accordance with a *psychobiological program*, psychosocial stimuli may evoke physiological responses similar to those described by Selye (1956). In turn, when these physiological responses occur chronically, they can lead to disease. Several intervening variables (individual susceptibility, personality, coping strategies, or social support) can moderate the link between psychosocial stimuli and disease. Levi emphasized that the sequence of events described by the model is not a one-way process but a *cybernetic system with continuous feedback*, a significant application of a human factors concept (Smith, 1966). The physiological responses to stress and disease can influence the psychosocial stimuli as well as the individual's psychobiological program. These feedback loops are important to an understanding of how stress reactions and disease states themselves can, in turn, act as additional stressors or mediate a person's response to environmental stressors.

Frankenhaeuser and her colleagues emphasized a psychobiological model of stress that defined the specific environmental factors most likely to induce increased levels of cortisol and catecholamines (Lundberg and Frankenhaeuser, 1980; Frankenhaeuser and Johansson, 1986). There are two different neuroendocrine reactions in response to a psychosocial environment: (1) secretion of catecholamines via the sympathetic–adrenal medullary system and (2) secretion of corticosteroids via the pituitary–adrenal-cortical system. Frankenhaeuser and her colleagues observed that different patterns of neuroendocrine stress responses occurred depending on the particular characteristics of the environment. They considered the most important environmental factors to be effort and the individual factors to be distress. The effort factor "involves elements of interest, engagements, and determination"; the distress factor "involves elements of dissatisfaction, boredom, uncertainty, and anxiety" (Frankenhaeuser and Johansson, 1986). Effort with distress is accompanied by increases in both catecholamine and cortisol secretion.

What Frankenhaeuser and her associates found was that effort without distress was characterized by increased catecholamine secretion but no change in cortisol secretion. Distress without effort was generally accompanied by increased cortisol secretion, with a slight elevation of catecholamines. Their approach emphasized the role of personal control in mediating the biological responses to stress. A lack of personal control over the stressors was almost always related to distress, whereas having personal control tended to stimulate greater effort. Studies performed by Frankenhaeuser and her colleagues showed that work overload led to increased catecholamine secretion but not to increased cortisol secretion when the employee had a high degree of control over the environment (Frankenhaeuser and Johansson, 1986).

Several studies have shown a link between elevated blood pressure and job stressors, especially workload, work pressure, and lack of job control. Rose et al. (1978) found that workload was associated with increased systolic and diastolic blood pressure. Van Ameringen et al. (1988) found that intrinsic pressures related to job content were related to increased standing diastolic blood pressure. The index of intrinsic pressures included a measure of quantitative workload (demands) and a measure of job participation (job control). Matthews et al. (1987) found that having few opportunities for participating in decisions at work was related to increased diastolic blood pressure. Longitudinal studies of job stress and blood pressure show that blood pressure increases were related to the introduction of new technologies at work and to work complexity (Kawakami et al., 1989). Schnall et al. (1990) demonstrated the link between hypertension and job stress and between emotions (e.g., anger and anxiety). James et al. (1986) demonstrated a relationship between emotions and increased blood pressure.

French (1963) and Caplan et al. (1975) have proposed a stress model that defined the interaction between the environment and the individual, including coping processes for controlling the external stressors. In their approach the development of stress is an outcome of an imbalanced interaction between the environmental resources that are available and the person's needs for resources. If the environmental demands are greater than a person's capacities and/or if the person's expectations are greater than the environmental supplies, stress will occur (Caplan et al., 1975; Cooper and Payne, 1988; Kalimo, 1990; Ganster and Schaubroeck, 1991; Johnson and Johansson, 1991; Cox and Ferguson, 1994). They proposed that social support from family and colleagues is a coping process that can mitigate the stress effects on health.

## 10 WORK ORGANIZATION AND PSYCHOSOCIAL INFLUENCES

The characteristics of a work organization are often sources of occupational stress that can lead to health consequences. Cooper and Marshall (1976) categorized these job stress factors into groups as those intrinsic to the job, the role in the organization, career development, the relationships at work, and the organizational structure and climate. Factors intrinsic to the job were similar to those studied and by Frankenhaeuser's group and French and Caplan. They included (1) physical working conditions; (2) workload, both quantitative and qualitative, and time pressure; (3) responsibilities (for lives, economic values, safety of other persons); (4) job content; (5) decision making; and (6) perceived control over the job. Smith and Carayon-Sainfort (1989) believed that the work organization level of psychosocial factors

dictated the extent of environmental exposure in terms of workload, work pace, work schedule, work–rest cycle, design of equipment and workstations, product and materials design, and environmental design. In addition, the psychosocial work environment affected a person's motivation to work safely, the attitude toward personal health and safety, and the willingness to seek health care. They postulated that the work organization defined the job stressors through the task demands, personal skill requirements, extent and nature of personal training, and supervisory methods that influenced the work methods used by employees (Carayon and Smith, 2000).

Many work organization factors have been linked to short- and long-term stress reactions. Short-term stress reactions include increased blood pressure, adverse mood states, and job dissatisfaction. Studies have shown a link between overload, lack of control and work pressure, and increased blood pressure (Matthews et al., 1987; Van Ameringen et al., 1988; Schnall et al., 1990). Other studies have found a link between job future uncertainty, lack of social support and lack of job control, and adverse mood states and job dissatisfaction (Karasek, 1979; Sainfort, 1989; Smith et al., 1992). Long-term stress reactions include cardiovascular disease and depression. Studies have shown that job stressors are related to increased risk for cardiovascular disease (Karasek, 1979; Karasek et al., 1988; Johnson, 1989). Carayon et al. (1999) have proposed that work organization factors can define or influence ergonomic risk factors for musculoskeletal: for example, the extent of repetition, force, and posture. Work organization policies and practices define the nature, strength, and exposure time to ergonomic risk factors.

According to Smith and Carayon-Sainfort (1989), stress results from an imbalance between various elements of the work system. This imbalance produces a load on the human response mechanisms that can produce adverse reactions, both psychological and physiological. The human response mechanisms, which include behavior, physiological reactions, and perception/cognition, act to exert control over the environmental factors that are creating the imbalance. These efforts to bring about balance, coupled with an inability to achieve a proper balance, produce overloading of

the response mechanisms that leads to mental and physical fatigue. Chronic exposure to these "fatigues" leads to stress, strain, and disease. This model emphasizes the effects of the environment (stressors), which can be manipulated to produce proper balance in the work system. These stressors can be categorized into one of the following elements of the work system: (1) the task, (2) the organizational context, (3) technology, (4) physical and social environment, and (5) the individual (see Figure 1).

The organizational context in which work is done often can influence worker stress and health (Landy, 1992). Career considerations such as over- and under-promotion, status incongruence, job future ambiguity, and lack of job security have been linked to worker stress (Cooper and Marshall, 1976; Cobb and Kasl, 1977; Jackson and Schuler, 1985; Sainfort, 1989 Israel, et al., 1996). In particular, companies that have the potential for reductions in the labor force (layoff or job loss) may be more susceptible to employees reporting more problems and more serious problems as an economic defense. These conditions may create a working climate of distrust, fear, and confusion that could lead employees to perceive a higher level of aches and pains.

Other organizational considerations that act as environmental stressors with social elements are work schedule and overtime. Shift work has been shown to have negative social, mental, and physical health consequences (Tasto et al., 1978; Monk and Tepas, 1985). In particular, night and rotating shift regimens affect worker sleeping and eating patterns, family and social life satisfaction, and injury incidence (Rutenfranz et al., 1977; Smith et al., 1982). Caplan et al. (1975) found that unwanted overtime was a far greater problem than simply the amount of overtime. Overtime may also have an indirect effect on worker stress and health because it reduces the amount of rest and recovery time, takes time away from relaxation with family and friends, and reduces time with these sources of social support that can buffer stress.

Technology is an environmental influence that can produce stress: for example, physical and mental requirements that do not match employee competencies, poorly designed software, and poor system performance, such as crashes and breakdowns (Turner and Karasek,

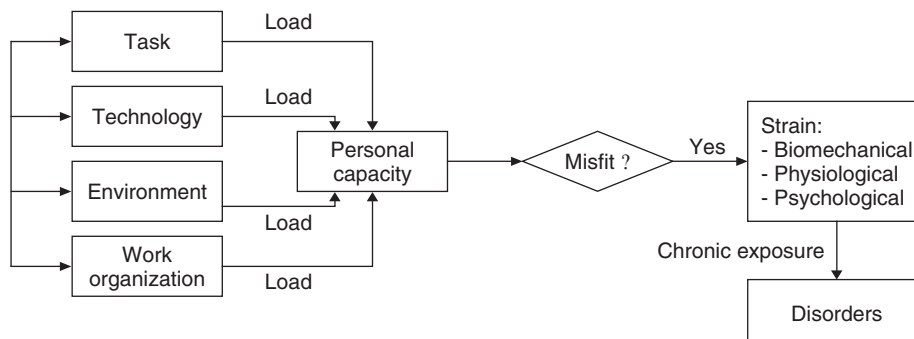

**Figure 1**   Balance model (Smith and Carayon-Sainfort, 1989) and stressor effects (Smith et al., 1999).

1984; Carayon-Sainfort, 1992). There is some evidence showing that computers can be a source of physical and mental stress [Smith et al., 1981, 1992; National Academy of Sciences (NAS), 1983]. New technology may exacerbate worker fears of job loss due to increased efficiency of technology (Ostberg and Nilsson, 1985; Smith 1987b). The way the technology is introduced may also influence worker stress and health (Smith and Carayon, 1995). For instance, when workers are not given enough time to get accustomed to the technology, they may develop unhealthy work methods.

## 11 ERGONOMIC WORK ANALYSIS AND ANTHROPOTECHNOLOGY

The development of ergonomics in France and French-speaking Belgium has been characterized by a distinctive effort to create a unified approach to work analysis. Those endeavors have produced a practice-oriented method aiming at improving work conditions through a multistep analysis and intervention process. The method places a strong emphasis on social aspects of the activities and on the operators' (i.e., workers) perspectives and experiences within the situation. The ergonomic work analysis (EWA) approach resulted chiefly from efforts of researchers at the Conservatoire National des Arts et Métiers (CNAM) with a significant role played by Alain Wisner and several others (e.g., De Keyser, De Montmollin, Daniellou, Faverge, Falzon, Laville, Leplat, and Ombredane). These researchers were convinced of the importance of having a common inquiry structure (i.e., a single ergonomic method) that would allow for a truly *interdisciplinary* approach to workplace ergonomics, as opposed to a *multidisciplinary* one. This unified method would serve as the framework enabling the integration of the different disciplines that provide the foundation for ergonomics.

The EWA method underscores the differences between the *task*, meaning work as prescribed or specified by management, and the *activity,* meaning work as actually performed and experienced by workers. The method considers that to be a critical gap and assumes that *tasks* as designed and described by engineers and managers tend to oversimplify the work situation missing critical complexities that constitute the essential reality of work and the core of ergonomic issues (Daniellou, 2005, De Keyser, 1991). While the EWA attempts to evaluate work situations from multiple viewpoints, it clearly emphasizes the workers' perspectives and the description of their actions. Significant attention is paid to the workers' efforts to meet production and procedural goals placed on them. It is posited that the approach places the operator at the center of the work situation and, therefore, of its (re)design (Laville, 2007).

As outlined by De Keyser (1991), the EWA procedure begins with an initial investigation of the request (i.e., the demand for the investigation), where the expectations and perspectives of stakeholders (e.g., corporate management, area supervisors, and employees) regarding the project are identified and considered. In this stage, as the demands and expectations for the study are spelled out, the analyst (ergonomist) would have

a clearer idea of what a successful intervention would need to accomplish (Wisner, 1995a). This step is followed by an analytical description of the physical, technical, economic, and social aspects of the situation and a detailed analysis of the work activities. A diagnostic is then established and recommendations for improvement defined. Depending on the nature of the activity, recommendations are expected to be pilot tested prior to full implementation. Follow-up on the performance of implemented solutions is advocated. Proponents of the EWA recognize that its application can be time consuming and unwieldy and concede that in most cases the process should be abbreviated (De Keyser, 1991).

According to Wisner (1995b, p. 1549), a main objective of the EWA is to learn how operators "constitute the problems of their work (situation and action) in a stable or variable way and, to a lesser extent, how they solve them." This process is termed "problem building" and is seen as critical in understanding work situations and in helping operators to improve their work conditions. Wisner (1995a) proposes that the operator's conceptualization of work problems (i.e., how they cognitively construct the issues) provide a better explanation for errors and accidents than the conditions under which the problem itself is solved. The author also posits that a vital aspect of the analysis includes what he calls "*self-confrontation*" or "*autoconfrontation*." The process involves a face-to-face discussion with workers focusing on potential discrepancies between their reported actions and what was observed by the analyst (Wisner, 1995a,b).

The EWA proponents argue for an inquiry that is primarily based on field research and call for the primacy of knowledge derived from natural/local settings over laboratory findings (De Keyser, 1992). Due to its emphasis on obtaining a rich or, in ethnographic parlance, "*thick*" description of the work situation from the operators' viewpoint, the EWA often makes use of qualitative, naturalistic, or ethnographic techniques. Wisner (1995b) remarks that the ergonomics discipline has clear connections with anthropology, and he defines "situated activity" as the focus of its analysis. The author admits, however, that when compared to actual anthropological studies the use of ethnographic methods in EWA is clearly restrained by the need to find an acceptable solution to a problem within a time frame.

As it evolved the nexus of the "Francophonic" ergonomics shifted toward the analysis of verbal communication among workers, with growing attention being paid to operators' cognition and the creation of meaning (De Keyser, 1991). Fittingly, Wisner (1995b) defines his viewpoint as one of an ergonomist or a cognitive psychologist who endeavors to understand cognitive phenomena but who also includes in his observation contextual aspects of the situation such as the physical environment, work organization, and the workers' prior experience, knowledge, and relationships. He sees cognitive anthropology as close to the principles of EWA as it attempts to understand the operator's own cognition as opposed to impose the observer's or management's one.

Wisner coined the term *anthropotechnology* to describe an approach that, similar to ergonomics, attempts

to adapt (or transfer) technology to a population by using knowledge from the social sciences in order to improve the design of productive systems (Gueslin, 2005). Different from most ergonomic applications, which typically address an individual or a small group of persons in a work situation, anthropotechnology focuses on collective, organizational, and even national human–technology fit issues.

It has been noted that efforts to transfer technologies to industrially developing countries (IDCs) have often been marred by health, economic, and environmental issues, including high prevalence of workplace injuries and illnesses, poor quality and productivity, and pollution (Moray, 2000; Shahnavaz, 2000; Wisner, 1985). Wisner's research compares the functioning of similar industrial facilities located in industrialized and developing countries and highlights geographical, historical, and cultural factors as key factors shaping the workers' activities and the overall system's performance. He sees the interface between ergonomics and anthropology as propitious to conduct in-depth analyses of the factors defining success or failure in technology transfers.

Anthropotechnology focuses on the differences between countries selling and buying technologies in terms of their social and industrial contexts as well as in regards to other anthropological domains such as physical anthropology (i.e., anthropometry), cultural anthropology (i.e., norms and values), and cognitive anthropology (i.e., role of prior knowledge on work situations including education and training) (Gueslin, 2005). It is an approach to ergonomics that attempts to link the reality of the individual human work to large-scale factors which affect the functioning of entire societies.

Antropotechnology emphasizes the importance of the (pluridisciplinary) work team in the successful technology transfer. It has a clear sociotechnical foundation, embracing the joint-optimization principle discussed elsewhere in this chapter. It shares some of its perspectives with macroergonomics, but it is clearly distinct in terms of its objectives, priorities, and methods.

## 12   COMMUNITY ERGONOMICS

Recently, human factors has looked beyond work systems to examine more complex environments where multiple systems interact with each other. Community ergonomics (CE) is an approach to applying human factors principles to the interaction of multiple systems in a community setting for the improvement of its quality of life (Smith et al., 1994; Cohen and Smith, 1994; Smith et al., 1996; Smith et al., 2002). CE evolved from two parallel directions, one being theories and principles in human factors and ergonomics, the other the evaluation of specific improvements in communities that led to theories and principles at the societal level of analysis. The CE approach focuses on distressed community settings characterized by poverty, social isolation, dependency, and low levels of self-regulation (and control). Deteriorating inner city areas in the United States are examples of such communities, as are underdeveloped countries and countries devastated by war and poverty. The practice of CE seeks to identify and implement

interventions that provide the disadvantaged residents of a community with the resources within their social environment that resolve their problems systematically in a holistic way. In macroergonomic terms this means achieving a good fit among people, the community, and the social environment. McCormick (1970) explained the difficulty in transforming the human factors discipline to deal with communities. He stated that the human factors aspects of this environment required a significant jump from the conventional human factors context of airplanes, industrial machines, and automobiles. In the first place, the systems of concern (the community) are amorphous and less well defined than are pieces of hardware. Lodge and Glass (1982) recognized the need for a systems approach to dealing with issues at a societal level. For improvement to occur, they advocated a cooperative, holistic approach with multiple reinforcing links from several directions. They pointed out correctly that providing jobs is an ineffective way to introduce change if training, day care, and other support systems are unavailable to the disadvantaged residents who are employed.

Several concepts of CE are extrapolated from behavioral cybernetic principles proposed by Smith (1966) regarding how a person interacts with her or his environment. CE proposes that community residents be able to track competently their environment and other community members within it. In addition, it is important that people be able to exert control over their lives within the environment and in social interactions. Residents need to be taught how to develop an awareness of the impact of their own actions on the environment and on others in their community. This understanding and control over their interactions with the environment and people enables residents to build self-regulating mechanisms for learning, social tracking, and feedback control of their lives. An effective self-regulating process is one that helps community residents identify situations of misfit between community residents and their environment, as well as allowing for the generation and implementation of solutions to improve fit and to deal with emerging challenges in a continuously changing and turbulent environment.

To put the situation in distressed communities in context, it can be likened to the cumulative trauma injuries and stress observed at the workplace. Many residents in a distressed inner city suffer from what can be termed *cumulative social trauma* (CST). Like work-related musculoskeletal disorders, CST results from long-term chronic exposure to detrimental circumstances in this case, societal conditions that create a cycle of dependency, social isolation, and learned helplessness. CST results from repeated exposure to poorly designed environments and/or long-term social isolation that leads to ineffective individual performance or coping abilities. Harrington (1962) observed a personality of poverty, a type of human being produced by the grinding, wearing life of the slums. Cumulative social trauma is the repetition of an activity or combinations of activities, environmental interactions, and daily life routines that develop gradually over a period of time and produce wear and tear on motivation, skill, and

emotions, leading to social and behavioral disruption, psychosomatic disorders, and mental distress.

The obstacles encountered on the path to progress in the declining areas of inner cities can be defined in terms of human errors by community residents and by the public institution employees who serve them that lead to a lack of system effectiveness and reliability. Human errors are decisions, behaviors, and actions that do not result in desired and expected outcomes: for example, failing to keep a job, relying on public assistance, failing to pay bills, being involved in illegal activities for the residents, and a lack of understanding, compassion, and effective services for the public employees. Social (and economic) system effectiveness and reliability are measured by the ability of public (and private) institutions to achieve positive community performance outcomes (Smith and Smith, 1994).

Social and economic achievements are enhanced by the level of the goodness of the fit between the characteristics and needs of community residents and those of the community environment. In the case of substantial misfit between people and the environment, poor urban residents are likely to make repeated "errors" in life which will result in poor economic and societal outcomes. Institutions with low system effectiveness and reliability do not provide adequate feedback (performance information or direction) and/or services to enable residents to correct their errors. One of the fundamental purposes of community ergonomics is to improve the goodness of fit between environmental conditions and residents' behaviors to reduce residents' errors. To be effective, interventions have to deal with the total system, including the multifaceted elements of the environment and community residents. The theory and practice of community ergonomics is based on the assumptions that individuals or community groups must attain and maintain some level of self-regulation and individuals or groups need to have control over their lives and their environments in order to succeed. This can be achieved by having residents participate actively in their own self-improvement and in improvement of their environment.

The resident–community–environment system has multilateral and continuous interactions among residents, groups, living conditions, public institutions, stores, and workplaces. These are linked through interactions and feedback from the interactions. Other communities and external public and private institutions that may have very different beliefs, values, and modes of behavior surround the community. Similarly, the community is surrounded by communication systems, architecture, transportation, energy systems, and other technology that influence and act on the community. These affect the life quality of individuals and groups in the community. This resident–community–environment system includes institutions for education, financial transactions, government and politics, commerce and business, law enforcement, transportation, and housing. The organizational complexity of this system affects the ways by which individuals and groups try to control the environment through their behavior.

According to Smith and Kao (1971), a *social habit* is defined as self-governed learning in the context of the control of the social environment. The self-governance of learning becomes patterned through sustained and persistent performance and reward, and these are critically dependent on time schedules. As these timed patterns become habituated, the individual can predict and anticipate social events, a critical characteristic in the management of social environments. Self-control and self-guidance in social situations further enhance the ability of the individual to adjust to various environments (old and new) by following or tracking the activities of other persons or groups. Social tracking patterns during habit cycles determine what is significant behavior for success or failure. Residents, groups, and communities develop and maintain their identity through the establishment and organization of social habits (i.e., accepted behaviors). In addition, the maintenance of group patterns and adherence to this process are achieved through social yoking (or mutual tracking), so that people can sense each other's social patterns and respond appropriately.

A resident–community–environment management process should build from the social habits of the community, coupled with a human-centered concept of community design. This seeks to achieve better community fit by making public and private institutions more responsive to resident capabilities, needs, and desires and residents more responsive to community norms. Smith and Kao (1971) indicated that cultural design could aid and promote development of individuals and communities if it is compliant with people's built-in or learned behavior. It can adversely affect behavior, learning, and development of individuals and communities if it is noncompliant with their needs and built-in makeup. Management of the integration of residents, the community, and the environment must be approached as a total system enterprise. The aim is to build proper compliances among the residents, the community, and the environment using social habits and individual control as key elements in compliance. This leads to the design of a resident–community–environment system that improves residents' perceptions, feedback, level of control, adherence to social habits, and performance through improved services and opportunities provided by public and private institutions.

The management process seeks to establish positive social tracking between the residents and public and private institutions. Residents can be viewed as being nested within the community. The guidance of a resident's behavior is determined by her or his ability to develop reciprocal control over the economic, social, and cultural institutions in the community using feedback from interactions with these institutions. The feedback concept is a significant aspect because it shows the resident the effectiveness of self-generated, self-controlled activity when interacting with the community and the environment. The quality of the feedback determines the course, rate, and degree of individual learning and behavior improvement in relation to interaction with the community and the environment.

The performance of the resident–community–environment system is dependent on critical timing considerations, such as work, school, and, public services

schedules. Successful participation in these activities can act as a developmental aspect of residents acquiring social habits for daily living. Some difficulties faced by the community are due to the misfit of critical timing factors between residents and institutions. There are many reasons for disruption: for example, residents not being motivated to adhere to a fixed schedule or the poor scheduling of the public services. An important element of a CE management process is to develop a tracking system to aid residents and public agencies in the sensing of critical aspects of timing and in the development of a "memory" for determining future events. The tracking system is aimed at building good habits of timing for the residents and the agencies. The absence of good timing habits results in delays in functioning, social disruption, organizational adjustment problems, emotional difficulty, and poor performance.

Smith et al. (2002) described seven principles that constituted the philosophy of the CE approach:

1. *Action Orientation.* Rather than trying to change community residents in order to cure them of unproductive behavior, CE believes in getting them actively involved in changing the environmental factors that lead to misfit. The CE approach strives to reach collective aims and perspectives on issues of concern and to meet specific goals and aspirations through specific actions developed by all involved parties. This process requires an organized and structured evaluation process and the formulation of plans for solutions and their implementation. The approach is based on new purposes, goals, and aspirations developed through community–environment reciprocal exchange rather than on existing community skills, needs assessments, or external resources. Other approaches have tended to become bogged down trying to fulfill institutional rules and requirements or institutional directives that pursue a good solution but to the wrong problems (Nadler and Hibino, 1994).

2. *Participation by Everyone.* Community improvements often fail because residents are not substantially involved in the process of selecting the aims, objectives, and goals. It is essential to have resident participation from start to finish. Such participation is a source of ideas, a means of motivation for the residents, and a way to educate residents to new ideas and modes of behavior. There are many mechanisms for participation, including individual involvement, action groups, and committees. Early involvement of strategic persons and institutions in the process brings the necessary concepts, technical expertise, and capital into the process and the solutions. Although participation by every resident of the community may not be possible at first, the goal is to get everyone involved at some point in some way. It is expected that reluctant and passive involvement will be minimized and will decrease continually throughout

a project or activity. Effective information transfer among individuals, organizations, and institutions is essential for success.

3. *Diversity and Conflict Management.* Communities are made up residents who may have differing perspectives, values, cultures, habits, and interests. Problems in a community are never neat and compartmentalized, and because the community system is complex, it is difficult to comprehend all of the perspectives. However, it is necessary to recognize the diversity in perspectives and opinions and find ways to work toward consensus. It is essential to formulate a process for managing diversity, conflict, and confusion that will occur in a community with many cultures and perspectives. Distressed communities typically have a low level of self-regulatory capability and high levels of diversity and dissention. It is important to spend the necessary time designing a process for handling diversity and conflict. Nadler and Hibino (1994) and Cohen (1997) have developed methodologies for working with diversity and conflict in designing solutions to problems.

4. *Encouraging Learning.* A well-designed process will allow residents and institutions to interact positively and effectively even in the conditions of a highly turbulent environment. It is expected that community residents and planners will learn from each other and from participating in the process. In addition, these learning effects will be transferred to subsequent related endeavors, with or without the presence of a formal community ergonomics process to facilitate the interaction. Thus, there is a transfer of "technology" (control, knowledge, skills) to the community in the form of the process and the learning experiences. Furthermore, participants will enhance their abilities in leadership, management, group activities, evaluation, and design learned while being involved in the CE process. Formal documentation of the system management process within the group setting as it occurs provides for better understanding and management of the community ergonomics process and provides historical documentation for future endeavors of a similar nature.

5. *Building Self-Regulation.* One aspiration of the community ergonomics process is to provide participants with an increased ability and capacity for self-regulation. *Self-regulation*, defined as the ability of a person or group to exert influence over the environmental context, is enhanced by creating specific tasks, actions, and learning opportunities that lead directly to the successful development of skill. When community members participate in a project that achieves specific goals as part of its evaluation, design, and implementation processes, they develop new abilities and skills to self-regulate themselves. This serves as motivation toward more community improvement activity.

6. *Feedback Triad.* Feedback is a critical aspect of the CE improvement process. Different levels of feedback provide opportunities for learning. Smith (1966) and Smith and Kao (1971) defined three levels of feedback for individual performances: reactive, instrumental, and operational feedback. *Reactive feedback* is an understanding of the response of the muscles in taking action, *instrumental feedback* is the feel of the tool being used to take the action, and *operational feedback* is the resulting change in the environment when action of the tool occurs. Smith (1966) stated that these are integrated into a feedback triad allowing for closed-loop control of the activity, social tracking, and self-regulation. Feedback that provides these levels of information at the community level is important in designing and implementing community environment improvements. Thus, mutatis mutandis, feedback on resident perspectives and actions provides reactive feedback, feedback on institutional perspectives and actions provides instrumental feedback, and feedback on the success of community improvements provides operational feedback. Reactive feedback is the personal sense that one's actions (or the group's actions) result in a perceived outcome on the environment. Instrumental feedback is sensed from subsequent movement of an institution or group in the form of milestones achieved and output produced. Operational feedback comes from the results of such activities as planning, designing, installing, and managing group intentions as well as the new policies, laws, buildings, and institutions resulting from such activities. These are examples of persisting results that can be sensed directly by community environment social tracking systems. Without the feedback triad, self-regulation by group participants would not be very effective and the system could quickly degenerate. Participants must sense that their personal actions, words, and participation have effects on themselves, on others, and on the environment.

7. *Continuous Improvement and Innovation.* The community ergonomics approach recognizes the need for continuous improvement, which can be achieved by continuous planning and monitoring of results of projects implemented. Private organizations can be encouraged to provide guidance and feedback on the purpose, goals, and management of improvement initiatives. Inputs from private organizations and governmental programs can be utilized to promote an entrepreneurial spirit that encourages effective community habits. These can be benchmarked against other communities and other programs. Valuable information can be elicited by studying the effects of a solution over a period of many years to prevent the redevelopment of a dysfunctional system and to give members of troubled communities opportunities for better lives.

This implies the need for ongoing monitoring to evaluate the operational requirements for implementation, measuring effectiveness, and use of feedback to alter programs already in existence. Consistent monitoring of citizen needs, desires, and values must be established to verify that programs and products are accessible, usable, useful, and helpful to community residents.

Community ergonomics is a long-overdue answer to the application of human factors engineering principles to address complex societal problems. Community ergonomics is a philosophy, a theory, a practice, a solution-finding approach, and a process, all in one. CE is a way to improve complex societal systems that are showing signs of CST (cumulative social trauma). CST is not to be taken lightly, as the costs are immense in every respect: financial, human, social, and developmental. When any group of people, a community, or a region is isolated, alienated, and blocked from access to resources needed to prosper, the consequences are long lasting and deeply detrimental.

Recently, concepts of CE have been developed specifically for corporations engaged in international development and trade (Smith et al., 2009). During the last half of the twentieth century, a struggle began for fairness, equality, freedom, and justice for people in many developing nations. This has occurred during a time of expansion of the global economy. Companies now operate in a complex world economy characterized by continuous change; a heterogeneous (often international) workforce at all job levels; increased spatial dispersion of their financial, physical, and human assets; increased diversification of products and markets; uneven distribution of resources; variable performance within and between locales; increased operational and safety standards; and differences in economic, social, political, and legal conditions. In this climate of increased international trade, important issues of social and cultural values need to be examined carefully. There is need for an understanding of how specific cultures and cultural values can affect corporate operations.

Companies have developed management practices in response to numerous obstacles encountered when they expand abroad or when they transfer processes abroad. Difficulties that they have encountered in their growth, expansion, internationalization, and globalization are due primarily to the following factors: (1) the lack of a process for effective transnational transfers; (2) the lack of knowledge of operational requirements and specifications in newly entered markets; (3) ignorance of cultural norms and values in different countries; (4) the lack of adaptability mechanisms; (5) a low tolerance for uncertainty, ambiguity, and change and diversity; and (6) a lack of acceptance by segments in the populations in which they are starting operations. One of the most important issues in acceptance by the local people is that a company's commitment to social responsibility has the same intensity as those striving for large profits and the use of cheap local natural resources and labor. In fact, some managers believe that social responsibility may conflict with corporate financial goals and tactics.

However, CE postulates that long-term corporate stability and success (profits) will occur only if there is local community support for the enterprise and its products. Social responsibility nurtures the mutual benefits for the enterprise and the community that lead to stability and success. CE proposes that multinational corporations must accept a corporate social responsibility that recognizes the universal rights of respect and fairness for all employees, neighbors, purchasers, and communities. Whether these rights are profitable or not in the short term or difficult to attain, such corporate social responsibility is a requirement if global ventures are to be successful in the long term. The survivability, acceptability, and long-term success of a corporation will depend not only on quick profits but also on social responsibility that builds long-term community acceptance and support of the enterprise. This will lead to greater accessibility to worldwide markets. Organizations must address multicultural design, a comfortable corporate culture, and principles of respect and fairness for employees, customers, and neighbors. This will improve the fit with the international cultures in which the corporation operates.

CE has developed principles for successful multinational organizational design (Smith et al. 2009). These principles focus on a goal of social responsibility, fairness, and social justice and do not threaten the prosperity of a company or organization. They are built on the premise that the society and communities in which a company operates should benefit from the presence of the company in the society. Thus, the corporation should contribute to the development, growth, and progress of local communities. These principles propose a reciprocal relationship between the hosting community or society and the outside corporation.

1. *Fit Principle*. Accommodations need to be made by companies for a diverse workforce. That is, companies need to design for cultural diversity. Corporations must understand and incorporate the norms, customs, beliefs, traditions, and modes of behavior of the local community into their everyday operations. In some communities multiple cultures will need to be included in this process. Often, there is a need to strike a balance among the various cultures, as they are not always compatible. The corporation's organizational structure and operational style need to be flexible to bridge the gap between the corporate and local cultures.

2. *Balance Principle*. The balance principle defines the need to find the proper relationship among components of a larger system. Based on this concept we believe that there is a need for balancing corporate financial goals and objectives with societal rights and corporate social responsibility. Companies are a part of a larger community, and through their employment, purchasing, civic, and charity activities they can influence community development and prosperity. As an integral part of this larger system, companies have a responsibility to promote positive balance for the benefit of the community and the corporation.

3. *Sharing Principle*. Traditionally, a corporation's success has been measured in terms of its financial growth, but there are other factors that will become more critical as social awareness becomes more prominent. For instance, customer loyalty, community support, and acceptability of products will be critically related to the corporation's long-term financial success. If a corporation chooses to invest some of its profits back into a community in ways that are significant to that community, the corporation may be viewed not only as a business but also as a community partner. In giving something back to the community the corporation is developing loyalty to its products and protecting its long-term profitability.

4. *Reciprocity Principle*. The reciprocity principle deals with the mutual commitment, loyalty, respect, and gain between producers and consumers. A bond results from the corporation giving something back to the community, which builds loyalty from the consumers to the company, and eventually leads to a genuine sense of loyalty from the organization back to the community. In this respect, what might have started as responsibility will over time become mutual loyalty and commitment. Within the corporate organization, the same phenomenon takes place when the organization shows responsibility toward its employees (producers), who in turn become loyal and committed partners with the corporation.

5. *Self-Regulation Principle*. Corporations should be viewed as catalysts of self-regulation and socioeconomic development in host communities. Communities and countries in disadvantaged economic conditions typically show symptoms of learned helplessness, dependency, isolation, and cumulative social trauma. Instead of perpetuating conditions that weaken people and institutions, an effort should be made to help people to self-regulate, grow, flourish, and become productive. In this effort, corporations are very important because they provide employment, training, and professional development opportunities that give people the tools to help themselves. Corporations can also invest in the community infrastructure, such as schools, clinics, and hospitals, which leads to stronger, healthier, and more independent communities in the future.

6. *Social Tracking Principle*. Awareness of the environment, institutional processes, and social interaction are necessary for people and corporations to navigate through their daily lives and for communities to fit into the broader world. Clear awareness helps to control the external world and leads to more robust, flexible, open system design. It is important for community members, employees, and corporations to be aware of their surroundings to be able to predict potential outcomes of actions taken. Similarly,

it is important for corporations to develop a certain level of awareness regarding the workforce, the community, and the social, economic, and political environment within which they operate. This includes the cultural values of the people affected by a corporation's presence in a particular community.

7. *Human Rights Principle*. The human rights principle underscores the belief that every person has the right to a reasonable quality of life, fair treatment, a safe environment, cultural identity, respect, and dignity. There is no reason for anyone not to be able to breathe fresh air, preserve their natural resources, achieve a comfortable standard of living, feel safe and dignified while working, and be productive. People should not be assigned a difference in worth based on class, gender, race, nationality, or age. The workplace is a good starting point to bring about fairness and justice in societies where these do not exist as a norm.

8. *Partnership Principle*. This principle proposes a partnership among the key players in a system in order to achieve the best possible solution: corporation, community, government, employees, and international links. By doing this, balance may be achieved between the interests of all parties involved and everyone is treated fairly. In addition, partnership assures commitment to common objectives and goals.

The essence of internationalization, globalization, and multiculturalism is in the culture and social climate that the corporation develops to be sensitive to the community and the diversity of the workforce. This includes respect, partnership, reciprocity, and social corporate responsibility toward employees, the community, and society as a whole. It requires seeking a balance between the corporate culture and that of the community where the business operates and the cultures brought into the company by the diverse employees. In the past, corporations have entered new markets all over the world, profiting from cheap labor and operating freely with little or no safety or environmental liability. However, the level of social awareness has increased all over the world, exposing sweat shops, inhumane working conditions, labor exploitation, and environmental violations across the board. The focus in the future will be on doing business with a social conscience. By doing this, corporations will become welcome in any part of the world they wish to enter.

## 13  CONCLUDING REMARKS

As ergonomics has matured as a science, the emphasis has broadened from looking primarily at the individual worker (user, consumer) and her or his interaction with tools and technology to encompass larger systems. A natural progression has led to an examination of how the social environment and processes affect an individual and groups using technology as well as how the behavior and uses of technology affect society.

We have described aspects of these reciprocal effects by emphasizing select theories and perspectives where social considerations have made a contribution to system design and operation.

We see ergonomics as an essential aspect of the continuous human effort to survive and prosper. It is central to our collective endeavor to improve work systems. Ergonomics answers to the social needs of effective utilization of human talent and skills and of respect and support for their different abilities. By reducing exposure to physical hazards, particularly those associated with the onset of musculoskeletal disorders, by controlling occupational stress and fatigue, ergonomics is essential for the improvement of work conditions and the overall health of the population. It is instrumental to the safety and functionality of consumer products and key to the reliability of systems on which we depend. In summary, ergonomics is a critical aspect for the well-being of individuals, for the effectiveness of organizations, and for the prosperity of national economies.

Ergonomics can be seen as a technology and part of a broader social context. As such, it responds to the needs, conditions, and structure of that society. Ergonomics technology evolution is shaped by ever-changing societal motivations. The relationships between ergonomics and societal demands can be understood as reciprocal: where social needs determine the direction of ergonomics development and ergonomic innovations once introduced in the environment allow the fruition and reinforcement of some aspects or drives of the social process.

Social needs for increased productivity, higher quality, better working conditions, and reliability changed over time as some of these drives become more prominent. As work systems become more complex and the workforce more educated and sophisticated, the consideration by the ergonomics discipline of broader social, political, and financial aspects has been heightened. These changes have been answered by ergonomics in different but ultimately interrelated approaches.

Earlier we highlighted the seminal contribution of Kurt Lewin to an understanding of the social aspects of work with emphasis on the humane side of the organization. Lewin focused on reconciling scientific thinking and democratic values in the workplace and on recovering the meaning of work. He was an early advocate of worker involvement and saw job satisfaction as an essential goal to be met by work systems. Lewin's ideas and later the application of general systems theory had deep implications for the ergonomics discipline. Work by researchers at the Tavistock Institute, also inspired by Lewin, led to establishment of the sociotechnical systems theory, which confirmed the importance of the social context in work systems optimization.

While Kurt Lewin was one of the leaders in defining the critical need for work to provide psychological and social benefits to the employees, others who followed him carried through with these ideas by turning them into reality at the workplace. At the heart of most of these ideas was the concept of participation by employees in the design and control of their own work and workplaces. French, Kahn, Katz, McGregor, K. U.

Smith, Emory, Trist, Davis, Drucker, Deming, Juran, Lawler, M. J. Smith, Hendrick, Noro, Imada, Karasek, Wilson, Carayon, and Sainfort have all promoted use of employee participation as a process or vehicle to engage employees more fully in their work as a source of motivation, as a means for providing more employee control over the work process and decision making, or as a mechanism to enlist employee expertise in improving work processes and products. The nature of employee participation has varied from something as simple as asking for employee suggestions for product improvements to something as complex as semiautonomous work groups, where the employees make critical decisions about production and resource issues. The critical feature of participation is the active engagement of employees in providing input into decisions about how things are done at the workplace. The social benefits of participation are in the development of company, group, and team cohesiveness and a cooperative spirit in fulfilling company and individual goals and needs. Individuals learn that they can contribute to something bigger than themselves and their jobs, learn how to interact with other employees and managers positively, and receive social recognition for their contributions. This "socialization" process leads to higher ego fulfillment, greater motivation, higher job satisfaction, higher performance, less absenteeism, and fewer labor grievances. Participatory ergonomics has become an essential aspect of work improvement.

The social side of work is more than just the positive motivation and ego enhancement that can occur with good workplace design; it is also the stress that can develop when there is poor workplace design. Work design theorists and practitioners have put substantial emphasis on the psychosocial aspects of work and how these aspects influence employee productivity and health (Smith, 1987a; Kalimo et al., 1997; Carayon and Smith, 2000; Kivimaki and Lindstrom, 2006). This tradition grew out of work democracy approaches in Scandinavia and Germany (Levi, 1972; Gardell, 1982) that emphasized the role of employee participation and codetermination in providing "satisfying" work. The absence of satisfying work and/or combinations of chronic exposure to high physical and psychological work demands were shown to lead to ill health and reduced motivation at work. Strong ties between poor working conditions, employee dissatisfaction, poor quality of working life, and negative outcomes for motivation, production, and health were documented Smith, 1987). Thus, social and psychological aspects of working conditions were shown to influence not only personal and group satisfaction, ego, motivation, and social and productive outcomes but also the health, safety, and welfare of the workforce. This tradition defined critical social and organizational design features that could be improved through organizational and job design strategies. Many of the strategies included considerations of employee involvement in the work process, social mechanisms such as laws and rules defining workplace democracy and codetermination, and health care approaches that encompass psychosocial aspects of work as a consideration.

Macroergonomics grew out of several traditions in organizational design, systems theory, employee participation, and psychosocial considerations in work design. Championed by Hendrick (1984, 1986, 2002) and Brown (1986, 2002), this tradition expanded the focus of work design from the individual employee and work group to a higher systems level that examined the interrelationship among various subsystems of an enterprise. By definition there are structures (organizational, operational, social) that define the nature of the interaction among the subsystems, and macroergonomics aims for the joint optimization of these subsystems. Hendrick (2002) describes how macroergonomics was a response to bad organizational design and management practices that minimized the importance and contributions of the human component of the work system. This is in line with and an elaboration of the prior traditions described above but with a primary focus on the systems nature of the work process and integration of the subsystems. At the heart of macroergonomics is the use of employee participation to achieve system integration and balance (Carayon and Smith, 2000; Brown, 2002).

Community ergonomics is a natural extension of macroergonomics to a higher level above the enterprise, in this case to the community. Like many of the preceding theories and concepts, an important aspect of community ergonomics is improvement in the quality of life for the people in the system. Such improvement concerns economic benefits, but there is also a strong emphasis on developing the social and psychosocial aspects of individual and community life that enhance overall well-being. Like macroergonomics, community ergonomics examines the subsystems in an enterprise and how to optimize them jointly to achieve benefits for the people. At a higher level, community ergonomics has provided advice to multinational enterprises in how to provide reciprocal benefits to the enterprise and the several communities in which the enterprise operates. Among the considerations is the critically important concept of the enterprise's sensitivity to, and accommodation of, social and cultural differences (Derjani-Bayeh and Smith, 2000; Smith et al., 2002).

## 1 INTRODUCTION

Methods are a core component in the successful practice of human factors and ergonomics (HF/E). Methods are necessary to (1) collect data about people, (2) develop new and improved systems, (3) evaluate system performance, (4) evaluate the demands and effects of work on people, (5) understand why things fail, and (6) develop programs to manage HF/E. A primary concern for the disciplines of HF/E resides in the ability to make generalizations and predictions about human interactions for improved productivity, safety, and overall user satisfaction. Accordingly, HF/E methods play a critical role in the corroboration of these generalizations and predictions. Without validated methods, predictions and generalizations would be approximate at best, and HF/E principles would present unfounded theories informed by common sense and by anecdotal observations and conclusions. HF/E methods are the investigative toolkits used to assess user and system characteristics as well as the resulting requirements imposed on the abilities, limitations, and requirements of each. HF/E methods are implemented via scientifically grounded empirical investigative

techniques that are categorized into experimental research, descriptive studies, and evaluation research. Further discrimination is made based on psychometric properties, practical issues, and descriptive, empirical, and evaluation research methodological processes.

By the very nature of its origin, HF/E is an interdisciplinary field of study comprising aspects of psychology, physiology, engineering, statistics, computer science, and other physical and social sciences. In a bibliometric analysis of the journal *Human Factors* a steady trend of more authors per paper was discovered (Lee et al., 2005). This may be an expression of the increasingly interdisciplinary nature of human factors research and a product of the need to address human interaction in more complex technology systems.

Why, then, bother with a chapter devoted to HF/E methods when it is an obvious union of well-documented methods offered by this wide array of subject matters? The answer is that the discipline of HF/E is concerned with understanding human-*integrated* systems. That is, HF/E researchers and practitioners strive to understand how the body, mind, machine, software, systems, rules, environment, and so on, work in harmony or dissonance and how to improve those relationships

and outcomes. Although HF/E is a hybrid of other disciplines concerned with designing systems and products for human use, it demonstrates unique characteristics that make it a distinct field of its own (Meister, 2004; Proctor and Vu, 2010).

Fitts's law provides a classic example of the application of basic psychological principles to HF/E problems. Fitts's law is a model of psychomotor behavior, predicting human reaction time. The model relates movement time, the size of two targets, and the distance between them (Fitts, 1954). Fitts's law is a principle that has been adapted and embedded within several HF/E studies of systems that employ similar types of psychomotor responses of the user. Examples include interface design selection, performance prediction, allocation of operators, and even movement time prediction for assembly line work.

However, the original Fitts's law was developed under certain assumptions in its application. This includes error-free performance and the assumption of one-dimensional movement along a single axis and specifies no guidelines for the input devices that control the movement (e.g., mouse, lever, etc.). This is due to the fact that the original Fitts's law was developed *independent* of any specific system, human variability, and other contextual factors. HF/E specialists therefore have to take these factors into account for the application of Fitts's law to various systems. An example of this is the work of MacKenzie, which extends Fitts's law to human–computer interaction (HCI) research and design. MacKenzie has, in basic research, manipulated Fitts's law to account for the use of a mouse and pointer, two-dimensional tasks, and more (MacKenzie, 1992a,b). Clearly, concessions were made in order to apply Fitts's law within the context of the HCI system.

As noted previously, Fitts's law supports the prediction of speeds but does not support the prediction of errors. Following the original work utilizing Fitts's law for HCI research, an error model for pointing has been developed. Wobbrock et al. (2008) developed an error model that can be used with Fitts's law to estimate and predict error rates along with speeds. In addition to predicting a new error model, their research also took a departure from Fitts's law. These researchers found that target size had a greater effect on error rate than target distance. This is contrary to what Fitts's law states—that target size and distance contribute proportionally to the index of difficulty (ID).

Perhaps the most demanding challenge encountered by HF/E investigators is deciding the most appropriate methodology to address their goals and research questions (Wickens et al., 2003a). Multitudes of basic scientific methodologies, principles, and metrics are available to HF/E researchers and practitioners. An accompanying challenge of HF/E methods emerges as how to use these methods to assess the human factor within the system context, a feature that is often absent in the traditionally basic research methods. The transformation of physical and social sciences into methodologies applicable to HF/E often generates conflicting goals and assumptions. The HF/E investigator is faced with trade-offs in how they select and actuate the methods. The distinctive

nature of the HF/E disciplines is certainly reflected in the methods used by both researchers and practitioners.

The appendix to this chapter is a set of tables that summarize the methods employed in a variety of HF/E investigations. This collection provides a snapshot of the current application of HF/E methods in the published scholarly journals *Ergonomics* and *Human Factors* for the period 2000–2010. Although the tables are not comprehensive, it is representative of the types of methods selected and how they are applied in the various subdisciplines of HF/E. The discipline(s), goal, and method(s) used by authors are underscored and labeled according to different methodological characteristics that are defined in this chapter. One can appreciate the variety of basic methods that HF/E investigators encounter in the generalization and prediction of human interaction with systems and physical machines.

The studies featured apply a range of methods, from highly controlled laboratory settings to loosely structured observational field studies. The variety of goals presented by these authors fit into two categories: (1) HF/E methods that develop and test scientific principles and theories as they apply to human-integrated systems and (2) HF/E methods that focus on applied problems, incorporating specific features of the target population, task environment, and/or the system. In both cases, the investigators are concerned with the human performance or behavior embedded in some system. HF/E researchers and practitioners should look regularly to the scientific literature to glean the types of methods that investigators select to achieve their goals.

No absolute right or wrong exists in method selection and application. However, some methods are more appropriate than others, influenced greatly by circumstantial factors. This is what makes this discipline of HF/E both exciting and frustrating at times for researchers and practitioners alike. The most common answer to the appropriateness of a method for a given HF/E objective is: *It depends*. The specific combination of methods used and control exerted depends heavily on task factors and study goals, among other key contextual factors. The studies listed in the HF/E literature sample and a handful of others referred to provide readers with real examples of the application of HF/E methods employed by investigators in an effort to realize a variety of goals under an assortment of assumptions. Four of the studies from the review have been selected as specific case studies of field studies, survey methodologies, empirical methods, and evaluation studies. Experience is one of the best tools to apply in the selection of methods. Much can be learned from the experiences of others, as their goals, methodologies, and procedures are published in the HF/E literature.

In this chapter we present the reader with critical issues in the selection and execution of HF/E methods such as the ethical issues of working with people, psychometrics issues, and practical constraints. We do not aim to provide readers with all the answers to problems in applying HF/E methods. Instead, readers should gain an improved sense of which questions they should ask prior to implementation of HF/E methods in research or practice. Moreover, we do not provide instructions for

the implementation of specific methodologies. Instead, we introduce the most relevant facets of methods for addressing critical issues. Classifications of methods are provided in ways that can direct HF/E investigators in their selection and planning. The data and information gathered through HF/E methods are analyzed and applied in ways unlike traditional psychology or engineering. Chapter 44 is devoted to HF/E outcomes.

## 2  HF/E RESEARCH PROCESS

Although a significant amount of improvisation is required of HF/E researchers to account for contextual factors while preserving experimental control, a general framework for HF/E investigations can be constructed. This framework is supported by psychometric attributes, previous research methods, principles, outcomes, and ethics of investigations. The foundation of this framework is the specific goals established for a given investigation. Figure 1 presents a schematic of the framework. Each decision point and its relative attributes are addressed throughout the chapter, beginning with assertion of HF/E goals.

### 2.1  Problem Definition

When evaluating human system interaction, first you must take into account the goals, knowledge, and procedures of the human operator; the system and its interface; and the operational environment (Bolton and Bass, 2009). What motivates HF/E investigations in addition to the underlying desire to improve human-integrated system safety and efficiency is usually the recognition of a problem by the HF/E researcher or specialist, management, or a funding agency. For example, the management team at a software call center may ask the usability group to evaluate the problematic issues of the installation of their software package. Alternatively, a government funding agency may issue a call for proposals to discover the source of errors in hospital staffs' distribution of medication to patients. HF/E investigators also come across ideas from reading relevant scientific literature, networking with colleagues and peers at work and conferences, observing some novel problem, or even attempting to reveal the source of unexplained variance in their or someone else's research. Problems usually stem from a gap in the research, contradictory sets of results, or the occurrence of unexplained facts (Weimer, 1995). These problems are influential in defining the purpose of the investigation at hand as well as subsequent decisions throughout the application of HF/E methodologies. The first important criterion is to determine the purpose or scope of the investigation. The goal of the investigation is critical. Methods selected have to be relevantly linked to the goal for the investigation to succeed.

Investigations may be classified as *basic* or *applied* (Weimer, 1995). Of course, as with most HF/E theories and principles, these are not completely dichotomous. Studies that are basic are explanation driven, with the purpose of contributing to the advancement of scientific knowledge. Basic research journals tend to be cited by other journals, thus demonstrating how instrumental basic research is in contributing to the scientific knowledge base (Lee et al., 2005). Basic investigations may

seem out of place because HF/E is so applied in nature. However, explanation-driven basic methods serve a critical role presenting solutions to real-world H/FE problems. Basic research is aimed at advancing the understanding of factors that influence human performance in human-integrated systems. The desired outcome of this type of research is to establish general principles and theories with which to explain them (Miller and Salkind, 2002). An example of basic research is a study of the impact of a variety of different feedback modalities on user performance in a series of drag-and-drop tasks with a desktop computer (Jacko et al., 2005). This publication reported the efficacy of some nonvisual and multimodal feedback forms as potential solutions for enhanced performance. Basic research may employ a variety of experimental methodologies. Basic investigations in HF/E are comparable to the nomothetic approaches used in psychology. The nomothetic approach uses investigations of large groups of people in order to find general laws that apply to everyone (Cohen and Swerdlik, 2002; Barlow and Nock, 2009).

Pollatsek and Rayner (1998) present classifications and explanations for several basic methodologies of tracking human behavior. These include psychophysical methods (subjective, discrimination, and tachiscopic methods), reaction time methods, processing time methods, eye movement methods, physiological methods, memory methods, question-answering methods, and observational methods. A characteristic of basic investigations is that the majority of these methods are operationalized in highly controlled settings, usually in an academic setting (Weimer, 1995). Most commonly, basic studies incorporate theories and principles stemming from behavioral research, especially experimental psychology. HF/E basic research goes beyond basic experimental psychology, conceiving the basic theories that explain the human–system interaction, not just the human in isolation (Meister, 1971). The development of human models of performance, such as ACT-R/PM (Byrne, 2001), and using them to evaluate software applications demonstrate the integration of basic theories of human information and physiological processes to create an improved understanding of human–system interactions relevant to a variety of applications.

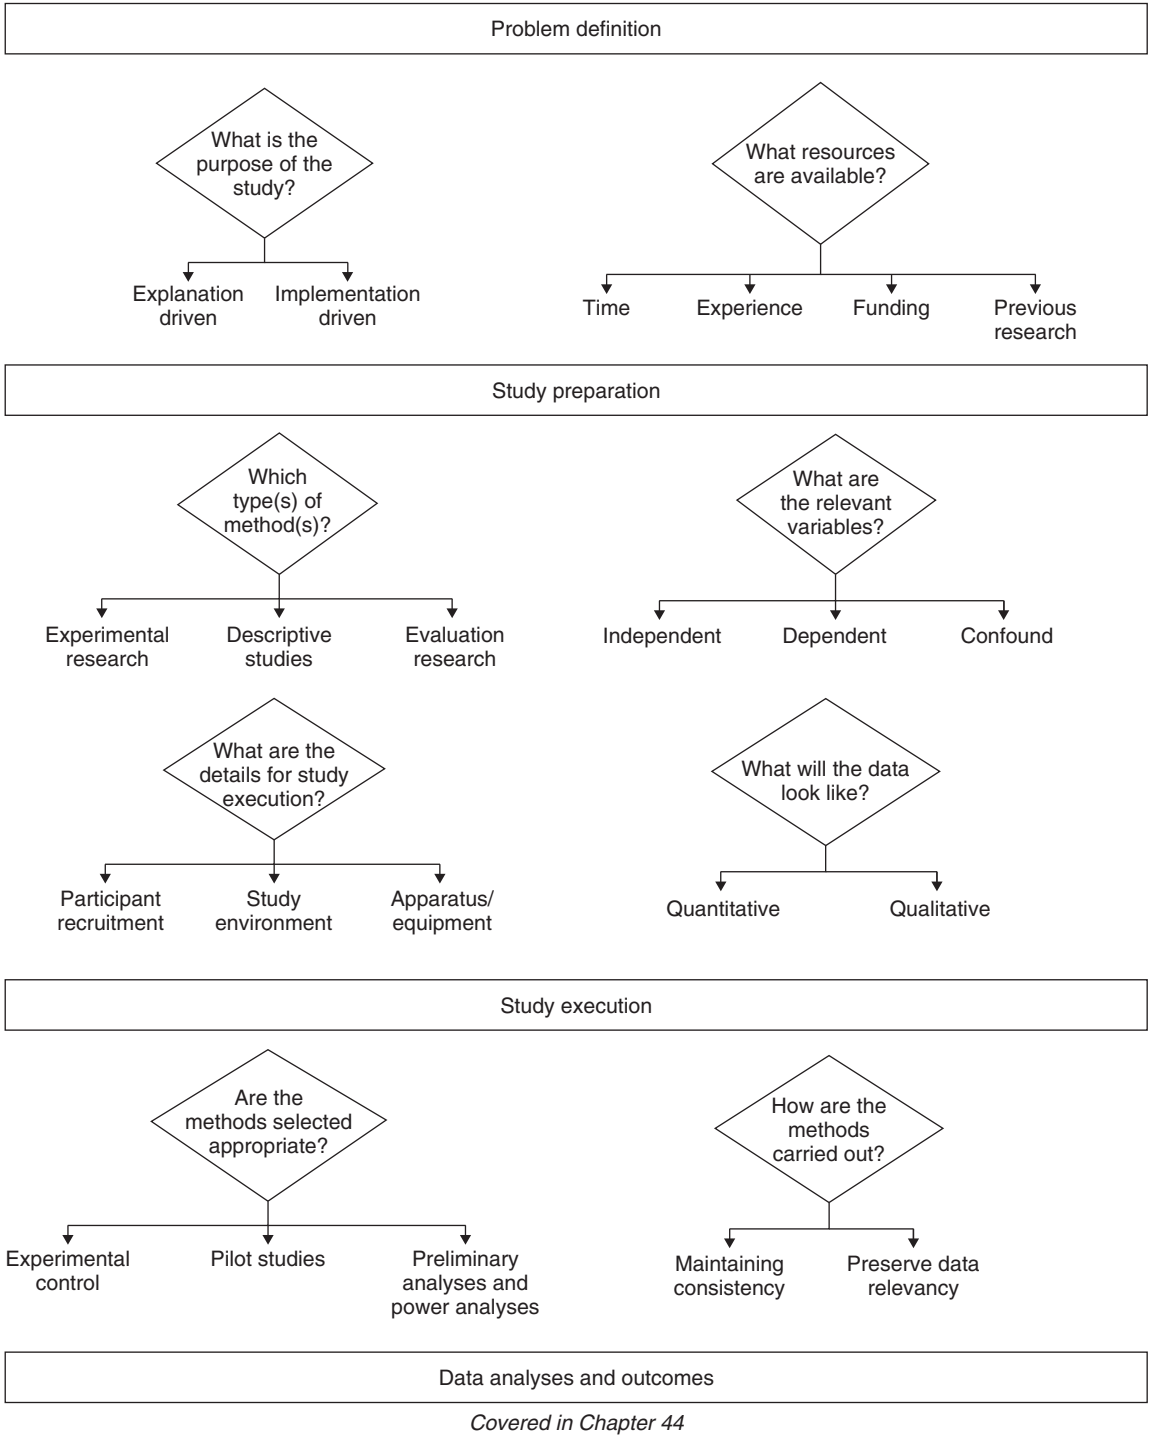
Applied research directs the knowledge from basic research into real-world problems. Work in applied research is focused on system definition, design, development, and evaluation. Applied investigations are, in a sense, supplements to basic research. They would lack merit in the absence of basic research. For example, unlike basic research journals that tend to be cited by other journals, applied journals are likely to cite other journals (Lee et al., 2005). A characteristic of applied investigations is that the problems identified are typically too specific for their solutions to be generalizable. These investigations are implementation driven, with very specific goals to apply the outcomes relevant to specific applications, tasks, populations, environments, and conditions. Applied studies focus on system definition, system design, development, and evaluation. Investigations of the applied nature are used to assess problems, develop requirements for the human and/or machine,


**Figure 1**  Framework of steps in selection and applications of HF/E methods.

and evaluate performance (Committee on Human Factors, 1983).

Applied or implementation-driven work is typically associated with work in the field. Participants, tasks, environments, and other extraneous variables usually need to closely match the actual real-world situation to truly answer the problems at hand. That said, applied methods are abundant and diverse and very much reflect the vast number of HF/E disciplines (mentioned above). Investigators often modify their techniques due to external demands and constraints of the operational system and environment (losing control over what is available for assessment and allowing confounding interactions to occur) (Wixon and Ramey, 1996). An example of this class of applied investigations from the literature summary is found in the analysis of interorganizational coordination after a railway accident (Smith and Dowell, 2000). Other studies have demonstrated that breakdown in the planning and execution of emergency response operations can have potentially disastrous consequences (Mendonca et al., 2001). These activities are often carried out under conditions of considerable time pressure and high risk emphasizing the need for interorganizational communication (Riley et al., 2006). Stanton and Young (1999) present a comparison of two car stereos to compare several applied methodologies. Some examples of applied methodologies include keystroke-level models (KLMs) (Card et al., 1983), checklists, predictive human error analyses, observations, questionnaires, task analyses, error analyses, interviews, heuristic evaluations, and contextual design.

Based on the framework presented in Figure 1, the development of a hypothesis is an important first step in both basic and applied research. Between the two types of research, the difference in the hypotheses is granularity. Hypotheses formulated for applied research are much more specific in terms of applied context. In either case, a hypothesis should be in the form of a proposition: *If A, then B*. Directional hypotheses are most commonly used in applied research. This is where an investigator makes a prediction hypothesis regarding the outcome of the research (Creswell, 2009). An example of a directional hypothesis would be "Scores for group B will be higher than for group A" following an intervention.

A problem must be testable if HF/E methods are to be applied. Generally, a problem is testable if it can be translated into the hypothesis format, and the likeliness of truth or falsity of that statement is attainable (Weimer, 1995). However, just the fact that a problem is testable does not ensure that results will be widely applicable or useful. Factors that can affect the applicability and acceptability of the results are discussed in subsequent sections.

## 2.2 Choosing the Best Method

The choice of HF/E method is influenced by several factors, as the decision to employ a specific methodology elicits several consequences relevant to the efficacy of that method in meeting the established goals. The ability to generalize the results of investigations is shaped by both the design/selection of methods and statistical analysis (see Chapter 44). The "study preparation" section of

the framework presented in Figure 1 illustrates the various factors influencing the selection of methods. The judicious selection and implementation of HF/E methods entails a clear understanding of what information will be collected or what will provide the information, how it will be collected, how it is analyzed, and how the method is presented as relevant to the predetermined objectives and hypotheses.

Several authors offer opinions on what the most important considerations should be in the selection of methods. Stanton and Young (1999) provide one of a handful of comparative examinations looking into the utility of various different descriptive methodologies for HF/E. They present case studies evaluating 12 different methodologies based on their use in the investigation of automobile radio controls. The authors evaluated the methods on the criteria of reliability, validity, resources required, ease of use, and efficacy. The accuracy required, criteria to be evaluated, acceptability of the method (to both participants and investigators), abilities of those involved in the process, and a cost–benefit analysis of the method are additional deciding factors for implementation. Later, Stanton et al. (2005) contributed to the literature again with a book detailing the results of a HF database with over 200 methods and techniques. At the very least, an investigator needs to be conscious of the attributes that are present in their chosen methods and the possible impact to avoid misrepresenting results and forming ill-conceived conclusions.

Kantowitz (1992) focused on reliability and validity by looking to problem representation, problem uniqueness, participant representativeness, variable representativeness, and setting representativeness (ecological validity). The specific selection of methodology is rarely covered in HF/E texts. Instead, most authors jump directly to method selection (e.g., descriptive, experimental, and evaluative) and look at a variable and metric definition. However, variable selection, definition, and the resulting validity are intertwined decisively with the methods selected and must link back in a relevant way to the investigation's objectives. In this section, methodological constraints are broken down into two categories:

1. *Practical concerns*
   - Intrusiveness
   - Acceptability
   - Resources
   - Utility
2. *Psychometric concerns*
   - Validity (uniqueness)
     - Construct validity
     - Content validity
     - Face validity
   - Reliability (representation)
     - Accuracy and precision
   - Theoretical foundation
   - Objectivity

Humans are by nature complex, unreliable systems. Kantowitz (1992) asserted that considered as a

stand-alone system human complexity supersedes that of a nuclear power plant. This creates an abundance of convolutions when considering the human system embedded within another system (social, manufacturing, technological). Humans can be inconsistent in their external and internal behaviors, which are often sensitive to extraneous factors (overt and covert). Undeniably, this creates a conundrum for the HF/E investigator. The impact of this variability can, to a certain extent, be mitigated through various strategies in method selection and implementation. This usually entails close examination and careful attention by the investigator to the relevant variables, including their definition, collection, and analysis. In addition to human fallibility, the selection of any given method and its execution is critically influenced by the objective of the study (basic/applied), objective clarification (i.e., hypothesis), experience of the investigator(s), resources (money, time, staff, equipment, etc.), and previously validated (relevant) research. Returning to the human side of method selection, the selection of the method is informed by the ethical and legal requirements of working with human beings as participants.

In practice, it is not feasible to comply with all of the psychometric and practical issues that occur in conjunction with HF/E methodologies. More often than not, the investigator must weigh the implications of their method choice on the desired outcome of the study. Investigators also prioritize the requirements placed on their work with respect to potential impact on the study. For example, the ethical treatment of human participants is of high priority, because an investigator's ethics approval organization [e.g., institutional review board (IRB) in the United States] or funding agency may choose to terminate the study if risks are posed by participation. In this section, we illustrate these potential issues further. It is important for the reader to have an awareness of these issues before our discussion of various methods. In this way, novices can examine the HF/E methods more critically with respect to practical constraints most relevant to their research and work.

### 2.2.1 Practical Concerns

Practical concerns for the application of HF/E methods should be fairly obvious to the HF/E investigator. However, they must be taken into account early in the planning process and revisited continually. Brief definitions for the practical concerns follow.

*Intrusiveness*   This is an appraisal of the extent to which the methodology used interferes with the system being measured. A measure that distracts the participant or interferes with their performance in other ways is intrusive. The extent to which an intrusive method causes covariance in recorded observations differs when applied to different scenarios (Rehmann, 1995). Task analysis is one of the least intrusive measures because in the initial stages of system design it can occur without a system being present to study (Wilson and Corlett, 2005).

*Acceptability*   This includes the appropriateness and relevance of the method as perceived by investigators, participants, and the HF/E community. For this, the investigator needs to perform an extensive literature review and also network with peers to understand their opinions of the method. Those who fund the research must also be accepting of the method (Meister, 2004).

*Resources*   This refers to the fact that many methods place prerequisites on investigator's resources. These include the time it takes for investigators to train and practice using the method, the number of people needed to apply the method, and any preliminary work that is needed before application of the method. In addition, the method may require the purchase of hardware and software or other special measurement instruments (Stanton and Young, 1999; Stanton et al., 2005). Investigations typically have limited financial assistance, which must be considered prior to the adoption of any methodology.

*Utility*   There are two types of utility relevant to HF/E methods: conceptual and physical utility (Meister, 2004). Research with conceptual utility yields results that are applicable in future research on human-integrated systems. Research that holds physical utility proves useful in the design and use of human-integrated systems. In general, investigators need to ensure usefulness and applicability of their proposed methods for the responsiveness of others to their results and easier dissemination of their findings in conference proceedings, journals, and texts.

### 2.2.2 Psychometric Concerns

In investigations of human-integrated systems, the methods used should possess certain psychometric attributes, including reliability, validity, and objectivity. Methods are typically used to apply some criteria or metric to a sample to derive a representation of the real world and subsequently link conclusions back to the established goals. As depicted in Figure 2, inferences are applied to the measurements to make generalizable conclusions about the real world. Interpretation is inclusive of statistical analyses, generalizations, and explanation of results (Weimer, 1995). The assignment of these inferences should be made to a unique set of attributes in the real world. How well these conclusions match the real world depends on a give and take between controlling for extraneous factors, without disrupting the important representative factors. For example, Figure 2 exemplifies a set of inferences in the shape of a square, which will not easily be matched up to the initial population sampled.

Several of the issues emergent in the selection and application of methods are attributable to representation and uniqueness (Kantowitz, 1992). Representation tends to inform issues of reliability, or the "consistency or stability of the measures of a variable over time or across representative samples" (Sanders and McCormick, 1993, p. 37). A highly reliable method will capture metrics with relatively low errors repeatedly over time. Attributes of reliability include accuracy, precision, detail, and resolution. Human and system reliability, which is a reference to failures in performance, is a topic apart from methodological issues of reliability.

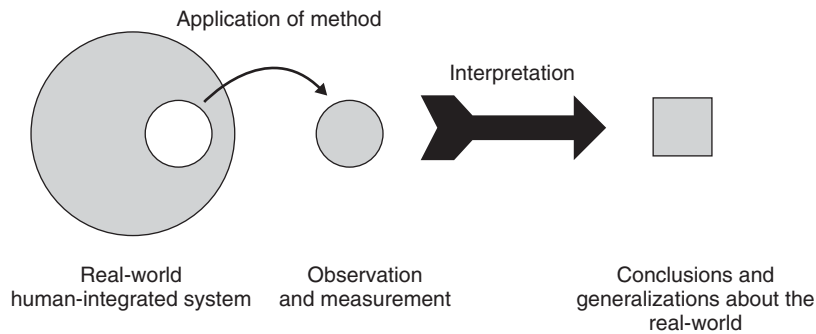
Validity is typically informed by the issues of uniqueness. Validity is the index of truth of a measure,


**Figure 2**  Application of HF/E methods.

or, in other words, if it actually captured what it set out to and not observing the extraneous (Kantowitz, 1992; Sanders and McCormick, 1993; Kanis, 2000; Wilson and Corlett, 2005). Both concepts are alluded to by many, defined by few, and measured by an even more select group of HF/E researchers and practitioners, with many different interpretations for this basic concept (Kanis, 2000). Despite the disparity in definitions and interpretations of the terms, it is generally agreed that these concepts are multifaceted.

Reliability and validity in HF/E are not dichotomous but lucid concepts as they may appear in the social sciences. The evolutionary nature of the HF/E discipline does not support such a "neatly organized" practice (Kanis, 2000). Reliability relates to how well the measure relates to itself, but validity relates to how well a measure correlates with external phenomena (Wilson and Corlett, 2005). A method must be reliable to be valid, but the reverse is not always true (i.e., reliable methods are not necessarily valid) (Gawron, 2000). Stanton and Young (1999) found this to be the case in their evaluation of hierarchical task analyses. The predictive validity of this method was found to be robust, but the reliability was less so. The authors concluded that the validity of the technique could not be accepted because of the underlying shortcomings in terms of

reliability. Types of validity include face, content, and construct. In this section we discuss different psychometric properties of both reliability and validity, how to control for them in the selection of methods, limitations imposed by the practical issues, and the resulting trade-offs. One disclaimer needs to be made before the discussion of validity and reliability that ensues: Although validity and reliability of methods enhance acceptance of the conclusion, they do not guarantee widespread utility of the conclusion (Kantowitz, 1992).

***Key Characteristics of Reliability***    Characteristics of reliability include accuracy and precision, which influence the consistency of the methodology over representative samples and the degree to which the methods and results are free from error. Accuracy is a description of how near a measure is to a standard or true value. Precision details the degree to which several methods provide closely related results, observable through distribution of the results. Test–retest reliability is a way to assess the precision of a given method. This is simply an assessment of correlations between separate applications of the methods. Sanders and McCormick (1993) report that for HF/E test–retest reliability scores of 0.80 and above are usually satisfactory. This score should be taken in context, however, because what determines an acceptable test–retest reliability score is intertwined with the specific contextual factors of the investigation.

The level of precision and/or accuracy sought in HF/E method selection and implementation is heavily contextually dependent. The investigator needs to select the method with reliability that is consistent with the requirements alluded to in the goals and problems. The KLM introduced by Card et al. (1983) was one of the first predictive methods for the field of HCI. This method predicts the time to execute a task given error-free performance using four motor operators, one mental operator, and one system response operator. KLM predicts error-free behavior, so the functions to calculate the time for the operators would probably be consistent between the applications of the method. The accuracy of the KLM method is purportedly high for certain tasks (Stanton and Young, 1999; Stanton et al., 2005). However, the accuracy of the method could deviate drastically from what Stanton and Young observed in their evaluation of car stereo designs,

**Figure 3**  Construct validity. (Adapted from Sanders and McCormick, 1993.)

when KLM is applied to a different scenario, with the overall precision of the method constant. Additional disadvantages of KLM include the fact that it only models error-free expert performance, does not take context into account, and can only deal with serial, not parallel, activity (Stanton et al., 2005).

***Face Validity*** Face validity is defined as the extent to which the results look as though the method captured what is intended, which is the degree of consensus that a measure actually represents a given concept (Sanders and McCormick, 1993; Wilson and Corlett, 2005). It is a gauge of the perceived relevance of the methods to the identified goals of the investigation without any explanation by the investigator. Research based on actual tasks evaluated by real users has high face validity and is more likely to generalize to similar systems (Sage and Rouse, 2009). Face validity is important not only with respect to acceptance of the results reported by the scientific and practicing communities but also from the perspective of the participants in the study. If a measure seems irrelevant or inappropriate to the participants, it may affect their motivation in a negative way. People may not take their participation seriously if the methods seem disconnected from the purported goals. This can be mitigated first by briefing the participants on the purpose of the methods used or by collecting measures of the performance in the background, so the participant is not exposed to the specifics of the study.

***Content Validity*** The content validity of a method is essentially the scope of the assessment relevant to the domain of the established goals of the investigation. The analysis of Web logs provides an example of content validity. For example, consider an investigation with the goal to report employee use of a corporate intranet portal, which provides information on insurance benefits. Simply reporting the number of hits the portal receives does not possess high content validity. This is because this method provides no indication if the employees are actually pulling content from the intranet site. The Web logging methodology could instead look at various facets of employee activity on the intranet site to illustrate a more complete representation of use as well as actually to talk to some employees to get verbalizations and perceptions about the intranet site.

***Construct Validity*** Construct validity is best defined as the degree to which a method can be attributed to the underlying paradigm of interest. Figure 3 exemplifies the concept of construct validity and other relevant features. The gray-shaded circle on the left represents the model or theory under scrutiny, and the white circle on the right represents the space that is assessed by the selected measures. The star marks the intersection of these two spaces, which represents the construct validity of the measure. It represents the aspects of the target construct that are actually captured by the methods used. This measure leaves out elements of the construct (because it cannot account for the entirety of the concept), called the *deficiency* of a measurement. Equally, there are areas unrelated to the construct that the measure captures. This undesired or unintended area measured is termed the *contaminant*.

Physiological methods, such as heart rate, are especially prone to construct validity issues. For example, heart rate may be affected by caffeine, medications, increased mental workload, age, or physical stressors such as exercise. Consider a study that aims to measure the mental workload experienced by drivers while driving under different weather conditions by recording each driver's heart rate. The investigation will not necessarily detect the changes in mental workload as affected by the conditions. Instead, the investigator will also have captured a measure of the effects of coffee consumption, age, recent physical activity, medications, and mental workload, so that the effects of mental workload are virtually inseparable from the other *extraneous* contamination variants. The investigator can mitigate these contaminants through exercising control in the applications of their methods. In this case, specifying inclusion criteria for subjects' selection and participation in the study would be advantageous. Methods of control are discussed further in this section.

***Controlling for Reliability and Validity*** If not controlled during the selection and application of HF/E methods, problems with validity and reliability can prove detrimental to the generalizability and predictive value of conclusion. The following issues in the results are probably ascribable to matters of validity and reliability:

- A lack of correlation between reality and the criteria used
- A correlation of the criteria with unknown bias(es), so even if changes are detected, the absolute value of the factor(s) cannot be determined
- Multivariate correlations, because the construct of interest is actually affected by several factors
- Interference from extraneous factors may inappropriately suggest causal relationships when it is in fact just a correlation

Psychometric issues may be mitigated through the control of extraneous factors that can affect the construct and collecting data/observations in representative environments. That being said, fundamental conflicts often arise in trying to ascertain control without sacrificing critically representative aspects of the system, task, or population. Furthermore, time, financial, and practical constraints can make it impossible to ascertain desired levels of validity of H/FE methods. There are methods and approaches for the analysis of HF/E outcomes, discussed in Chapter 44, which can potentially account for some of the validity and reliability issues. Yet much like HF/E in the design process, the earlier changes are made in the selection and applications of a methodology to correct for validity and reliability issues, the more easily the changes are implemented and the greater positive impact they will have on the methodological outcome.

***Control*** Control in the selection and application of methods strives to challenge the sources of variance to which HF/E is highly prone. Sources of variance can include noise from the measurements, unexpected variance of the construct, and unexpected participant

behavior (Meister, 2004). It is the regulation of standard conditions to reduce the sources of variance. Variance is detrimental to HF/E methods because it restricts the certainty of inferences made. Control removes known confounding variables by making sure that the extraneous factors do not vary freely during the investigation (Wickens et al., 2003a). Control is not absolute. An investigator can exercise various levels of control to ensure minimal effects of confounding variables. Methods that lack control can lead to data that are virtually uninterpretable (Meister, 2004).

Ways to reduce variance include choosing appropriate participants, tasks, contexts, and measures; eliminating confounding variables to reduce covariance effects; implementing methods consistently; and increasing the structure with which the methodology is utilized. For example, control was exercised in research conducted to predict performance on a computer-based task for people with age-related macular degeneration (AMD). Great control was exercised in the selection of participants who had AMD and age-matched controls (Jacko et al., 2005). The selection of participants controlled for the exclusion of any person who had any ocular dysfunction other than AMD. Great care was also taken in ensuring that the variation of age between the experimental and control groups was consistent. If age had not been controlled for in recruitment, the differences between the two groups could be a result of interactions between age and ocular disease. Methods of control will be introduced in relation to experimental studies, descriptive studies, and evaluations.

***Participant Representativeness***    As stated earlier, human behavior is sensitive to a variety of factors, and interactions often surface between specific characteristics of the participant and the environment. The extent to which the results of investigations are generalizable depends on those connections between the characteristics of those observed and the actual population. Prior to beginning HF/E research, it is critical to know whether the users in the actual population will be beginners or experts, the frequency of system use, and the degree of discretion they will have in using the system (Wilson and Corlett, 2005). Although it is not always necessary only to sample participants from the actual population (Kantowitz, 1992), consistency checks should be made. In a study of age-related differences in training on home medical devices, presented in the literature summary table (Mykityshyn et al., 2002), the investigators needed to recruit persons from the aging population so that their age-related capabilities, mental and physical, would be consistent with that in the general population. Relevant aspects or attributes should be identified and present in the same proportion as the real population in order to specify and characterize the target user group (Sanders and McCormick, 1993; Wilson and Corlett, 2005).

***Variable Representativeness***    The selection of methods mandates the selection of necessary measures and variables. For HF/E, measurement is the assignment of value to attributes of human-integrated systems. Assigning value can be accomplished through various methods, such as nominal, ordinal, interval, and ratio scales. In Chapter 44 we discuss HF/E outcome measurements and their analysis in detail. A given measure affords a specific set of statistical summary techniques and inferences that have implications on validity and reliability.

Measurement selection and its assignment of value to events in human-integrated systems should be guided by theory and previous studies. In HF/E it is most germane to include more than one measure. Three classes of variables have been identified as necessary to capture human-integrated systems: (1) *system descriptive criteria*, which evaluate the engineering aspects of a system; (2) *task performance criteria*, which indicate the global measure of the interaction such as performance time, output quantities, and output qualities; and (3) *human criteria*, which capture the human's behavior and reactions throughout task performance through performance measures (e.g., intensity measures, latency measures, duration measures), physiological measures, and subjective responses (Sanders and McCormick, 1993).

Table 1 presents examples of task performance, human criteria, and system criteria. System descriptive criteria tend to possess the highest reliability and validity, followed by task performance criteria. Human criteria are the noisiest, with the most validity and reliability issues. Note that human criteria demonstrate the broadest classification of measurements. This is due to the inherent variability (and noise) in human data. These metrics—performance, physiological, and subjective responses—portray a more complete characterization of human experience when observed in combination. Performance optimization should not be pursued, say, at the cost of high levels of workload observed through heart rate and subjective measures using the NASA-TLX subjective assessment of mental workload. A useful guide in the selection of specific human measures is Gawron's *Human Performance, Workload, and Situational Awareness Measures Handbook* (2008), where over 100 performance, workload, and situational awareness measures are defined operationally for application in different methodologies.

"The utility of human factors research is linked intimately to the selection of measures" (Kantowitz,

**Table 1   Classification of Criteria Addressed in HF/E Methods**

| System Descriptive Criteria | Task Performance Criteria | Human Criteria |
|---|---|---|
| Reliability | Quantity of output | Performance |
| Quality measures | Output rate | Frequency |
| Operation cost | Event frequency | Latency |
| Capacity | Quality of output | Duration |
| Weight | Errors | Reliability |
| Bandwidth | Accidents | Physiological |
| | Variation | Cardiovascular |
| | Completion time | Nervous system |
| | Entire task | Sensory |
| | Subtask time | Subjective opinion |
| | | Situation awareness |
| | | Mental workload |
| | | Comfort |
| | | Ease of use |
| | | Design preference |

1992, p. 387). Validity and reliability of results are best substantiated when the three classes of criterion are addressed in the methodology. In fact, the selection of measurements or metrics is second in importance to method selection. Measurement and methodology are not independent concepts, and the selection of both are closely related and often iterative (Drury, 2005). The interpretation of results is greatly influenced by the combination of measures chosen in a particular test plan. Robust measurement techniques can make the interpretation process a much more streamlined process.

**Objectivity**   A second issue of variable representativeness is the level of objectivity in its definition and measurement. Objectivity is a function of the specific techniques employed in collecting and recording data and observations. Data and observations recorded automatically are the most objective approach. Objective variables can be captured without probing the participant directly. In contrast, in the collection of highly subjective variables, the participant is the *medium of expression* for the variable (Meister, 2004). The investigator may also interject subjectivity. Investigators can impose subjectivity and bias in how they conduct the investigation, which participants they choose to collect data from, and what they attend to, observe, and report.

For instance, three levels of objectivity can be demonstrated in capturing task time for a person to complete the assembly of widgets on a manufacturing line. A highly objective method may involve the use of the computer to register and store task time automatically based on certain events in the process (e.g., the product passes by a sensor on the manufacturing line). A less objective method would be to have the investigator capture the assembly with a stopwatch, where the investigator determines the perceived start and completion of the assembly. Finally, the least objective, most subjective method would be to ask the participant, without using a clock, to estimate the assembly time. Clearly, the level of objectivity in the methods influences the accuracy and precision of the outcomes. Subjective measures are not unwarranted and are in fact quite important. In the assembly example, if the worker perceives the assembly time for a certain component as very long, even if a more objective assessment method does not detect it as long, the workers' perceptions still affect the quality of the work they produce and the amount of workload they perceive, ultimately affecting the quality of the system and its resulting widgets. In eliciting covert mental processes from people for measurement and assessment, the investigator does, however, need to ensure that the results obtained will adequately answer the questions defined in the formulation of a project's goals.

Finally, how researchers choose to interpret the results of methods may also induce subjectivity into the outcome. By decreasing the level of involvement of either participant or investigator in the expression of performance, an increase in the overall objectivity of the method and outcomes can be realized. Tables 2 and 3 provide a taxonomy of methods and measures that summarize Meister's (2004) work. Subjective and objective methods are outlined with a specific example of each class of methods. In conclusion, both subjective and objective measurements have their place in HF/E investigations (Wickens et al., 2003a)

**Setting Representativeness**   Setting representativeness is the coherence between the environment where methods are performed and the real-world environment of the target situation where the results are to be applied. This is not necessarily a judgment of realism but, rather, the level of comparability between how the participants' physical and psychological processes are affected by the context of the study (Kantowitz, 1992). This informs the investigator's consideration for collecting data in the laboratory versus in the field. Another term for setting representativeness is the *ecological validity* of the study. Ecological validity influences the generalizability of the results but can also influence the behavior of those who participate in the investigation. Research has shown that participants can exhibit different behavior when they know they are being observed, a phenomenon known as the *Hawthorne effect* [for a complete overview of the Hawthorne effect, see Gillespie (1991)]. The more representative the task and environment and the less intrusive the investigations to the participants' behaviors, the better this effect can be mitigated. The investigator may retain a more complete picture of human behavior with a complex system in the actual, operational environment (Meister, 2004), which supports fewer objective measures.

HF/E investigators must ultimately decide where the best location is to collect data: in the field or in the laboratory. The collection of data in a field study versus in a highly controlled laboratory setting is a trade-off that HF/E practitioners and researchers continually debate in the execution of methods. Field research typically provides an investigation of the means to look at the system in order to shape their assumptions about the construct, in a way that informs the selection and implementation of other methods (Wixon and Ramey, 1996). Field studies naturally include context from the environment, supervision, motivation, and circumstances, although the investigator must keep in mind that their presence will also add an additional context, which could potentially invalidate the study (Wilson and Corlett, 2005). Wixon and Ramey (1996) claim further that most field studies are best suited for situations about which little is known, saving time in the laboratory studying the wrong problem. Conversely, fieldwork serves the purpose as an executable setting to validate theories and principles developed in more controlled, laboratory environment environments. Case Study 1 provides a summary of HF/E work from the literature in which field studies have been used.

## CASE STUDY 1: Effects of Task Complexity and Experience on Learning and Forgetting

The goal of this study by Nembhard (2000) was to investigate how task complexity and experience affect individual learning and forgetting in manual sewing tasks using worker-paced machinery that placed high demands on manual dexterity and hand–eye coordination.

**Table 2 Taxonomy of HF/E Objective Method**

Objective Methods

| Outcome Measure | Method | Description | Example(s) |
|---|---|---|---|
| Performance measures | Unmanaged performance | Measures of human-integrated system performance through unnoticed observations<br><br>*Assumptions*: (1) System of measurement is completely functional; (2) mission, procedures, and goals of the system are fully documented and available; (3) expected system performance is available in quantitative criteria to link human performance with system criteria | Evaluation of an advance brake warning system in government fleet vehicles (Shinar, 2000) |
| | Empirical assessment | Comparison of conditions of different system and human characteristics in terms of treatment conditions<br><br>*Assumption*: Experimental control of variables and representativeness will enable conclusions about the correlation between manipulated conditions for valid, generalizable results | Investigation of multimodal feedback conditions on performance in a computer-based task (Vitense et al., 2003) |
| | Predictive models of human performance | Applying theories of cognition and physiological processes and statistics to predict human performance (involves no participation by human participants)<br><br>*Assumptions*: (1) The model explains the cognitive processes to a reasonable degree; (2) the model incorporates contextual factors relevant to the operational environment | ACT-R/PM, a cognitive architecture to predict human performance using drop-down menus (Byrne, 2001) |
| | Analysis of archival data | Aggregated of data sets aimed at the representation of a particular facet of human-integrated systems; HF/E archival data from journal articles, subdivided into subtopics such as computers, health systems, safety, and aging<br><br>*Assumptions*: (1) Differences between individual study situations are small in nature; (2) error rate predicts performance with validity; (3) the models will be informed continually by new data studies | Anthropometric differences among occupational groups (Hsiao et al., 2002) |

**Methods** A notable amount of related research had been conducted in this domain through laboratory studies. Although the previous research was strong in finding causal inferences, it could not validate the findings for real-world situations. This gap in the knowledge base motivated the author to study the effects of task complexity and experience on performance in the factory. In the design of the study, the author ascribed task complexity and worker experience (e.g., training for their task) as two prominent factors determining the trends of learning and forgetting during task performance. Task complexity was measured by three variables: complexity of the method, machine, and material. Over the course of one year, the study captured 2853 episodes of learning/forgetting from all the workers. User performance was sampled 10 times per week and averaged to derive the learning/forgetting. The complexity variables and the worker experience variable were recorded in combination with each learning and forgetting episode.

**Analyses** Based on the data collected, the parameters, and the variables derived (e.g., prior expertise, steady-state productivity, rate of learning, and degree of forgetting), a mathematical model of learning and forgetting was developed. Then, using statistical methods such as Kolmogorov–Smirnov, analysis of variance (ANOVA), pairwise comparisons, and regression, the effects of learning and the effects of task complexity and experience on learning/forgetting were extrapolated.

Methodological Implications

1. *Expensive to Conduct*. As this study shows, a field study requires a larger number of samples (i.e., 2853 episodes) or observations to mitigate extraneous confounds. Thus, it can take more time and be costly.

2. *Strongly Valid*. Because the research hypotheses and questions are tested under real situations, the validity of the argument is usually strong. In fact, this served as the major motivation for this

**Table 3 Taxonomy of HF/E Subjective Methods**

Subjective Methods

| Outcome Measure | Method | Description | Example(s) |
|---|---|---|---|
| Observational measures | Observations | Information about what happened and is happening in the human-integrated system; status of the person(s) and system components and their characteristics of the outcomes<br>*Assumptions*: (1) What the observation recorded is the essence of what actually happened; (2) observers record the situation veridically; (3) interobserver differences are minimal with respect to reliability; (4) no questions are probed during observation | Task analyses of automated systems with which humans interact (Sheridan, 2002) |
| | Inspection | Similar to observation, but objects have a role in what is considered; comparisons between the object at hand and a predetermined guideline for the required characteristics of both the object and the target user<br>*Assumption*: The object of inspection has some deficiency, and the standards provided are accurate in representing what is truly required. | Ergonomic redesign of a poultry plant facility; data collected on tracking employee musculoskeletal disorders are compared against Occupational Safety and Health Administration (OSHA) guidelines (Ramcharan, 2001) |
| Self-reported measures | Interviews and questionnaires | Direct questioning for the participant(s) to express converts mental processes, including reasoning of perceptions of their interaction<br>*Assumptions*: (1) People can validly describe their response to different stimuli; (2) the words and phrasing used in the questions accurately capture what is intended; (3) credibility of the respondent in their ability to answer the questions; (4) formality of structure required in responses | Case study of disaster management (Smith and Dowell, 2000) |
| | Concurrent verbal protocol | Verbal protocols to elicit convert participant information processing while executing a task; participant explains and justifies actions while performing the task<br>*Assumption*: People can better explain processes when there are aspects of the ecological validity | Study of mental fatigue on a complex computer task (van der Linden et al., 2003) |
| Judgmental measures | Psychophysical methods | Questions that determine thresholds for discrimination perceptual qualities and quantities; size weight, distance, loudness, and so on<br><br>*Assumptions*: (1) The participant has a conceptual frame of reference for evaluations; (2) the judgment is a result of analysis of internal stimuli | Investigation of time estimation during sleep deprivation (Miro et al., 2003) |

study. This enables improved implementation of the results of this study back into the field more easily than those laboratory-based conjectures of potential causal relationships.

3. Complex *Analyses*. The data from a field study are naturally large and complex because they were captured under real situations. That is, they are subject to a lot of extraneous noise in the system observed. Therefore, strategic analytical methods are quite useful. For example, this study simplified the presentation of data by introducing a mathematical model of learning/forgetting.

Typically, the data from field methods are more subjective (coming mostly from surveys and observations), which affects the analysis of the outcomes. Three widely recognized field methods are (1) ethnography (Ford and Wood, 1996; Woods, 1996), (2) participatory design (Wixon and Ramey, 1996), and (3) contextual design (Holtzblatt and Beyer, 1996). These types of methods typically illustrate the big picture and do not provide the investigator with a simple yes-or-no answer (Wixon and Ramey, 1996). Instead, the data gathered tend to be information rich, somewhat subjective, and highly qualitative.

### 2.2.3 Trade-Offs

**Control versus Representation** The need for experimental control and representative environments, tasks, and participants creates a fundamental conflict. It is impossible to have both full control and completely representative environments (Kantowitz, 1992). This is because in representative environments participants control their environment, as they want to, barring any artificial constraints. Both highly controlled and representative methods serve important roles in HF/E. The answer of which to sacrifice, when faced with this predicament, is entirely dependent on the objectives of the study and the availability of resources. Ideally, an investigation should be able to incorporate aspects of both. The selection of H/FE methodologies is largely directed by the investigator's needs and abilities in terms of objectivity and control and how the results are to be applied (Meister, 2004). In fact, investigators often include specific aspects of the operational system while controlling aspects of the testing environment. The applied nature of HF/E (even in basic research) leads investigators to simulate as much as they can in a study while maintaining control on extraneous factors (Meister, 2004).

Ideally, HF/E researchers and practitioners strive to generalize the results of investigations to a range of tasks, people, and contexts with confidence. Intuitively, it becomes necessary to apply methods to a range of tasks, people, and contexts to achieve this. Conflict often arises in terms of the available resources for the investigations (time and money). That said, the level of representation achieved through a method should be selected consciously, addressing the set goals, what is known about the method, and the practical limitations. Of course, the larger the sample size, the more confidence in results, but the larger sample usually entails higher financial and time investments. Furthermore, human limitations such as fatigue, attention span, and endurance may impose constraints on the amount of information to be gathered. It is also critical to consider the implications of method choice in terms of the analysis used. For example, investigations which collect and manipulate a large numbers of variables can take months to mine and analyze the data. Qualitative data or videos can take a significant amount of time to code for analysis. For this reason, the reader is encouraged to review Chapter 44 prior to using HF/E methods.

There is a point of diminishing returns when it comes to increasing the size of the sample or number of observations. In other words, the amount of certainty or knowledge gained from the additional observation may or may not be worth the time and effort spent in its collection and analysis. Sanders and McCormick (1993) introduced three factors that can influence sample size:

1. *Degree of Accuracy Required*. The greater the required accuracy, the larger the sample size required.
2. *Variance in the Sample Population*. The greater the variance, the larger the sample size required.
3. *Statistic To Be Estimated*. A greater number of samples are required to estimate the median than

the mean with the same degree of accuracy and certainty.

### 2.2.4 Incorporating Theory and Previous Work

The number of factors to consider in the selection of HF/E methodologies may seem an impossible task. However, method selection is greatly informed by theory as well as previous applications of the methodologies, as documented in the literature. The investigator needs to examine the existing knowledge base critically as well as talk with other HF/E investigators to gain practical insight. This serves as one of the best ways to justify the selection of methods for the problem at hand. In the selection of methods, only those that offer evidence of practicality and validity should be selected.

When conducting a critical examination of the literature, readers should be cognizant of the following factors, adapted from Weimer (1995):

- What are the authors' goals, both explicit and inferred from the text?
- What prior research do they reference and how do they interpret it?
- What are their hypotheses?
- How are the methods linked to the hypothesis?
- What are the variables (independent, dependent, and control) and, operationally, how are they defined?
- Are extraneous variables controlled and how?
- What are the relevant characteristics of the participant population?
- How did the authors recruit the participant population and how many people did they use?
- Was the research done in a laboratory or in the field?
- Did they use any special measurement equipment, technologies, surveys, or questionnaires?
- What statistical tests were run?
- What was the resulting statistical power?
- How do the authors interpret the results?
- How well do the authors' results fit with the existing knowledge base?
- Are there any conflicts in the interpretation of data between authors of different studies?

Investigators who are able to find literature relevant to their objective problem(s) can apply methods based on what others have applied successfully. However, because the subject matter and context of HF/E are so varied, care should be taken in this extrapolation. In the application of historically successful methods, the investigator must justify any deviation he or she made from the accepted status quo of the method. Basic research typically has the most to gain from such literature reviews.

Applied research is somewhat more problematic, as the methods are more diversified according to the conditions specified in the target application. Additionally, there are issues in the documentation of

applied methods (Committee on Human Factors, 1983). The historical memory of human factors methods resides largely in the heads and thick report files of the practitioners. Probing colleagues and other HF/E practitioners for their practical experience in using applied methods is therefore useful.

The survey of relevant literature is such a critical step in investigation that it can, by itself, serve as a complete method. A thorough literature search for theory and practice combined with discussions of methodological issues prevent investigators from reinventing the methodological approach. It may also save time through the avoidance of the common pitfalls in the execution of certain methods and analyses. In fact, literature reviews can substitute the need for the application of methods if the experimental questions have already been addressed. A *meta-analysis* is a specific method for the combination of statistical results from several studies (Wickens et al., 2003a).

Basic HF/E investigations, theories, and principles from psychology, physiology, and engineering all merit review. Theory is especially important because it can direct attention in complex systems as to where to focus resources. Knowledge of existing theories provides blueprints for the selection and application of methods as well as the explanation of results (Kantowitz, 1992). Theory is essential in the planning process because of the need to link the methodological processes and hypotheses strongly to the problem and goals of the investigation. However, when applying theories and principles, the investigator must ensure that the end results are in line with the theories employed.

The guidelines for critical examinations of the literature serve another role for the selection and application of HF/E methods. Investigators should realize that others will, one day, examine their work critically in a similar fashion. That said, consideration of these systematic evaluations in the design of methods can save undue hardship later during analysis and especially in the course of result interpretation. Similar to the design of systems, it is easier to make changes in the beginning steps of method formulation than to make changes to, or draw logical and meaningful conclusions from, ill-conceived outcomes of the method.

The decision of what methods are generally accepted by the community as standard and valid is difficult. The field of human factors, relative to more basic research, is much less grounded in terms of methodology. With the continued introduction of new technologies and systems, investigators are continually deriving new methods, metrics, and inferences. Despite this ongoing development, it is the investigator's responsibility to consider the issues of validity, reliability, and practical issues of a method before implementing it and reporting the ensuing results. Furthermore, in the report of results HF/E investigators need to clearly mark what is informed by theory and what, in actual fact, is their own speculation. Speculations are easily mistaken for fact when not labeled explicitly as such (Meister, 2004). This is true even when examples of a method exist in the literature, as the new method of application must be validated. What should be considered is *how* the

authors in the scientific literature justified a method (and those who do not justify should be looked at with some skepticism).

## 2.3 Working with Humans as Research Participants

Many HF/E methodologies require humans to serve as participants, providing data needed in the analysis of the system. As researchers (and humans beings ourselves), we are bound to the ethical handling of participants and their data. The foundation of ethical concerns is to ensure that the investigators do not sacrifice participants' general health, welfare, or well-being in lieu of achieving results for their research goals. Professional and federal agencies have assembled specific guidelines aimed at the appropriate treatment of people and their data in research and analysis funded by U.S. federal monies. The federal code of regulations for the protection of human subject (U.S. Department of Health and Human Services, 2009) (for investigators in the United States) and the American Psychological Association ethical guidelines for research with human participants (American Psychological Association, 2010) should be familiar to anyone conducting research with people as participants. Basically, these principles entail (1) guarding participants from mental or physical harm, (2) guarding participants' privacy with respect to their actions and behavior during the study, (3) ensuring that participation in the research is voluntary, and (4) allowing the participant the right to be informed about the nature of the experimental procedure and any potential risks (Wickens et al., 2003a).

Although the associated risk of HF/E investigations may seem minor, the rights of participants should not be taken lightly. Several historical events have informed the development of codes of conduct under which participants experienced undue mental and/or physical harm. Perhaps the most widely known is the Nuremberg Code, written by American judges in response to scientific experiments (mental and physical) in which prisoners were exposed to extreme medical and psychological tests in Nazi concentration camps. The Nuremberg Code was the first of its kind and mandates that the duties of those conducting research have the responsibility to protect the welfare of the participant ["Nuremberg Code (1947)," 1996].

Even after the Nuremberg Code, several instances of unethical treatment of human participants were documented. In 1964 the Declaration of Helsinki was developed to provide guidance to those conducting medical trials (World Medical Association, 2002). Finally, in 1979 the Belmont Report (Office for Human Research Protections, 1979) was released partly in response to inappropriately conducted U.S. human radiation experiments (U.S. Department of Energy, 2004). The three principles emergent from the Belmont Report were (1) *respect* in recognition of the personal dignity and autonomy of individuals and special protection for those with diminished autonomy, (2) *beneficence* by maximizing the anticipated benefits of participation and minimizing the risks of harm, and (3) *justice* in the fair

distribution of research benefits and burdens to participants (Office for Human Research Protections, 1979).

To aid researchers in ethical conduct, many institutions have an institutional review board (IRB) to provide guidance and approval for the use of human participants in research. Each protocol must be approved by the IRB before experimentation can begin. The IRB may review, approve, disapprove, or require changes in the research activities proposed. Approval is based on the disclosure of experimental details by the investigator(s). For example, many IRBs request the following information:

- Completion of educational training for research involving human participants by all persons (investigators and support staff) involved in the study
- A description of the research in lay language, including the scientific significance and goals:
  - Description of participant recruitment procedures (even copies of advertisements)
  - Inclusion/exclusion criteria for participant entry and justification for the specific exclusion of minorities, women, or minors
  - Highlights of the potential benefits and risks
  - Copies of all surveys and questionnaires
  - Vulnerable groups such as minors
- Funding of the research
- Location of the research
- How the data will be archived and secured to ensure participant privacy

In addition, researchers are instructed to create an informed consent form for the participants to sign. This document, approved by the IRB, explains the nature and risks of the study, noting voluntary participation and stating that withdrawal from the study is possible at any time without penalty.

Although the documentation and certification to ensure the welfare of participants may impose a lot of paperwork, these factors do have implications as to the quality of results in HF/E. The more comfortable participants are, the more likely they are to cooperate with the investigator during human–system investigations (and return for subsequent sessions). This contributes to the acceptability of a method by participants, one of the practical criteria to be used in method selection described in Section 2.2.

### 2.4   Next Steps in Method Selection

Operational methods are most commonly classified into three categories: (1) experimental studies, (2) descriptive studies, and (3) evaluative studies. The selection of methodology from one of these categories will lead the investigator through a series of directed choices, as depicted in Figure 1. These decisions include:

- What are the relevant variables?
  - How are they defined?
  - How are they captured?

- What will the actual measurements look like?
  - Is it qualitative?
  - Is it quantitative?
  - Is it a combination of both?
- What levels of experimental control and representativeness will be exercised?
  - Who are the participants?
  - Where will the study be conducted?
  - What equipment and measurement tools are needed?

The selection of method type, variables, measurements, and experimental control factors are much intertwined. There is no specific order to be followed in answering these questions except what is directed by the priorities established in the problem definition phase. The choices available in response to each question are limited, according to the method that is applied. Furthermore, the psychometric and practical issues introduced in this section must be verified routinely during the selection of specific plans for improved robustness of predictability and generalizability of the investigation outcomes.

In the remainder of this chapter we introduce the three different operational approaches. Specific examples of methodologies in each category are provided, along with answers to the questions outlined above and in Figure 1. The execution of each method will also serve as a point of discussion. Although the number of issues to consider in HF/E methods is sizable, the implications of improper use of methods can be far reaching. The careless application of HF/E methods may result in lost time, lost money, health detriments, discomfort, dissatisfaction, injury, stress, and loss of competitiveness (Wilson and Corlett, 2005).

## 3   TYPES OF METHODS AND APPROACHES

The taxonomy of HF/E methodologies is not straightforward, as there are areas that overlap within these defining characterizations (Meister, 2004). However, a classification enables guidance in methodology selection. There are several different classifications of methods in the literature, each author presenting the field in different scope, point of view, and even terminology. One of the more detailed and comprehensive taxonomies is that of Wilson and Corlett (2005). The authors classify methods as (1) general methods, (2) collection of information about people, (3) analysis and design, (4) evaluation of human–machine system performance, (5) evaluation of demands on people, and (6) management and implementation of ergonomics into group and subgroup. The authors then detail 35 groups of methods each with subgroup classifiers. Finally, the authors present techniques that are used in each method and common measures and outcomes.

Other authors, this handbook included, present a more simplified classification of methodological processes. Although the taxonomy presented by Wilson and Corlett (2005) has utility, that level of detail is beyond

the scope of this chapter. Instead, methods are broken down in a manner similar to those of Meister (1971), Sanders and McCormick (1993), and Wickens et al. (2003a).

Methodologies will be classified as *descriptive, experimental*, and *evaluation based*. Thus far, classifications of basic and applied research goals and attributes that methods can possess in terms of validity, reliability, and objectiveness have been covered. Each of the three classes of research best serves a different goal while directing the selection of research setting, variables, and participants (to meet the demands of validity, reliability, and objectiveness). Although some overlap exists between descriptive, experimental, and evaluation-based methods, HF/E research can usefully be classified into one of the three (Sanders and McCormick, 1993).

## 3.1 Descriptive Methods

Descriptive methods assign certain attributes to features, events, and conditions in an attempt to identify the variables present and their values in order to characterize a specific population and sometimes determine the relationships that exist (Sanders and McCormick, 1993; Gould, 2002). Descriptive methods do not involve the manipulation of an independent variable but instead focus on nonexperimental strategies (Smith and Davis, 2008). The investigator is typically interested in describing a population in terms of attributes, identifying any possible parallels between attributes (or variables). The variables of interest encompass who, what, when, where, and how. The objective of descriptive research is to obtain a "snapshot" of the status of an attribute or phenomenon. The results of descriptive methods do not provide causal explanation of attributes. Correlation is the only relationship between variables that can be determined unless the specific attributes of relationships are captured.

There are three primary rationales for descriptive research: no alternative exists to natural observation, unethical behavior would be involved if certain factors were manipulated, and finally it is advantageous in the early stages of research to conduct descriptive research prior to experimental manipulation (Gould, 2002). The third reason demonstrates the utility of descriptive research, in that it provides a basis for conducting additional, more specific investigations. Descriptive methods are identified by the characterization of system states, populations, or interactions in its most natural form, without manipulation of conditions (as in the case of empirical methods). The results of descriptive research methods often serve as motivation for experimental or evaluative research. Furthermore, assumptions of populations, environments, and systems underlie just about any research. These assumptions may be implicit or explicit, well founded, and in some cases unfounded. Descriptive methodologies clear up assumptions by providing investigators with an improved characterization of the target population, environment, or system.

Descriptive studies may be cross-sectional or longitudinal. *Cross-sectional descriptive studies* take a one-time snapshot of the attributes of interest. The collection of anthropometric data from schoolchildren and dimensions of their school furniture was a cross-sectional assessment of these two attributes (Agha, 2010). The majority of available anthropometric data in the scientific knowledge base is, in fact, cross-sectional, representative of a single population (usually military) at one point in time (the 1950s).

*Longitudinal studies* follow a sample population over time and track changes in the attributes of that population. A longitudinal study asks the same question or involves observations at two or more times. There are four different types of longitudinal studies, dictated by the type of sampling used in the repeated methodology (Menard, 2002):

1. *Trend Studies*. The same inquiries are made to different samples of the target population over time.
2. *Cohort Studies*. Track changes in individuals with membership in an identified group that experiences similar life events (e.g., organizational, geographical groups) over time.
3. *Panel*. The same inquiries are made to the same people over time.
4. *Follow-Up*. Inquiries are made to the participants after a significant amount of time has passed.

### 3.1.1 Variables

Descriptive studies ascribe values to characteristics, behaviors, or events of interest in a human-integrated system. The variables captured can be qualitative (such as a person's perceived comfort) and/or quantitative (such as the number of female employees). These variables sort out into two classes: (1) criterion variables and (2) stratification variables. Criterion variables summarize characteristic behaviors and events of interest for a given group (such as the number of lost-time accidents for a given shift). Stratification variables are predictive variables that are aimed at the segmentation of the population into subgroups (e.g., age, gender, and experience).

### 3.1.2 Key Concern: Sampling

As noted by the classification of longitudinal descriptive studies, the approach to selecting participants is a critical factor in descriptive studies. The plan used in sampling or acquiring data points directs the overall validity of the method. To establish a highly representative sample, the investigator can try to ensure equal probability for the inclusion of each member of a population in a study through random sampling of the target population. However, this is not always feasible to do, as monetary and time constraints sometimes compel investigators to "take what they can get" in terms of participants. Still, if sampling bias has occurred, it can skew data analysis and suggest inferences that lack validity and reliability.

The solution is to review prior research, theories, and their experience to estimate the potential impact of bias factors on the variables of interest. Keep in mind that both analyst and participant bias can adversely affect reliability and validity of a study (Stanton et al., 2005).

A classic example of sampling bias occurs in telephone-administered surveys. This method neglects the proportion of the population whose socioeconomic status does not afford a home telephone. This can translate into bias in the variables gathered. Investigators need to weigh the potential impact on this "participant misrepresentation" in the potential confounding of their data.

Common types of bias issues include the following (Arleck and Settle, 1995):

- *Visibility Bias*. Bias results when some units of a population are more visible than others (e.g., the telephone example provided above).

- *Order Bias.* This occurs when the log of potential participants is in a specific order, such as birth dates or alphabetical order.

- *Accessibility Bias.* When measures are collected in the field, certain persons in the population are more accessible than others (e.g., teachers vs. the administrative staff).

- *Cluster Bias*. When a method targets clusters of participants from the sample frame, some clusters may be interrelated such that they share similar opinions, experiences, and values (e.g., workers from the third shift of a manufacturing operation).

- *Affinity Bias.* Usually a problem in fieldwork, the investigator may be more likely to select people based on extraneous physical and personality traits (e.g., approaching only those who seem to be friendly and cooperative).

- *Self-Selection Bias*. Persons in the population can, by choice, elect to participate in the descriptive methodology (e.g., people who respond to customer feedback surveys are only those who have a complaint).

- *Nonresponse Bias*. Typically associated with mail or e-mail surveys, those who elect not to respond could do so at random or due to some feature of the survey (e.g., the amount of personal information requested was too intrusive for some participants).

### 3.1.3   Techniques Employed

Observational techniques, surveys, and questionnaires are techniques most commonly associated with descriptive research methods. Descriptive methods may collect data in the field or laboratory or through survey methods. Participants must be recruited from the real world for representation sake, but the actual methods may be carried out in the laboratory (Sanders and McCormick, 1993). Typically, methods are conducted in a laboratory when the measurement equipment is too difficult to transport to a participant. This is often the case for anthropometric studies.

*Surveys, questionnaires*, and *interviews* embody the second class of methods used most often in descriptive studies. They are information-gathering tools to characterize user and system features. The data collected with the surveys can be qualitative, from open-ended

response questions, or employ quantitative scales. Surveys and questionnaires are very challenging to design with the assurance of valid, reliable results (Wickens et al., 2003a). They are susceptible to bias attributable to the investigator's wording and administration of questions as well as to the subjective opinions of those being questioned.

Survey and questionnaire design and administration are topics complicated enough for an entire handbook of its own. In fact, for more detailed explanations of questionnaire and survey design, readers are encouraged to review texts such as *The Survey Research Handbook* (Arleck and Settle, 1995) or *Survey Methodology* (Groves et al., 2009). In the scope of this chapter, the advantages and common pitfalls of surveys and questionnaires will be introduced. Interviews can be considered similar to questionnaires and surveys because they share the element of question and response (Meister, 2004), with the exception of aural administration (in most cases). Interviews are characterized by their ability to be conducted with more than one investigator or respondent and the range of formality they may take on. Interviews typically take more time, and for this reason, questionnaires are often used in lieu of interviews.

Interviews and questionnaires are useful for their ability to extract the respondent's perceptions of the system and their performance and behaviors for descriptive studies. That said, the construct validity of participant responses and both the inter- and intrarater reliability of responses are difficult to validate and confirm before analysis of the data collected. Case Study 2 provides examples of surveys and interviews employed in descriptive research.

### CASE STUDY 2: Computer use among older adults in a naturally occurring retirement community

***Goal***   The goal of this study by Carpenter and Buday (2007) was to examine patterns of computer use and barriers to computer use for older adults living in a naturally occurring retirement community (NORC).

***Methods***   Adults over age 65 in the NORC were invited to participate in an interview regarding their current service needs, recent service use, and preferences. Door-to-door solicitation, media announcements, booths at health fairs and local grocery stores, presentations to community groups, and direct mailings were used to recruit participants.[*] The participants were subsequently screened by phone to ensure that they met the residency and age requirements. Subsequent in-home interviews lasted approximately 2 h. The interview contained questions about demographics, social impairment, physical and mental health, and cognitive impairment. Questions were also asked regarding computer use, frequency of use, purpose, and barriers to computer usage. They interviewed a total of 324 older adults, of which 115 were computer users and 209 were nonusers.

[*] For an example of surveys through electronic media, see Rau and Salvendy (2001)

***Analyses***   Various analytical techniques were used, such as paired *t*-test and hierarchical regression analysis. Particularly, hierarchical regression analysis was used to identify characteristics that differentiated computer users from nonusers.

Methodological Implications:

*More Expensive to Conduct*. Because the interview had to take place in each participant's home, this method is more costly than a survey in terms of time and money.

*Benefits of Interviews:* By utilizing trained interviewers, consistency is likely. Unlike a survey, which can be distributed using various means, the structured interview format remains consistent. The interview format also allows for individuals who both use the computer and do not use computers to be sampled, wheras an electronic survey would miss the portion of the population that does not use a computer.

*Judicious Design of Interview Content*. Authors of this study identified two different types of participants: those who use computers and those who do not. Despite the two different categories, the interviewer asked both sets of individuals what prevents them from using the computer or from using it more than they currently do.

---

The selection of which questions to ask; how, procedurally, the questions are presented; and the responses collected are therefore critical in a situation so prone to bias. The responses given are dependent on the participants' psychological abilities, especially their memory (Meister, 2004). Respondents may interpret words and phrases in ways that may produce invalid responses. They may also have trouble in the affirmation and expression of their internal states. Finally, the level of control exercised over responses is important. Structured responses, such as multiple-response questions, can pigeonhole respondents into an ill-fit self-categorization. An alternative is the use of free-response answers and less formal interviews, which create data that are highly subjective and qualitative, making analysis and comparisons difficult. Specific scaling techniques for self-reported measures are detailed in Chapter 44.

*Observation techniques* consist of an investigator sensing, recording, and interpreting behavior. They capture covert behavior with clarity but demonstrate difficulty in estimates of tacit behavior. Meister (2004) asserts: "Observation is the most 'natural' of the measurement methods, because it taps a human function that is instinctive" (p. 131). Observations may be casual and undirected or direct with a definite measurement goal and highly structured. In planning observational methods, Wickens et al. (2003a) suggest that the investigator predefine the variables of interest, the observational methods, how each variable will be recorded, the specific conditions that afford a specific observation, and the observational time frame. These observational categories form a taxonomy of specific pieces of information

to be collected during the course of the observation. Furthermore, defining observational scenarios can enable the investigator to sample only at times when events are occurring that are relevant to the study's goals. This prevents the investigator from filtering through extraneous events and data related with the situation. Observational methods often use some data-recording equipment to better enable the investigator to return to specific events, code data postobservation, and archive raw data for future investigations. Commercial software programs are available that enable the investigator to flag certain events in the video stream for frequency counts and to return for a closer observation.

Observation-based methods are appropriate when working under constraints that limit contact with the participant or interference with the task, such as observing a team of surgeons in an operating room. There are also times when observations are useful because the population cannot express their experience accurately in alternative terms. This is especially the case when working with children, who are sometimes unable to use written surveys or respond to questionnaires. As with most descriptive methods, observation is useful in conceptual research as the precursor to empirical or evaluative research.

Some important factors in the implementation of observation include the amount of training required of observers, inter- and intraobserver reliability of the recorded data, the intrusiveness of the observation on the situation of interest, and how directly observable the variable of interest is (e.g., caller frustration is more difficult to measure than the frequency of calls someone makes to a technical support center). Table A1 in the appendix to this chapter provides the reader with real-world examples of descriptive studies that have been published in the past five years.

## 3.2   Empirical Methods

*Empirical research methods*, also known as *experimental methods*, assess whether relationships between system, performance, and human measures are due to random error or there is a causal relationship. The question in empirical research is: "If *x* is changed, what will happen to *y*?" at different levels of complexity. In empirical research the investigator typically manipulates one or more variables to appraise the effects on human, performance, or system criteria. The investigator manipulates the system directly to invoke an observable change (Drury, 2005).

Empirical methods are beneficial because the manipulations of variables enable the observation of circumstances that may occur infrequently in the operational (i.e., real) world. What's more, this manipulated situation allows for the application of more robust measurement approaches by removing the negative consequences of employing invasive implications to safety- or time-critical situations. The ability to exercise control in the situation to reduce variability may also provide the advantage of smaller sample sizes.

However, these benefits are not without cost. Drury (2005) asserts that face validity is sacrificed in the use of empirical methods; much more persuasion is necessary

for acceptance of the studies. Sanders and McCormick (1993) state that increases in precision, control, and replication are coupled with a loss of generalizability. It is then difficult to make an argument for applicability when dealing with theoretical questions. For this reason, many HF/E practitioners take their inferences and theories developed in highly controlled empirical research and confirm them via field-based descriptive and evaluation-based studies (Meister, 2004). Representation and validity of results are often the most problematic concerns with conducting empirical methods.

### 3.2.1  Variables

For investigators to hypothesize potential relationships between human and system components, they must select variables. *Independent variables* are those factors that are manipulated or controlled by the investigator and are expected to illicit some change in system and/or human behavior in an observable way. Independent variables can be classified as task related, environmental, or participant related and occur at more than one level. *Dependent variables* are measures of the change imposed by the independent variable(s). Extraneous variables are those factors that are not relevant to the hypotheses but that may influence the dependent variable. If extraneous variables are not controlled, their effect on the dependent variable could confound the observed changes triggered by the dependent variable.

Dependent variables are much like the criterion variables used in descriptive studies, with the exception that physical traits such as height, weight, and age are uncommon. Of course, the independent and dependent variables should be linked back to the hypotheses and goals. The best approach, when possible, is the assessment of human behavior in terms of performance, physiological, and subjective dependent measurements to tap accurately into the construct of interest. The goal of empirical research is to detect variance in the dependent variables triggered by different levels of the independent variable(s). Variable selection and definition play a key part in the structuring of an experimental plan.

### 3.2.2  Selecting Participants

While descriptive methods typically require sampling from an actual population, empirical research directs the investigator to select participants who are representative of those in the target population. Certain traits of the population are more important than others, depending on the task and the physical and mental traits exhibited by the target population. The HF/E investigator needs to seriously contemplate if the participant population will be influenced by the independent variable in the same ways as the target population and which factors are extraneous. To determine this, a review of previous theory and literature is once again valuable. Of additional value in narrowing the scope of participant characteristics are descriptive studies: observations, interviews, and questionnaires. These studies can characterize the target population and help an investigator to incorporate the necessary subjective features.

In some circumstances, members of the target population are so highly skilled and trained in their behavior and activities that it is difficult to match participants of similar skill levels. The investigator may find that they can circumvent this by training. Learning is typically estimated by an exponential model; there is an asymptotic point where there is little improvement in the knowledge or skill acquired (Gawron, 2008). The investigator may train participants to a certain point so that their interactions can match more closely those of the target population. Training can be provided to the participants through a specific regimen (e.g., subjects are exposed to three practice trials), they may be trained until they ascertain a specific performance level (e.g., accuracy, time to complete), or the training can be self-directed (i.e., the participant trains until he or she has attained a self-perceived comfort level). Circumstances exist where the amount of time and money to train is prohibitive or training for the construct of interest is simply unrealistic. For example, in studies that employ flight simulators, it is not feasible to train a group of undergraduates to the same level as that of rated pilots although they can be compared to beginning pilots who have not had any flight training (e.g., Pritchett, 2002; Donderi et al., 2010).

Another issue that surfaces in conjunction with the selection of participants is interparticipant variability. This could be age, experience, formal training, or skill. When variability is attributable to differences in knowledge and skill level, the same approach can be taken as mentioned above to train participants to a certain skill level. Variability among participants can create confounding variables for the analysis and interpretation of the data. If this variability is indicative of the actual population (and is desired), the investigator can take specific measures in assigning participants to the experimental conditions.

### 3.2.3  Key Concern: Experimental Plan

The experimental plan is the blueprint for empirical research. It outlines in detail how the experiment will be implemented (Wickens et al., 2003a). The key components of the experimental plan include:

- Defining variables in quantifiable terms in order to determine:
  - The experimental task
  - The levels of manipulation for the independent variable (e.g., the experimental conditions)
  - Which aspects of the behavior to measure: the dependent variable
  - The strategy for controlling confounding variables
  - The type of equipment used for data collection (e.g., pencil and paper, video, computer, eye-tracker)
  - The types of analytical methods that can be applied (e.g., parametric vs. nonparametric statistical)

- Specification of the experimental design in order to determine:
  - Which participants will be exposed to different experimental conditions
  - Order of exposure to treatments
  - How many replications will be used
  - The number of participants required and recruitment methods (e.g., statistical power)

Experimental designs represent (1) different methods for describing variation in treatment conditions, (2) the assignment of participants to those conditions, and (3) the order in which participants are exposed to treatments (Williges, 1995; Meister, 2004). The basic concept of experimental design is discussed here, but for a more thorough discussion the reader is encouraged to review Williges (1995). A more statistically based account may be found in Box et al. (1978). The assignment of participants to treatment conditions is accomplished by means of two-group designs, multiple-group designs, factorial designs, within-subject designs, and between-subject designs. Two-group, multiple-group, and factorial designs describe ways in which the independent variable(s) of interest are broken down into quantifiable, determinant units. Between- and within-subject designs detail how the levels are assigned to the participants. Following is a brief description for each type of design and the conditions that are best supported by each design [Wickens et al. (2003a), compiled from Williges (1995)].

1. *Two-Group Design*. An evaluation is conducted using one independent variable with two conditions or treatment levels. The dependent variable is compared between the two conditions. Sometimes there is a *control condition*, in which no treatment is given. Thus the two levels are the presence or absence of treatment.

2. *Multiple-Group Design*. One independent variable is specified at more than two levels to gain more information (often, more diagnostic) on the impact of the independent variable.

3. *Factorial Design*. An evaluation of two or more independent variables is conducted so that all possible combinations of the variables are evaluated to assess the effect of each variable in isolation and in interaction.

4. *Between-Subject Design*. Each experimental condition is given to a unique group of participants, and participants experience only one condition. This is used widely when it is problematic to expose participants to more than one condition and if time is an issue (e.g., fatigue, learning, order effects).

5. *Within-Subject Design*. Each participant is exposed to every experimental condition. This is called *repeated-measure design* because each participant is observed more than once. It typically reduces the number of participants required.

6. *Mixed-Subject Design*. Variables are explored within and between subjects.

Factorial designs are the most comprehensive type of experimental design. Furthermore, this design enables the variation of more than one system attribute during a single experiment; it is more representative of the real-world complexity of keeping track of the interactions between factors. Factorial designs are common in HF/E empirical work. Terminology is used to explain factorial designs quickly in the reporting of results. For example, if an empirical result has employed four independent variables, the design would be described as a four-way factorial design. If each of three of the independent variables has two levels, and the fourth has three levels, these levels are disclosed by describing the experiment as using a $2 \times 2 \times 2 \times 3$ factorial design.

Between-subject designs are highly susceptible to variation between groups on extraneous factors. This variation can impose constraints on the interpretation and generalizability of the results and can impose the risk of concluding a difference between the two groups based on the independent variable when in fact it is the other intragroup variation. The randomized allocation of participants to groups does not ensure the absence of intergroup variation on factors such as education, gender, age, and experience. These factors are identified through experience, preliminary research, or literature reviews. If extraneous factors have a potential influence on the dependent variable, the investigators should do their best to distribute the variation among the experimental groups. Randomized blocking is a two-step process of separating participants based on the intervening factors; an *equal* number of participants from each block are randomly assigned a condition.

Within-subject designs are prone to order effects. That is, participants might exhibit different behaviors depending on the sequence in which they are exposed to the conditions. Participants may exhibit improved performance over consecutive trials due to learning effects or degraded performance over the consecutive trials due to fatigue or boredom. Unfortunately, fatigue and learning effects do not tend to balance each other out. In terms of fatigue, the investigator may offer the participants rest breaks between sessions or schedule several individual sessions with each participant over time (Gawron, 2008). Learning effects can be mitigated if the participants are trained to a specified point using the techniques mentioned previously.

Investigators may also use specific strategies for assigning the order of conditions to participants. If each condition is run at a different place in the sequence among participants, the potential learning effects may be averaged out; this is called *counterbalancing* (Wickens et al., 2003a). This can be accomplished through randomization, which requires a large number of participants to be effective (imbalance of assignment is likely with a smaller sample). Alternatively, there are structured randomization techniques, which ensure that each "sequence" is experienced. However, to mitigate the learning impact effectively, the number of participants needs to be a multiplier of the number of sequences (which is difficult in studies with many variables), and this may be implausible, depending on the constraints of the study.

Carryover effects are also a possible effect in with-subject designs if conditions are consecutively run repeatedly. Say that in an experimental design there are four conditions, $a$, $b$, $c$, and $d$, and the following orders have been determined for the experimental runs of four participants:

- Order 1: $a-b-c-d$
- Order 2: $b-c-d-a$
- Order 3: $c-d-a-b$
- Order 4: $d-a-b-c$

Note that in these four orders each condition is in a sequentially unique position each time. However, condition $a$ always precedes $b$, $b$ always precedes $c$, and $c$ always precedes $d$. Features of one condition could potentially influence changes in the participants' behaviors under subsequent conditions. As an example, consider an empirical study that strives to understand the visual search strategies employed by quality control inspectors in the detection of errors under a variety of environmental conditions. If one condition is more challenging and it takes an inspector longer to find an error, the inspectors might well change their visual search strategies in reaction, based on the prior difficulties. An investigator may therefore have to employ a combination of random assignment and structured assignment of conditions.

Empirical research methods are typically conducted in the lab but can be gathered in the field as well. The field offers investigators higher representation, but their control of independent and extraneous variables diminishes significantly. The advantages of working in a laboratory setting include the high level of control an investigator can exercise in the specification of independent variable levels and the blocking of potential confounding variables.

The importance in empirical research of running a pilot study cannot be understated. This provides the investigator with a preview of potential issues with equipment, participants, and even the analysis of data. Even with a thorough experimental plan, investigators can encounter unplanned sources of variability in data or unknown confounding variables. This "practice run" can help an investigator to circumvent such problems when collecting actual data. The potential sunk cost of experimental trials that yield contaminated data drives the need for pilot studies.

Empirical investigations possess many advantages in terms of isolating the construct of interest, but the amount of control applied to the empirical setting can drastically limit the generalizability of the results. Empirical research is typically more *basic* in nature, for it drives the understanding of principles and theories which can then be applied to (and validated by) real-world systems. Case Study 3 provides readers with a review of one empirical investigation using a mixed factorial design. In addition, Table A2 provides several more examples of contemporary empirical work in HF/E.

## CASE STUDY 3: Multimodal Feedback Assessment of Performance and Mental Workload

***Goal*** The goal of this study by Vitense et al. (2003) was to establish recommendations for multimodal interfaces using auditory, haptic, and visual feedback.

***Methods*** To extract and assess the complexity of HCI with multimodal feedback in a quantifiable way, the authors conducted a highly controlled empirical study. Thirty-two participants were selected carefully in order to control extraneous factors and to meet hardware requirements. These inclusion criteria were right-handedness, normal visual acuity, and near-normal hearing capability. Appropriate software and hardware were developed and purchased to generate the multimodal feedback to match both the real world and research published previously.

To investigate three different modalities and all possible combinations of the modalities, this study used a $2 \times 2 \times 2$ factorial, within-subject design. Participants used a computer to perform drag-and-drop tasks while being exposed to various combinations of multimodal feedback. Training sessions were conducted to familiarize participants with the experimental tasks, equipment, and each feedback condition. NASA-TLX and time measurement were employed to capture the workload and task performance of participants quantitatively.

***Analyses*** A general linear model repeated-measures analysis was run to analyze the various performance measures and the workload. Interaction plots were also used to present and explain some significant interaction among visual, auditory, and haptic feedback.

Methodological Implications:

*A small number of observations is required*. By controlling uninteresting factors from an experiment, unnecessary variability can be decreased. Thus, as you can see in this case study, empirical studies generally employ smaller numbers of participants than do other types of studies (e.g., descriptive).

*Factors are difficult to control*. Controlling extraneous factors is not an easy task. As this case study shows, careful selection of participants and training were necessary to reduce contaminant variability.

*A covert, dynamic HF/E phenomenon is easier to capture*. Human subjects are easily affected by various extraneous factors, making isolated appraisal of the construct difficult. In this example, the authors conducted a highly controlled experiment in an attempt to extract subtle differences in the interactions among feedback conditions.

## 3.3 Evaluation Methods

Evaluation methods are probably the most difficult to classify because they embody features of both descriptive and empirical studies. Many of the techniques and

tools used in evaluation methods overlap with descriptive and empirical methods. Evaluation methods are chosen specifically because the objectives mandate the evaluation of a design or product, the evaluation of competing designs or products, or even the evaluation of methodologies or measurement tools. The goals of evaluation methods also match closely both descriptive and field methods, but with more of an applied flavor. Evaluation methods are a critical part of system designs, and the specific evaluation methodology used depends on the stage of the design. These methods are highly *applied* in nature, as they typically reference real-world systems.

The purpose of evaluation research embodies (1) understanding the effect of interactions for system or product use (akin to empirical research), (2) descriptions of people using the system (akin to descriptive research), and (3) assessment of the outcomes of system or product use compared to the system or product goal (akin to descriptive research), to confirm intended and unintended outcomes of use (unique to evaluation methods).

Evaluation research is part of the design process. Evaluations assess the integrity of a design and make recommendations for iterative improvements. Therefore, they can be used at a number of points during the design process. The stage of the product or system, including concept, design, prototype, and operational products, is the authority in mandating which techniques to use. Stanton and Young (1999) usefully categorized 12 evaluation methods according to applicability to the various product stages. Table 4 presents a summary of their classification. It is interesting to note that the further along the design process is, the greater the number of applicable techniques. The ease with which methods are applied is therefore a function of the abstraction in the design process. Those products with a physical presence or systems that are tangible are compatible with a wider variety of methodological techniques. This does not imply greater importance in using evaluation methods at later design stages. In fact, evaluations can have the greatest impact in the conceptual stage of product design, when designers express the most flexibility and acceptance of change.

Evaluation methods typically have significant constraints placed on their resources in terms of time, money, and staff. Therefore, these factors, combined with the goal of the evaluation, direct the selection of methods. The relevant questions to consider when selecting a method for evaluation include:

- Resource-specific criteria
  - What is the cost−benefit ratio for using this method?
  - How much time is available for the study?
  - How much money is available for the study?
  - How many staff members are available for implementation and analysis of the study?
  - How can designers be involved in the evaluation?
- Method-specific criteria

- What is the purpose of the evaluation?
- What is the state of the product or system?
- What will the outcome of the evaluation be? (e.g., a report, presentation, design selection)

Evaluation methods typically serve three roles: (1) functional analysis, (2) scenario analysis, and (3) structural analysis (Stanton and Young, 1999). *Functional analyses* seek to understand the scope of functions that a product or system supports. *Scenario analyses* seek to evaluate the actual sequence of activities that users of the system must step through to achieve the desired outcome. *Structural analysis* is the deconstruction of the design from a user's perspective. The selection of variables for evaluation research methods is influenced largely by the same factors that influence variable selection in both descriptive and empirical studies. Quantifiable, objective criteria of system and human performance are most useful in making comparisons of competing designs, systems, or products.

### 3.3.1 Key Concern: Representation

The research setting, tasks, and participants need to be as close to the real world as possible. A lack of generalizability of evaluation research to the actual design, users, tasks, and environment would mean significant gaps in the inferences and recommendations to be made. Sampling of participants should follow those guidelines outlined previously for descriptive studies.

The research setting should be selected based on the constraints listed above. The research needs to ask: "Do you gain more from watching the interactions in context than what you lose from lack of control (Woods, 1996)?" In evaluation studies, field research can provide an in-depth understanding of the goals, needs, and activities of users. But pure field methods such as ethnographic interviews create extensive challenges in terms

**Table 4 Assessment Techniques in the Product Design Process**

| Product Phase | Assessment Techniques |
| --- | --- |
| Concept | *5/12 methods applicable:* checklists, hierarchical task analysis (HTA), repertory grids, interviews, heuristics |
| Design | *10/12 methods applicable:* KLM, link analysis, checklists, protective human error analysis (PHEA), HTA, repertory grids, task analysis for error identification (TAFEI), layout analysis, interviews, heuristics |
| Prototype | *12/12 techniques applicable:* KLM, link analysis, checklists, PHEA, observation, questionnaires, HTA, repertory grids, TAFEI, layout analysis, interviews, heuristics |
| Operational | *12/12 techniques applicable:* KLM, link analysis, checklists, PHEA, observation, questionnaires, HTA, repertory grids, TAFEI, layout analysis, interviews, heuristics |

of budgets, scheduling, and logistics (Woods, 1996). Evaluation methods often succumb to constraints of time, financial support, and expectations as to outcomes. That said, investigators must leverage their resources to best meet those expectations. Practitioners must adopt creative techniques to deal with low-fidelity prototypes (and sometimes no prototype) and limited population samples. The prioritization of methodological decisions must be clearly aligned with the goals and expectations of the study.

Case Study 4 provides readers with an example of one evaluation study. Additionally, Table A3 provides several more examples of evaluation studies.

### CASE STUDY 4: Fleet Study Evaluation of an Advance Brake Warning System

**Goal**   The goal of this study by Shinar (2000) is to evaluate the effectiveness of an advance brake warning system (ABWS) under true driving conditions.

**Methods**   This case study is one of several evaluation studies of the ABWS. Prior to study execution, a simulation study proved the ABWS effective in decreasing the possibility of rear-end crashes (from 73 to 18%). However, the assumptions made in developing the simulation caused limitations in the applicability of its results and conclusions to real-world situations. The inadequacies in the previous study motivated this longitudinal field study investigating 764 government vehicles. Half of the vehicles were equipped with an ABWS, and the other vehicles were without an ABWS. Over four years, the 764 vehicles were used as government fleet vehicles and all crashes involving the vehicles were tracked. This tracking process was carried out unbeknownst to the vehicle drivers. Because the accidents happened for a variety of reasons, it was difficult to distinguish whether a collision was relevant or not. Although the assessment of causality could not be objective, judgments by the investigator were made conservatively in order to improve the validity and integrity of study results.

**Analyses**   A paired $t$-test was used to detect a statistically significant difference in the number of accidents between the two automobile systems. Because the data were gathered under real circumstances, some uncontrolled factors potentially confounded the results. For example, the average distance driven by the control group was different from that of the treatment group.

Those factors were accounted for by introducing more diagnostic evaluative measures, such as the number of rear-end collisions per kilometer for a specific region.

Methodological Implications:

*Specific to a Certain Design or System*. One salient characteristic of evaluation studies is that they target a specific design or system. In this case study the target system is an ABWS.

*Emphasizing Representation*. The major reason that the author was not satisfied with the simulation method was that it lacked representation of the real world, due to some assumptions. Thus, the second study was conducted using actual operating vehicles. Often, investigators must do both for a more complete understanding of the HF/E related to the systems of interest.

*Lacking Control*. Representation is not obtained without cost. Under real situations, experimenters cannot control extraneous, confounding factors. As a result, this author had difficulty distinguishing relevant crashes from irrelevant ones. To compensate, the experiment took place over the course of four years, which increased the sample size to a more acceptable level for analysis.

## 4   CONCLUSIONS

The selection and application of HF/E methods are part art, part science. There is a certain creative skill for the effective application of HF/E methods. Furthermore, that creative skill is acquired through practice and experience. HF/E investigators must be knowledgeable in several areas, be able to interpret theories and principles of other sciences, and integrate them with their own knowledge and creativity in valid, reliable ways to meet the investigation's goals. Of course, all this is to be accomplished within the constraints of time and resources encountered by researchers and practitioners. An awareness of HF/E methods—their limitations, strengths, and prior uses—provides an investigator with a valuable toolkit of knowledge. This and practical experience lend the investigator the ability to delve into the complex phenomena associated with HF/E.

## APPENDIX: EXEMPLARY STUDIES OF HF/E METHODOLOGIES

**Table A1  Examples of Descriptive Studies**

| Study | HF/E Subdiscipline | Goal | Methodology | Analysis Methods |
|---|---|---|---|---|
| School furniture match to students' anthropometry in the Gaza Strip (Agha, 2010) | Anthropometry | To compare primary school students' anthropometry to the dimensions of school furniture whether the furniture used matches the students' anthropometry | *Field study:* Measured anthropometric data from randomly selected 600 male schoolchildren from five schools were used to assess ratio measures of stature | Stature categorized in quartiles; derivative ratios calculated to obtain a range of anthropometric proportions |

**Table A1** (*continued*)

| Study | HF/E Subdiscipline | Goal | Methodology | Analysis Methods |
|---|---|---|---|---|
| Comparing safety climate in naval aviation and hospitals: implications for improving patient safety (Singer et al., 2010) | Safety | To compare results of safety climate survey questions from health care respondents with those from naval aviation, a high-reliability organization | *Survey:* Designed to include comparable items were used — PSCHO survey for hospital personnel and command safety assessment (CSAS) for naval aviators. They received 13,841 completed surveys in U.S. hospitals, 5,511 in VA hospitals, and 14,854 among naval aviators for a total of 34,206 individuals. | Calculated percent of problematic response (PRR) for each survey item and for safety climate overall on average for U.S. hospitals, VA hospitals, and naval aviators. Significance tests were performed for all comparisons of categorical data with $p < 0.001$ for all but one question which used $p < 0.0445$. |
| Effects of driver fatigue monitoring — an expert survey (Karrer and Roetting, 2007) | Fatigue | To evaluate how experts perceive future driver fatigue monitoring; identify objectives and predicted effects of these systems | *Survey:* The survey was distributed to two expert groups: researchers working in the field of driver fatigue monitoring and professional drivers in order to examine differences between the expert groups. Questions were asked to rank the objective of driver fatigue monitoring. On the second portion of the survey they were asked to rank whether or not they agreed or disagreed with possible positive and negative outcomes of driver fatigue monitoring while taking into consideration three different types of automated feedback types. Based on the criteria they set for their ''experts,'' they used 19 researcher surveys and 52 surveys from professional drivers. | ANOVA |
| Anthropometric differences among occupational groups (Hsiao et al., 2002) | Anthropometry | To identify differences in various body measurements between occupational groups in the United States | Archival data collected in the third National Health and Nutrition Examination Survey (NHANES III 1988–1994) were analyzed. | Two-tailed *t*-test |
| Comprehending product warning information: age-related effects and roles of memory, inferencing, and knowledge (Hancock et al., 2005) | Aging, warning perception | To show age-effect comprehension of warnings by comparing younger (18–23 years) and older (65–75 years) adults | The first experiment measured younger and older adults' comprehension of real-world warnings through a verification test presented either immediately after reading the warnings or after a delay. In the second experiment younger and older adults read fabricated warnings that were inconsistent with real-world knowledge. There were 52 younger and 47 older participants. | Univariate ANOVA |

**Table A1** (*continued*)

| Study | HF/E Subdiscipline | Goal | Methodology | Analysis Methods |
|---|---|---|---|---|
| Ergonomics of electronic mail address systems: related literature review and survey of users (Rau and Salvendy, 2001) | E-mail, user-centered design | To obtain information on preferences, dislikes, and difficulties associated with the e-mail address system | *Survey*: Conducted through e-mail and a newsgroup. Seventy questions were administered regarding respondents' use of and attitude toward their electronic mail systems. 160 electronic questionnaires were returned. | Analysis of correlations |
| Effects of task complexity and experience on learning and forgetting: a field study (Nembhard, 2000) | Cognitive processes (learning, memory) | To examine the effects of task complexity and experience on parameters of individual learning and forgetting | *Longitudinal and field study*: 2853 learning and forgetting episodes were captured over the course of a year. The episodes captured and averaged performance data, task complexity, and task experience for each employee on a weekly basis. | Mathematical model development; Kolmogorov–Smirnov; ANOVA; pairwise comparison; regression analysis |
| Computer use among older adults in naturally occurring retirement community (Carpenter and Buday, 2007) | HCI, aging | To examine patterns of computer use and barriers to use among older adults | *Field interviews*: Demographic data were collected and social impairment was obtained with the Older American Resources and Services Assessment Questionnaire (OARS) Social Resources Rating Scale. Physical health was assessed using the Cornell Medical Index Health Questionnaire and items from the Duke Older Americans Resources and Services survey. Cognitive impairment was measured using the blessed orientation–memory–concentration test (BOMC). Mental health was assessed using the short form of the Geriatric Depression Scale. Questions were also asked regarding computer use, frequency of use, purpose, and barriers to computer usage. | *t*-Test; regression analysis; |
| Case study of co-ordinative decision making in disaster management (Smith and Dowell, 2000) | Organizational behavior | To report a case study of interagency coordination during the response to a railway accident in the United Kingdom | Interviews were conducted to capture workers' accounts of a railway incident. Interviews were audiorecorded. Investigators also reviewed documentation taken in relation to the accident. | Critical decision method |
| Traffic sign symbol comprehension: a cross-cultural study (Shinar et al., 2003) | Surface transportation system (highway design), warning perception | To understand the cultural difference in comprehending sign symbol among five countries | One thousand unpaid participants were recruited. Participants were presented with 31 multinational traffic signs and asked their comprehension of each. | ANOVA; arcsin $\sqrt{p}$ transformation |

**Table A2  Examples of Empirical Studies**

| Study | HF/E Subdiscipline | Goal | Methodology | Analysis Methods |
|---|---|---|---|---|
| Detection of temporal delays in visual–haptic interfaces (Vogels, 2004) | Displays and controls, multimodality | To address the question of how large the temporal delay between a visual and a haptic stimulus can be for the stimuli to be perceived as synchronous | Three different experiments were conducted to remove unintended methodological factors and to investigate deeply. Learning effect was controlled through training. | Mathematical model developed and applied to quantify the data; ANOVA used to analyze the quantified mathematical model |
| Adjustable typography: an approach to enhancing low-vision text accessibility (Arditi, 2004) | Accessibility, typography | To show that adjustable typography enhances text accessibility | Participants who had low vision were allowed to adjust key font parameters (e.g., size and spacing) of text on a computer display monitor. After adjustment, the participants' accuracy on a reading task was collected. Participants completed the experiment within a single experimental session due to the fatigue experienced in this predominantly older population (mean age = 68.6 years). | Box-and-whisker plot; regression analysis |
| No evidence for prolonged latency of saccadic eye movements due to intermittent light of a CRT computer screen (Jainta et al., 2004) | Psychomotor processes (eye movement) | To show that there is no clear relationship between latency of saccadic eye movements and the intermittency of light of cathode-ray tubes | A special fluorescent lamp display was used to control the refresh rate. An eye tracker captured saccadic eye movements. | ANOVA with repeated measures; Greenhouse–Geisser adjusted error probabilities |
| Physical workload during use of speech recognition and traditional computer input devices (Juul-Kristensen et al., 2004) | Work physiology (physical workload), HCI | To investigate musculoskeletal workload during computer work using speech recognition and traditional computer input devices | The workload of 10 participants while performing text entry, editing, and reading aloud with and without the speech recognition program was studied. Workload was measured using muscle activity (EMG). | Nonparametric statistics (e.g., Wilcoxon's ranked-sign test, Mann–Whitney test) |
| Attentional models of multitask pilot performance using advanced display technology (Wickens et al., 2003b) | Aerospace systems, attention | To compare air traffic control presentation of auditory (voice) information regarding traffic and flight parameters with advanced display technology presentation of equivalent information | Pilots were exposed to both auditory and advanced display technology conditions. Performance with the information presented in each condition was assessed. A Latin square design was used to counterbalance order effects. | Within-subjects ANOVA and regression analysis |

**Table A2  (*continued*)**

| Study | HF/E Subdiscipline | Goal | Methodology | Analysis Methods |
|---|---|---|---|---|
| Role of spatial abilities and age in performance in an auditory computer navigation task (Pak et al., 2008) | Aging, displays, and controls | To investigate the relationship between spatial ability and performance in a nonvisual computer-based navigation task for participants in three age groups: younger (ages 18–39), middle aged (40–59) and older (60–91) | Over the course of two days, prescreened participants were given cognitive battery tests and ability tests concerning their working memory, attention , and spatial abilities..On the second day, participants dialed into a fictional interactive voice response system to complete tasks such as obtaining information in a banking or electric utility context. | Regression analysis |
| Measuring the fit between human judgments and automated alerting algorithms: a study of collision detection (Bisantz and Pritchett, 2003) | Aviation, automation | To evaluate the impact of displays on human judgment using the *n*-system lens model; to explicitly assess the similarity between human judgments and a set of potential judgment algorithms for use in automated systems | Using a flight simulator, the approach of an oncoming aircraft was manipulated. Data were collected on the performance of the automation system and its effect on pilot judgments. A time-sliced approach was used to capture wider environmental conditions. | Within-subjects ANOVA used on a transformation of the data |
| Bimodal displays improve speech comprehension in environments with multiple speakers (Rudmann et al., 2003) | Displays and controls | To prove that showing additional visual cues from a speaker can improve speech comprehension | Twenty-four participants were exposed to voice recordings with and without visual cues. In some trials, noise distracters were introduced. The level of participant comprehension was assessed while listening to the recording, and eye movement data were collected. | Within-subjects ANOVA |
| Performance in a complex task and breathing under odor exposure (Danuser et al., 2003) | Displays and controls (olfactory displays) | To investigate the influence of odor exposure on performance and breathing | Fifteen healthy individuals were each exposed to different odors. To capture the emotional status, a self-assessment manikin (SAM) was used. | ANOVA with repeated measures; Wilcoxon's ranked-sign test |
| Time estimation during prolonged sleep deprivation and its relationship to activation measures (Miro et al., 2003) | Fatigue | To investigate the effect of prolonged sleep deprivation for 60 h on time estimation | *Longitudinal*: For 60 h of sleep deprivation, time estimations were measured every 2 h. Skin resistance level, body temperature, and Stanford sleepiness scale scores were collected. | ANOVA with repeated measures; regression analysis (linear, quadratic, quintic, and sextic) |

**Table A2** (*continued*)

| Study | HF/E Subdiscipline | Goal | Methodology | Analysis Methods |
|---|---|---|---|---|
| Impact of mental fatigue on exploration in a complex computer task: rigidity and loss of systematic strategies (Van Der Linden et al., 2003) | Fatigue; HCI | To investigate the impact of mental fatigue on how people explore in a complex computer task | Sixty-eight participants (psychology students) performed a complex computer test using the think-aloud protocol. Data were collected on mental fatigue and performance through observation, videotaping, the activation–deactivation checklist, and the rating scale mental effort. | Multivariate test ($\alpha = 0.10$); univariate/post hoc tests ($\alpha = 0.05$) |
| What to expect from immersive virtual environment exposure: influences of gender, body mass index, and past experience (Stanney et al., 2003) | Virtual reality | To investigate potential adverse effects, including sickness, associated with exposure to virtual reality and extreme responses | Of the 1102 subjects recruited for participation, 142 (12.9%) dropped out because of sickness. Qualitative measurement tools were used to assess motion sickness with the motion history questionnaire and simulator sickness. Sessions were videotaped for archival purposes. | Spearman's correlation test; Kruskal–Wallis nonparametric test; chi-squared test |
| Control and perception of balance at elevated and sloped surfaces (Simeonov et al., 2003) | Work physiology | To investigate the effects of the environment characteristics of roof work (e.g., surface slope, height, and visual reference) on standing balance in construction workers | Twenty-four participants were recruited. The slope of a platform, on which they stood, was varied. At each slope the participant performed a manual task and were asked afterward to rate their perceived balance. Instrumentation measured the central pressure movement. Each subject received the same 16 treatments ($4 \times 2 \times 2$). Balanced to control order effects. | ANOVA with repeated measures and the Student–Newman–break Keuls multiple-range test used when ANOVA indicated significance |
| Multimodal feedback: an assessment of performance and mental workload (Vitense et al., 2003) | Displays and controls (multimodality), HCI | To establish recommendations for the incorporation of multimodal feedback in a drag-and-drop task | The NASA-TLX was used to assess workload. Time measures, such as trial completion time and target highlight time, were used to capture performance as it was affected by multimodal feedback. | Interaction plots |
| Contribution of apparent and inherent usability to a user's satisfaction in a searching and browsing task on the Web (Fu and Salvendy, 2002) | Usability, World Wide Web | To investigate the impact of inherent and apparent usability on user's satisfaction of Web page designs | The questionnaire for user interaction satisfaction was used to measure the levels of users' satisfaction with a browsing task completed on one of four interfaces. | ANOVA; stepwise regression analysis |

**Table A3  Examples of Evaluation Studies**

| Study | HF/E Subdiscipline | Goal | Methodology | Analysis Methods |
|---|---|---|---|---|
| Handle dynamics predictions for selected power hand tool applications (Lin et al., 2003) | Biomechanics | To test a previously developed model of handle dynamics by collecting muscle activity (EMG) data | Muscle activity (EMG) was collected to calculate the magnitude of torque that participants experienced. | Regression analysis |
| Learning to use a home medical device: mediating age-related differences with training (Mykityshyn et al., 2002) | Aging, training | To examine the differential benefits of instructional materials, such as a user manual or an instructional video, for younger and older adults learning to use a home medical device | *Longitudinal*: The NASA task load index (TLX) was used to assess the workload associated with instructional methods. A longitudinal study, there was a two-week retention session used between training and measurement. | ANOVA |
| The influence of distraction and driving context on driver response to imperfect collision warning systems (Lees and Lee, 2007) | Surface transportation system (driver behavior) | To determine how false (FA) and unnecessary alarms (UA) impact collision warning system (CWS) effectiveness | A driving simulator was used to investigate the influence of accurate, UA, FA, and no warnings from the CWS effect driver performance during noncritical and critical events. A total of 64 drivers between the ages of 20 and 35 were prescreened for simulator sickness prior to participation. The CWS utilized an auditory alarm to warn the driver of impending rear-end collisions. . | ANOVA; Tukey-Kramer |
| Fleet study evaluation of an advance brake warning system (Shinar, 2000) | Accident, surface transportation system | To prove the effectiveness of an advanced brake warning system (ABWS) | *Longitudinal and field study*: Traced accidents of vehicles with ABWS-installed government vehicles (382) and non-ABWS vehicles (382) for 4 years. | *t*-Test; chi-square test |
| Continuous assessment of back stress (CABS): a new method to quantify low-back stress in jobs with variable biomechanical demands (Mirka et al., 2000) | Work physiology | To compare three different back-stress modeling techniques for the continuous assessment of lower back stress in various situations and to incorporate them into a hybrid model | *Field study and observation*: 28 construction workers were observed and videotaped while on the job. Based on this videotaped observation, three models of each task that induced biomechanical stress were created. Each model was evaluated based on the extent to which it modeled the actual biomechanical stress experienced. | Time-weighted histograms to aggregate and compare the output from three different models |

# CHAPTER 11

# ANTHROPOMETRY FOR PRODUCT DESIGN

**Kathleen M. Robinette**
**Air Force Research Laboratory**
**Wright-Patterson Air Force Base, Ohio**

## 1 INTRODUCTION

Did you know that designing for the 5th percentile female to the 95th percentile male can lead to poor and unsafe designs? If not, you are not alone. These and similar percentile cases, such as the 99th percentile male, are the only cases presented as anthropometry solutions to many engineers and ergonomics professionals. In this chapter we review this and other anthropometry issues and present an overview of practical effective methods for incorporating the human body in design.

*Anthropometry*, the study of human body measurement, is used in engineering to ensure the maximum benefit and capability of products that people use. The use of anthropometric data in the early concept stage can minimize the size and shape changes needed later, when modifications can be very expensive. To use anthropometry knowledge effectively, it is also important to have knowledge of the relationships between the body and the items worn or used. The study of these relationships is called *fit mapping*. Databases containing both anthropometry and fit-mapping data can be used as a lessons-learned source for development of new products. Therefore, anthropometry and fit mapping can be thought of as an information core around which products are designed, as illustrated in Figure 1.

A *case* is a representation of a combination of body measurements, such as a list of measurements on one subject, the average measurements from a sample, a three-dimensional scan of a person, or a two- or three-dimensional human model. If the relationship between the anthropometry and the fit of a product is simple or known, cases may be all that is needed to arrive at an effective design. However, if the relationship between the anthropometry and the fit is complex or unknown, cases alone may not suffice. In these situations, fit mapping with a prototype, mock-up, or similar product is needed to determine how to accommodate the cases and to predict accommodation for any case.

The chapter is divided into three sections. Section 2 deals with the selection of cases for characterizing anthropometric variability. Section 3 covers fit-mapping methods. Section 4 is devoted to some of the benefits of the newest method in anthropometric data collection, three-dimensional anthropometry.

## 2 ANTHROPOMETRY CASES: ALTERNATIVES, PITFALLS, AND RISKS

When a designer or engineer asks the question "What anthropometry should I use in the design?" he or she is essentially asking, "What cases should I design around?" Of course, the person would always like to be given one case or one list of measurements and be told that nothing else is needed. That would make it simple. However, if the question has to be asked, the design is probably more complicated than that, and the answer is correspondingly more complicated as well. In this section we discuss alternative ways to determine which cases to use.

### 2.1 Averages and Percentiles

Since as early as 1952, when Daniels (1952) presented the argument that no one is average, we have known that anthropometric averages are not acceptable for many applications. For example, an average human head is not appropriate to use for helmet sizing, and an average female shape is not appropriate for sizing apparel. In addition, we have known since Searle and Haslegrave (1969) presented their debate with Ed Hertzberg that the 5th and 95th percentile people are no better. Robinette and McConville (1982) demonstrated that it is not even possible to construct a 5th or 95th percentile human figure: The values do not add up. This means that 5th or 95th percentile values can produce very unrealistic figures that do not have the desired 5th or 95th percentile size for some of their dimensions.

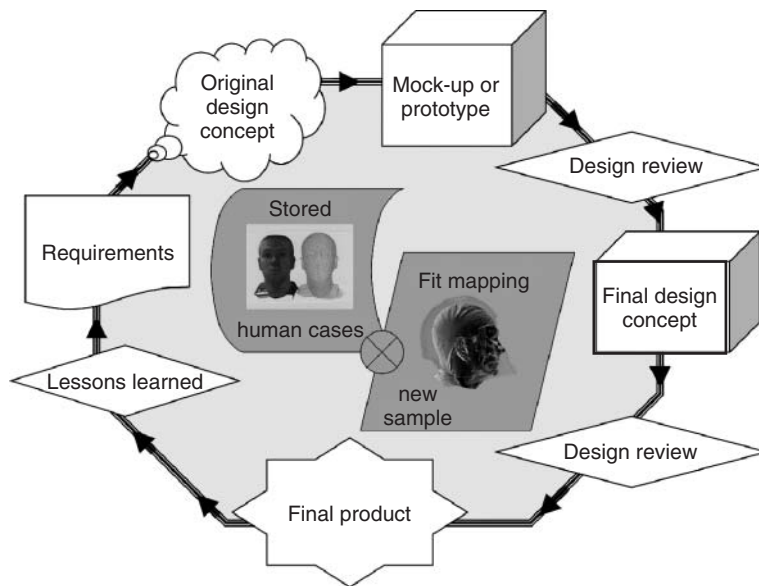
The impact of using percentiles can be huge. For example, for one candidate aircraft for the T-1 program, the use of the 1st percentile female and 99th percentile male resulted in an aircraft that 90% of females, 80% of African-American males, and 30% of white males


**Figure 1**  Anthropometric information as a design core.

could not fly. The problem is illustrated in Figure 2. The pilots needed to be able, simultaneously, to see over the nose of the plane and operate the yoke, a control that is similar to a steering wheel in a car. For the 99th percentile seated eye height, the seat would be adjusted all the way down to enable the pilot to see over the nose. For the 1st percentile seated eye height, the seat would be adjusted all the way up. Since the design used all 1st percentile values for the full-up seat position, it accounted for only a 1st percentile or smaller female thigh size when the seat was all the way up. As a result, it did not accommodate most female pilots' thigh size without having the yoke interference as pictured in Figure 2. For designs such as this, where there are conflicting or interacting measurements or requirements, percentiles will not be effective. Cases that have combinations of small and large dimensions are needed.

To understand when to use and when not to use averages and percentiles, it is important to understand what they are and what they are not. Figure 3 illustrates average and percentile values for stature and weight. Sample frequency distributions for these two measurements are shown for the female North American data from the CAESAR survey (Harrison and Robinette, 2002) in the form of histograms. The averages for 5th and 95th percentiles are indicated. The *frequency* is the count of the number of times that a value or range of values occurs, and the vertical bars in Figure 3 indicate the number of people who had a stature or weight of the size indicated. For example, the one vertical bar to the right of the 95th percentile weight indicates that approximately 10 people have a weight between 103 and 105 kg. Percentiles indicate the location of a particular cumulative frequency. For example, the 50th percentile is the point at which 50% have a smaller value, and the 95th percentile is the point at which 95% have a smaller value.

**Figure 2**  Problem that occurred when using 1st percentile female and 99th percentile male.

The *average* is a value for one measurement that falls near the middle of the distribution for that measurement. In this case the arithmetic average is shown. Another kind of central value is the 50th percentile, which will be
**Figure 3**   Stature and weight univariate frequencies, CAESAR, U.S. females.

the same as the arithmetic average when the frequency distribution is symmetric. The stature distribution shown in Figure 3 is approximately symmetrical, so the average and the 50th percentile differ by just 0.5%, whereas the weight distribution is not symmetric, so the average and the 50th percentile differ by 5.4%.

### 2.1.1   Percentile Issues

Percentile values refer only to the location of the cumulative frequency of one measurement. This means that the 95th percentile weight has no relationship to the 95th percentile stature. This is illustrated in Figure 4, which shows the two-dimensional frequency distribution for stature and weight along with the one-dimensional frequency distributions that appeared in Figure 3. Stature values are represented by the vertical axis and weight by the horizontal. The histogram from Figure 3 for stature is shown to the right of the plot, and the histogram from Figure 3 for weight is shown at the top of the

plot, each with its respective 5th and 95th percentile values. Each of the circular dots in the center of the plot indicates the location of one subject from the sample of CAESAR U.S. females. The ellipse toward the center that surrounds many of the dots is the 90% ellipse; in other words, it encircles 90% of the subjects.

If a designer uses the "5th percentile female to the 95th percentile female" approach, only two cases are being used. These two cases are indicated as black squares, one at the lower left and the other at the upper right of the two-dimensional plot in Figure 4. The one at the lower left is the intersection of the 5th percentile stature and the 5th percentile weight. The one at the upper right is the intersection of the 95th percentile stature and the 95th percentile weight. The stature range from the 5th to 95th percentile falls between the two horizontal 5th and 95th percentile lines and contains approximately 90% of the population. The weight range from the 5th to 95th percentile falls between the
**Figure 4** Bivariate frequency distribution of stature and weight, CAESAR, U.S. females.

two vertical 5th and 95th percentile lines and contains approximately 90% of the population. The people who fall between the 5th and 95th percentiles for both stature and weight are only those people who fall within the intersection of the vertical and horizontal bands. The intersection contains only approximately 82%. If a third measurement is added, it makes the frequency distribution three-dimensional, and the percentage accommodated between the 5th and 95th percentiles for all three measurements will be fewer still.

The bar in the weight histogram in Figure 3 that is just to the right of the 95th percentile is the same as the bar that is just to the right of the 95th percentile weight in Figure 4. As stated above, approximately 10 subjects fall at this point. If you look at the two-dimensional plot, you can see that these 10 subjects who are at approximately the 95th percentile weight have stature values from as small as 1500 mm to as large as 1850 mm. In other words, women in this sample who have a 95th percentile weight have a range of statures that

extends from below the stature 5th percentile to above the stature 95th percentile. This means that if the product has conflicting requirements, the 5th to 95th percentile cases would not work effectively. For example, suppose that a zoo has an automatically adjusting platform for an exhibit that adjusts its height based on the person's weight, and the exhibit designers want to make a window or display large enough so that the population can see the exhibit. If this is designed for the 5th percentile person to the 95th percentile person, they would design for (1) the 5th percentile stature with the 5th percentile weight as one case and (2) the 95th percentile weight with the 95th percentile stature as the other case. Let us use the same female population data to see what the 5th and 95th percentiles would accommodate. At the 5th percentile case the platform would be full up and the stature accommodated would be 1525 mm. At the 95th percentile case the platform would be full down and the stature accommodated would be 1767 mm. This range of stature is 1767 − 1525 = 242

mm. This will accommodate the 5th percentile female to the 95th percentile female, but not the 5th percentile stature with an average weight or the 5th percentile weight with the average stature. The female who has a 5th percentile weight of 49.2 kg but an average stature of 1639 mm would need 114 mm more headroom. The female who has an average weight but a 5th percentile stature may not be able to see the display because the weight-adjusted platform is halfway down. This is illustrated in Figure 5.

### 2.1.2 When to Use Averages and Percentiles

Averages, percentiles, and other one-dimensional summary statistics such as the standard deviation, minimum, and maximum are very useful for comparing measurements captured in different ways or for comparing samples from different populations to determine if there are size and variability differences. For example, Krul et al (2010) provide a good example of the use of summary statistics for comparing self-reported values to measured values for stature, weight and body mass index. In Table 1, one-dimensional summary statistics from the U.S. CAESAR sample (Harrison and Robinette, 2002) are compared with summary statistics from the U.S. ANSUR survey (Gordon et al., 1989) illustrating another example of the proper use of summary statistics. The CAESAR sample was taken from a civilian population, whereas the ANSUR sample was taken from a military population, the U.S. Army. The U.S. Army has fitness and weight limitations for its personnel. As a result, the ANSUR sample has a more limited

range of variability for weight-related measurements. The effect of this can be seen by examining the differences in the weight and buttock–knee length ranges (minimum to maximum) versus the ranges for the other measurements that are less affected by weight.

You might also notice that the difference between CAESAR and ANSUR females in buttock–knee length is greater than the difference in CAESAR and ANSUR males in buttock–knee length. This highlights a key difference between men and women. Women tend to gain weight in their hips, buttocks, and thighs, whereas men tend to gain weight or bulk in their waists and shoulders.

The ANSUR/U.S. CAESAR differences in Table 1 are contrasted with another comparison of anthropometric data in Table 2. This compares the U.S. CAESAR data with those collected in The Netherlands on the Dutch population (TN). The Dutch claim to be the tallest people in Europe, and this is reflected in all the heights and limb lengths. Both the male and female Dutch subjects are more than 30 mm taller on average than their U.S. counterparts.

Averages and percentiles and other one-dimensional statistics can also be very useful for products that do not have conflicting requirements. In these instances the loss in accommodation with each additional dimension can be compensated for by increasing the percentile range for each dimension. For example, if you want to ensure 90% accommodation for a simple design problem (one that has no interactive measurements) with five key measurements, you can use the 1st and 99th percentile

**Figure 5** Woman with 5th percentile stature and average weight is not accommodated.

**Figure 6**  Moving the percentile values out farther to get a desired joint accommodation of 90%.

values instead of the 5th and 95th. Each of the five measurements restricts 2% of the population, so at most you would have $5 \times 2\% = 10\%$ disaccommodated. This approach is illustrated in Figure 6. The bars represented by the 5th percentile values would be moved to where the stars are in the figure.

To summarize, percentiles represent the proportion accommodated for one dimension only. When used for more than one dimension, the combination of measurements will accommodate less than the proportion indicated by the percentiles. If the design has no conflicting requirements, you can sometimes compensate by moving out the percentiles. However, if the design has conflicting requirements, using percentiles may accommodate very few people, and an alternative set of cases is required.

## 2.2  Alternative Methods

There are two categories of alternatives to percentiles: (1) use a sample of human subjects as fit models or (2) select a set of cases or representations of people with relevant size and shape combinations. Generally, using a random sample with lots of subjects is not practical, although new three-dimensional modeling and CAD technologies may soon change this. Therefore, the selection of a small number of cases that effectively represent the population is preferable. The first method is typical practice in the apparel industry, but only

for one subject (a sample of one) for a central size referred to as the base size. They adjust for the rest of the population using a process called grading. The grade is expressed as the increment of change from one size to the next starting with the base size for a list of measurements. Therefore grading uses the second method or what we refer to as cases. The success or failure of the fit of the garment for the target population is dependent upon the selection of the initial subject as well as the selection of the cases, the grade increments.

### 2.2.1  Case Selection

The purpose of using a small number of cases is to simplify the problem by reducing to a minimum the amount of information needed. Generally, the first thing reduced is the number of dimensions. This is done using knowledge of the product and by examining the correlation of the dimensions that are related to the product. The goal is to keep just those that are critical and have as little redundant information as possible. For example, eye height, sitting, and sitting height are highly correlated; therefore, accommodating one could accommodate the other, and only one would be needed in case selection. The risk is that something important will be missed and therefore will not be well accommodated.

It is easiest if the number of critical dimensions can be reduced to four or fewer, because all combinations

of small and large proportions need to be considered. If there are two critical dimensions, the minimum number of small and large combinations is four: small–small, small–large, large–small, and large–large. If there are three critical dimensions, the minimum number of small and large combinations is eight: small–large–large, small–small–large, small–large–small, small–small–small, large–small–small, large–small–large, large–large–small, and large–large–large. With more than four the problem gets quite complex, and a random sample may be easier to use.

The next simplification is a reduction in the combinations used. Often in a design, only the small or large size of a dimension is needed. For example, for a chair hip breadth, sitting might be one of the critical dimensions but only the large size is needed to define the minimum width of the seat. If it does not have any interactive or conflicting effect with the other critical dimensions, it can be used as a stand-alone single value. Also, if two or more groups have overlapping cases, such as males and females in some instances, it is possible to drop some of the cases.

This process is best explained using an example of a seated workstation with three critical dimensions: eye height, sitting; buttock–knee length; and hip breadth, sitting. The minimum seat width for this design should be the largest hip breadth, sitting, but this is the only seat element that is affected by hip breadth, sitting, so it interferes with no other dimension. The desired accommodation overall is 90% of the male and female population. First the designer selected the hip breadth, sitting value by examining its summary statistics for the large end of its distribution. These are shown in Table 3. As can be seen from the table, the women have a larger hip breadth, sitting than the men. Therefore,

**Table 3 Hip Breadth, Sitting Statistics from U.S. CAESAR Survey (mm)**

|         | N    | Mean | 95th Percentile | 99th Percentile | Maximum |
|---------|------|------|-----------------|-----------------|---------|
| Females | 1264 | 410  | 501             | 556             | 663     |
| Males   | 1127 | 376  | 435             | 483             | 635     |

the women's maximum value will be used. If the 99th percentile is used, approximately 1% of U.S. civilian women would be estimated to be larger. If 90% are accommodated with the remaining two dimensions, only 89% would be expected to be accommodated for all three. It would be simplest to use the maximum and then accommodate 90% in the other two. This was the approach used by Zehner (1996) for the JPATS aircraft. An alternative is to assume some risk in the design and to select a smaller number than the maximum. This is a judgment to be made by the manufacturer or customer.

Next we examine the two-dimensional (also called *bivariate*) frequency distribution for eye height, sitting and buttock–knee length. The distribution for female subjects from the CAESAR database is shown in Figure 7, and the distribution for male subjects is shown in Figure 8. The stars in Figures 7 and 8 represent the location of the 5th and 95th percentiles, and the probability ellipses enclose 90% of each sample. To achieve the target 90% accommodation, cases that lie on the elliptical boundary are selected. Boundary cases chosen in this way represent extreme combinations of the two measurements. For example, in Figure 7, cases 1 and 3 represent the two extremes for buttock–knee length, and cases 2 and 4 represent the two extremes for eye height, sitting. Note that the cases are moderate

**Figure 7** Bivariate frequency distribution for eye height, sitting and buttock–knee length for CAESAR U.S. female sample (N = 1263) with four female cases shown; 90% probability ellipse.
**Figure 8** Bivariate frequency distribution for eye height, sitting and buttock–knee length for U.S. male sample (*N* = 1125); 90% probability ellipse.

in size for one dimension but extreme for the other. The boundary ellipse provides combinations that are not captured in the range between small–small (5th/5th) or large–large (95th/95th) percentiles. Case selection of this type makes the assumption that if the boundary cases are accommodated by the design, so are all those within the probability ellipse. Although this assumption is valid for workspace design, where vision, reach, and clearance from obstruction are key issues, it is not necessarily true for design of clothing or other gear worn on the body. In the latter application, an adequate number of cases must be selected to represent the inner distribution of anthropometric combinations, which should be given much more emphasis than the boundary cases.

The dimensions for the eight cases represented in Figures 7 and 8 are shown in Table 4. Note that this table includes the same hip breadth, sitting for all cases. This is the hip breadth, sitting taken from Table 3 and represents the smallest breadth that should be used in the design. The dimensions for each case must be

applied to the design as a set. For example, the seat must be adjustable to accommodate a buttock–knee length of 510 mm at the same time that it is adjusted to accommodate an eye height, sitting of 725 mm and a hip breadth, sitting of 663 mm to accommodate case 1.

An option for reducing the number of cases is to drop those that are overlapping or redundant. If the risk is so small that differences in men and women will affect the design significantly, it is possible to drop some of the overlapping cases and still accommodate the desired proportion of the population. For example, male cases 5 and 8 are not as extreme as female cases 1 and 4, and the accommodation risk due to dropping them is small. The bivariate distribution in Figure 9 illustrates buttock–knee length and eye height, sitting for both men and women. The final set of anthropometric cases is shown, as well as the location of the dropped cases, 5 and 8.

### 2.2.2 Distributing Cases

As introduced in Section 2.2.1, all of the prior examples make the assumption that if the outer boundaries of the distribution are accommodated, all of the people within the boundaries will also be accommodated. This is true for both the univariate case approach (upper and lower percentile values) and the multivariate case approach (e.g., bivariate ellipse cases, as above). For products that come in sizes or with adjustments that are stepped rather than continuous, this may not be a valid assumption. Imagine a T-shirt that comes in only X-small and XX-large sizes. Few people would be accommodated. For these kinds of products, it is necessary to select, or distribute, cases both *at* and *within* the boundaries.

For distributing cases it is important that there be more cases than expected sizes or adjustment steps to

**Table 4  Case Dimensions for Seated Workstation Example (mm)**

| Females | Case 1 | Case 2 | Case 3 | Case 4 |
|---|---|---|---|---|
| Buttock–knee length | 510 | 600 | 660 | 600 |
| Eye height, sitting | 725 | 820 | 795 | 690 |
| Hip breadth, sitting | 663 | 663 | 663 | 663 |
| Males | Case 5 | Case 6 | Case 7 | Case 8 |
| Buttock–knee length | 541 | 655 | 690 | 595 |
| Eye height, sitting | 760 | 890 | 855 | 725 |
| Hip breadth, sitting | 663 | 663 | 663 | 663 |

ensure that people are not missed between sizes or steps. A good example of distributed cases is shown by Harrison et al. (2000) in their selection of cases for laser eye protection (LEP) spectacles. They used three key dimensions: face breadth for the spectacle width, nose depth for the distance of the spectacle forward from the eye, and eye orbit height for the spectacle height. They used bivariate plots for each of these dimensions with the other two and selected 30 cases to characterize the variability for all three. They also took into account the different ethnicities of subjects when selecting cases to ensure adequate accommodation of all groups. One of their bivariate plots with the cases selected is shown in Figure 10.

For the LEP effort, the critical dimensions were used to select individual subjects, and their three-dimensional scans were used to characterize them as a case for implementation in the spectacle design. Figure 11 illustrates the side view of the three-dimensional scan for one of the cases. By using distributed cases throughout the critical dimension distribution, a broader range is covered than using the equivalent number of subjects in

**Figure 9**  Bivariate frequency distribution for eye height, sitting and buttock–knee length for U.S. male ($N = 1127$) and female ($N = 1263$) sample. Cases 5 and 8 were not included in the final set due to proximity to cases 1 and 4.

**Figure 10**  Plot 2 of the three critical dimensions and the cases for the LEP.
**Figure 11**  Side view of one LEP case.

a random sample, and no assumption about the range of accommodation within one size is made. This permits evaluation of the range of fit within a size and the degree of size overlap during the design process.

### 2.2.3  Principal-Components Analysis

In the examples above, the set of dimensions was reduced using judgment based on knowledge of the problem and the relationship between measurements. Principal-components analysis (PCA) can be helpful in both understanding the relationship between relevant measurements and reducing the set of dimensions to a small, manageable number. This technique has been used effectively for aircraft cockpit crew station design (Bittner et al., 1987; Zehner et al., 1993; Zehner, 1996).

Human dimensions often have some relationship with each other. For example, sitting height and eye height, sitting are highly correlated. The relationships between a set of dimensions can be expressed as either a correlation or a covariance matrix. PCA uses a correlation or covariance matrix and creates a new set of variables called *components*. The total number of components is equal to the number of original variables, and the first component will always represent the greatest amount of variation in the distribution. The second component describes the second greatest, and so on. An examination of the relative contributions, or correlations, of each original dimension and a particular component can be used to interpret and "name" the component. For example, the first component usually describes overall body size and is defined by observing a general increase in the values for the original anthropometric dimensions as the value, or score, of the first component increases.

The premise in using PCA for accommodation case selection is that if most of the total variability in the relevant measurements can be represented in the first

two or three components these components can be used to reduce and simplify your case selection. For example, to write the anthropometric specifications for cockpit design in Joint Primary Air Training System (JPATS) aircraft, Zehner (1996) used the first and second components from a PCA on six cockpit-relevant anthropometric dimensions. The first two components explained 90% of the total variability for all six combined measurements. This was approximately the same for each gender (conducted in separate analyses). Zehner then used a 99.5% probability ellipse on the first two principal components to select the initial boundary cases. One of the genders is shown in Figure 12. Combining the initial set of cases from both genders (with some modification) resulted in a final set of JPATS cases that offered an accommodation of 95% for the women and 99.9% for the men. The first principal component was defined as size; the second was a contrast between limb length and torso height (short limbs/tall torso vs. long limbs/short torso).

Unlike compiled percentile methods (or compiled bivariate approaches when there are more than two variables), multivariate PCA takes into account the simultaneous relationship of three or more variables. However, with PCA the interpretation of the components may not always be clear, and it can be more difficult to understand what aspect of size is being accommodated. An alternative way to use PCA is to use it only to understand which dimensions are correlated with others and then select the most important single dimensions to represent the set as a key dimension. In this way, the key dimension is easier to understand.

The chief limitation of PCA is that all of the dimensions are accepted into the analysis as if they have equal design value and PCA has no way to know the design value. As a result, accommodating the

**Figure 12**  PCA bivariate and 99.5% boundary for the first and second principal components for one gender of the JPATS population. Initial cases 1–8 for this gender are regularly distributed around the boundary shape.

components will accommodate some of the variability of the less important dimensions at the expense of the more important ones. Also, PCA is affected by the number of correlated dimensions used of each type. For example, if 10 dimensions are used and 9 of them are strongly correlated with one another, the one dimension that is not correlated with any other may end up being component 4. Since it is one of 10 dimensions, it represents 10% of the total variability. So it is possible to accommodate 90% of the variability in the first three components and not accommodate the most important dimension. Therefore, when using PCA it is important to (1) include only dimensions that are both relevant and important and (2) check the range of accommodation achieved in the cases for each individual dimension.

## 3  FIT MAPPING

Fit mapping is a type of design guidance study that provides information about who a product fits well and who it does not. When anthropometry is used in product design without the knowledge of fit, many speculations must be made about how to place the anthropometry in the design space and the range of accommodation. As a result, even with digital human models and computer-aided design, it is often the case that the first prototypes do not accommodate the full range of the population and may accommodate body size regions that do not exist in the population.

Fit mapping combines performance testing of prototypes or mock-ups with anthropometric measurement to "map" the fit effectiveness of a product for different body sizes and shapes. Fit effectiveness means that the desired population is accommodated without wasted sizes or wasted accommodation regions. Because most performance-based fit tests cannot be done on digital models, fit mapping involves using human subjects to do the assessments. The following is a list of things needed for a fit-mapping study:

1. Human subjects drawn to represent a broad range of variability
2. A prototype or sample of the product (multiple samples of each size is desirable)
3. A testable concept-of-fit definition
4. An expert fit evaluator or one who is trained to be consistent using the concept-of-fit definition
5. Anthropometry measuring equipment
6. Multivariate analysis software and knowledge
7. Survey data from the target population with relevant measurements

The study process consists of:

1. Scoring the fit for each size that the subject can don against the concept of fit
2. Measuring the subjects
3. Analyzing the data to determine:
   a. The key size-determining dimensions
   b. The range of accommodation for each size with respect to the key dimensions
   c. General design or shaping issues
   d. Size or shape gaps in target population coverage
   e. Size or shape overlaps in target population coverage

The end result of the study is that wasted sizes or adjustment ranges are dropped, sizes or adjustment ranges are added where there are gaps, and design and reshaping recommendations are provided to make the product fit better overall. One example of the magnitude of the improvement that can be achieved with the use of fit mapping was demonstrated in the Navy women's uniform study (Mellian et al., 1990; Robinette et al., 1990). The Navy women's uniform consisted of two jackets, two skirts, and two pairs of slacks. The fit mapping consisted of measuring body size and assessing the fit of each of the garments on more than 1000 Navy women. Prior to the study, the Navy had added odd-numbered sizes in an attempt to improve fit, because 75% of all Navy recruits had to have major alterations. The sizes included sizes 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 18, 20, and 22, with three lengths for each, for a total of 42 sizes.

The results indicated three important facts. First, there was 100% overlap in some of the sizes. For each of the items, sizes 7 and 8, 9 and 10, 11 and 12, 13 and 14, and 15 and 16 fit the same subjects equally well. Second, the size of best fit was different for nearly every garment, with some women wearing up to four different sizes. For example, one woman had the best fit in a size 8 for the blue skirt, size 10 for the white skirt, size 12 for the blue slacks, and size 14 for the white slacks. Third, most women did not get an acceptable fit in any size.

The size overlap was examined and it was determined that the difference between the sizes was less than the manufacturing tolerance for a size, which was $\frac{1}{2}$ in. Therefore, the manufacturers had actually used exactly the same pattern for sizes 7 and 8, 9 and 10, 11 and 12, 13 and 14, and 15 and 16. Therefore, sizes 7, 9, 11, 13, and 15 in all three of their lengths could be removed with no effect on accommodation.

The difference in which size fits a given body was resolved by renaming the sizes for some of the garments, to make them consistent. This highlights the fact that the size something is designed to be is not necessarily the size it actually is. Fabric, style, concept of fit, function, and many other factors affect fit. Many of these cannot be known without fit testing on human subjects.

Finally, the women who did not get an acceptable fit in any size were proportioned differently than the size range. They had either a larger hip for the same waist or a smaller hip for the same waist as the Navy size range. This is an example of an interaction or conflict in the dimensions. All of the sizes were in a line consisting of the same shape scaled up and down. This is consistent with common apparel sizing practice. Most apparel companies start with a base size, such as a 10 or a 12, and scale it up and down along a line. The scaling is called *grading*. This is illustrated in Figure 13. The grading line is shown in bold in Figure 13. The sizes

that fall along this line are similar to those used in the Navy women's uniform. Note the overlapping of the odd-numbered sizes with the even-numbered sizes in one area. This is the area where there were more sizes than necessary. Also, note that above and below the grading line, no sizes are available.

Figure 14 illustrates the types of changes made to the sizing to make it more effective. (Note that the sample of women shown is that of the civilian CAESAR survey, not Navy women, who do not have the larger waist sizes.) The overlapping sizes have been dropped. The sizes shown above the grade line have a larger hip for

**Figure 13**   Before fit mapping apparel sizes.

**Figure 14**   After fit-mapping sizes.

the same waist and are called plus hip (+), and the sizes below the line have a smaller hip for the same waist and are called minus hip (−). Before these sizes were added, women who fell in the plus-hip region had to wear a size with a very large waist in order to fit their hip. Then they had to have the entire waist-to-hip region altered. Women who fell in the minus-hip region previously had to get a garment that was way too large in the hips in order to get a fit for their waist. Adding sizes with the modified hip-to-waist proportion resulted in accommodating 99% of the women without needing alternations. The end result of adjusting the sizing based on fit mapping was to improve accommodation from 25 to 99%, with the same number of sizes (Figure 14).

## 4  THREE-DIMENSIONAL ANTHROPOMETRY

Three-dimensional anthropometry has been around since the advent of stereophotography. Originally stereopairs had to be viewed through a stereoviewer and digitized manually, and it was very time consuming. This process is described by Herron (1972). However, digital photography allowed us to automate the process, and this has dramatically affected our ability to design effectively. Automated three-dimensional scanning began to take off in the 1980s (Robinette, 1986). Now there are many tools available to use and analyze three-dimensional scan data, and the first civilian survey to provide whole-body scans of all subjects, CAESAR, was completed in 2002 (Blackwell et al., 2002; Harrison and Robinette, 2002; Robinette et al., 2002). We describe briefly here some of the benefits of the new technology.

### 4.1  Why Three-Dimensional Scans?

By far the biggest advantage of three-dimensional surface anthropometry is visualization of cases, particularly

the ability to visualize them with respect to the equipment or apparel they wear or use. When cases are selected, some assumptions are made about the measurements that are critical for the design. Three-dimensional scans of the subjects often reveal other important information that might otherwise have been overlooked. An example of this is illustrated in Figure 15. When designing airplane, stadium, or theater seats, two common assumptions are made: (1) that the minimum width of the seat should be based on hip breadth, sitting and (2) that the minimum width of the seat should be based on the large male. In Figure 15 we see the scans of two figures overlaid, a male with a 99th percentile hip breadth, sitting and a female with a 99th percentile hip breadth, sitting. The male figure is in dark gray and the female in light gray. It is immediately apparent that the female figure has broader hips than the male. Although she is shorter and has smaller shoulders, her hips are wider by more than 75 mm (almost 3 in.). Second, it is also clear that the shoulders and arms of the male figure extend out beyond the female hips. The breadth across the arms when seated comfortably is clearly a more appropriate measure for the spacing of seats.

For the design of a vehicle interior, measures such as buttock–knee length and eye height, sitting are often considered to be key. Figure 16 shows two women who

**Figure 15**  View of male and female with 99th percentile hip breadth, sitting.

**Figure 16**  Two women with the same buttock–knee length and eye height, sitting.

have the same buttock–knee length and eye height, sitting. However, it is immediately clear from the image that because of the difference in their soft tissue distribution, they would have very different needs in terms of steering wheel placement. These things are much more difficult to comprehend by looking at tables of numbers. Three-dimensional anthropometry captures some measurements, such as contour change, three-dimensional landmark locations, or soft tissue distribution that cannot be captured adequately with traditional anthropometry. Finally, three-dimensional anthropometry offers the opportunity to measure the location of a person with respect to a product for use in identifying fit problems during fit mapping and even for creating custom fit apparel or equipment. For example, by scanning subjects with and without a flight helmet and examining the range of ear locations within the helmet, fit problems due to ear misplacement can be identified. This is illustrated in Figure 17.

Figure 17 shows four examples of using three-dimensional anthropometric measurement to visualize and quantify fit. This figure was created using scans of the subjects with and without the helmet and superimposing the two images in three dimensions using software called Integrate (Burnsides et al., 1996). The image at the upper left of Figure 17 shows the location of the ears of eight subjects in the helmet being tested. The red curved lines show the point at which the subjects complained of ear pain. The image at the lower left shows the locations of two different subjects in the same helmet as they actually wore it to fly, demonstrating different head orientations. The image at the upper right shows the 90 and 95% accommodation ellipses for the point on the ear called the *tragion* for those subjects who did not complain of ear pain. The image at the lower right shows the spread of the *tragion* points for those

subjects who did not complain of ear pain along with one of the subject's ears (subject 4). It can be seen that the points are not elliptical but seem to have a concave shape, indicating a rotational difference between ear locations. These four images together with the fit and comfort evaluations completed by the subjects enable an understanding of the geometry of ear fit in that helmet. Without the three-dimensional images, the fit and comfort scores are difficult to interpret.

The new challenge is to combine static three-dimensional models with human motion. The entertainment industry has been combining these two technologies, but their interest is in rapidly characterizing and sensationalizing the unreal rather than representing truth. Cheng and Robinette (2009) and Cheng et al. (2010) describe the challenge of characterizing true human variability dynamically and present some approaches to addressing the challenge.

## 5  SUMMARY

Whether a product is personal gear (such as clothing or safety equipment), the crew station of a vehicle, or the layout of an office workspace, accommodating the variation in shape and size of the future user population will have an impact on a product's ultimate success. This chapter describes and demonstrates the use of cases, fit mapping, and three-dimensional anthropometry to design effectively, simultaneously minimizing cost and maximizing accommodation. In the section on cases alternatives to the often misused percentiles are discussed, including the use of PCA. The section on fit mapping explains how to incorporate knowledge of the relationship between the human and the product. The best anthropometric data in the world are not

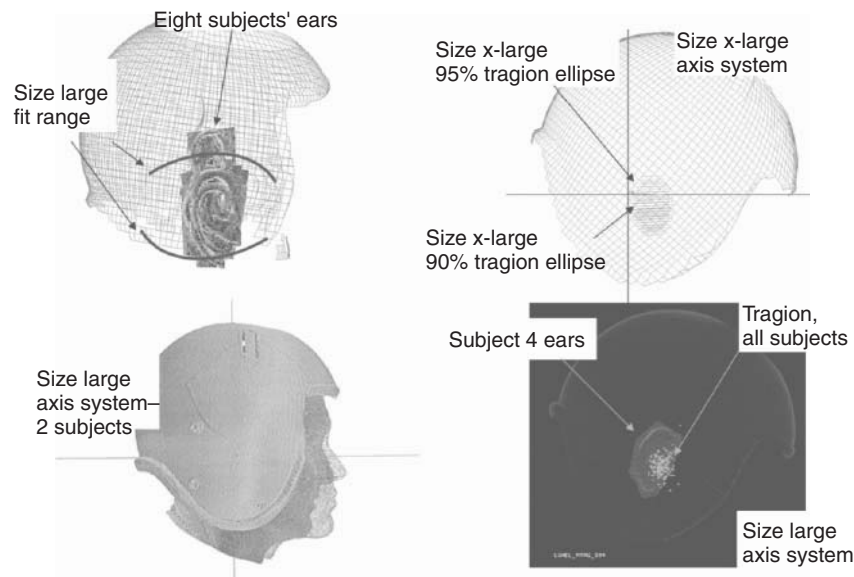

**Figure 17**  Three-dimensional scan visualizations to relate to fit-mapping data for ear fit within a helmet.

sufficient to create a good design if the relationship between the anthropometry and the product proportions that accommodate it is not known. Fit mapping is the study of this relationship. The fit-mapping process is described with examples to demonstrate its benefits.

Finally, for complex multidimensional design problems, three-dimensional imaging technology provides an opportunity to visualize and contrast the variation in a sample and to quantify the differences between locations of a product on subjects who are accommodated versus those who are not. The technology can also be used to capture shape or morphometric data, such as contour change, three-dimensional landmark locations, or soft tissue distribution that cannot be captured adequately with traditional anthropometry. Therefore, three-dimensional anthropometry offers comprehension of accommodation issues to a degree not possible previously.

**Columbus, Ohio**

## 1 DEFINITIONS

Occupational biomechanics is an interdisciplinary field in which information from both the biological sciences and engineering mechanics is used to quantify the forces present on the body during work. Biomechanics assumes that *the body behaves according to the laws of Newtonian mechanics*. Kroemer has defined mechanics as "*the study of forces and their effects on masses*" (Kroemer, 1987, p. 170). The object of interest in occupational ergonomics is a quantitative assessment of mechanical loading occurring within the musculoskeletal system. The goal of such an assessment is to quantitatively describe the musculoskeletal loading that occurs during work so that one can derive an appreciation for the degree of risk associated with work-related tasks. This

high degree of precision and quantification is the characteristic that distinguishes occupational biomechanics analyses from other types of ergonomic analyses. Thus, with biomechanical techniques the ergonomics can address the issue of "how much exposure to the occupational risk factors is too much exposure?"

The workplace biomechanical approach is often called industrial or occupational biomechanics. Chaffin et al. (2006) defined occupational biomechanics as "the study of the physical interaction of workers with their tools, machines, and materials so as to enhance the worker's performance while minimizing the risk of musculoskeletal disorders." The current chapter addresses occupational biomechanical issues concepts as they apply to work design.

## 2   ROLE OF BIOMECHANICS IN ERGONOMICS

The approach to a biomechanical assessment is to characterize the human−work system situation through a mathematical representation or model. The model is intended to represent the various underlying biomechanical concepts through a series of rules or equations in a "system" that helps us understand how the human body is affected by the various main effects and interactions associated with risk factor exposure. One can think of a biomechanical systems model as the "glue" that holds our logic together when considering the various factors that would affect risk in a specific work situation.

The advantage of representing the worker in a biomechanical model is that the model permits one to quantitatively consider the *trade-offs* associated with workplace risk factors to various parts of the body in the design of a workplace. It is difficult to accommodate all parts of the body in an ideal biomechanical environment since improving the conditions for one body segment often make things worse for another part of the body. Therefore, the key to the proper application of biomechanical principles is to consider the appropriate biomechanical trade-offs associated with various parts of the body as a function of the work requirements and the various workplace design options and constraints. Ultimately, biomechanical analyses would be most effective in predicting workplace risk during the design stage before the physical construction of the workplace has begun.

This chapter will focus upon the information required to develop proper biomechanical reasoning when assessing physical demands of a workplace. The chapter will first present and explain a series of key biomechanical concepts that constitute the underpinning of biomechanical reasoning. Second, these concepts will be applied to the various parts of the body that are often affected during work. Once this reasoning is established, we will examine how the various biomechanical concepts must be considered collectively in terms of trade-off when designing a workplace from an ergonomic perspective under realistic conditions. The logic in this chapter will demonstrate that one *cannot* successfully practice ergonomics by simply memorizing a set of "ergonomic rules" (e.g., keep the wrist straight or don't bend from the waist when lifting) or applying a generic checklist to a workplace situation. These types of rule-based design strategies often result in suboptimizing the workplace ergonomic conditions or changing workplaces with no payoff.

## 3   BIOMECHANICAL CONCEPTS

### 3.1   Load−Tolerance

A fundamental concept in the application of occupational biomechanics to ergonomics is that one should design workplaces so that the load imposed upon a structure does not exceed the tolerance of the structure (Figure 1). Figure 1 illustrates the traditional concept of biomechanical risk in occupational biomechanics (McGill, 1997). This figure illustrates how a loading pattern is developed on a body structure that is repeated as

**Figure 1**   Traditional concept of biomechanical risk.

the work cycles recur during a job. Structure tolerance is also shown in this figure. When the magnitude of the load imposed on a structure is less than the tissue tolerance, then the task is considered safe and the magnitude of the difference between the load and the tolerance is considered the safety margin. Implicit in this figure is the idea that risk occurs when the imposed load exceeds the tissue tolerance. While tissue tolerance is defined as the ability of the tissue to withstand a load without damage, ergonomists are beginning to expand the concept of tolerance to include not only mechanical tolerance of the tissue but also the point at which the tissue exhibits an inflammatory reaction.

A recent trend in occupational tasks has been increased repetition while handling lighter loads. The conceptual load−tolerance model can also be adjusted to also account for this type of risk exposure. Figure 2 shows that occupational biomechanics logic can account for this trend by decreasing the tissue tolerance over time. Hence, occupational biomechanics models and logic are moving toward systems that consider manufacturing and work trends in the workplace and attempt to represent these observations (such as cumulative trauma disorders) in the model logic.

### 3.2   Acute versus Cumulative Trauma

In occupational settings two types of trauma can affect the human body and lead to musculoskeletal disorders in occupational settings. First, *acute* trauma can occur

**Figure 2**   Realistic scenario of biomechanical risk.

when a single application of force is so large that it exceeds the tolerance of the body structure during an occupational task. Acute trauma is associated with large exertions of force that would be expected to occur infrequently, such as when a worker lifts an extremely heavy object. This situation would result in a peak load that exceeds the load–tolerance.

*Cumulative* trauma, on the other hand, refers to the repeated application of force to a structure that tends to wear down a structure, thus lowering its tolerance to the point where the tolerance is exceeded through a reduction of this tolerance limit (Figure 2). Cumulative trauma represents more of a "wear and tear" on the structure. This type of trauma is becoming more common in occupational settings as more repetitive jobs requiring lower force exertions become more prevalent in industry.

The cumulative trauma process can initiate a response resulting in a cycle that is extremely difficult to break. As shown in Figure 3, the cumulative trauma process begins by exposing the worker to manual exertions that are either frequent (repetitive) or prolonged. The repetitive application of force can affect either the tendons or the muscles of the body. If the tendons are affected, the tendons are subject to mechanical irritation as they are repeatedly exposed to high levels of tension. Groups of tendons may rub against each other. The physiological response to this mechanical irritation can result in inflammation and swelling of the tendon. The swelling will stimulate the nociceptors surrounding the structure and signal the central control mechanism

(brain) via pain perception that a problem exists. In response to this pain the body attempts to control the problem via two mechanisms. First, the muscles surrounding the irritated area will coactivate in an attempt to stabilize the joint and prevent motion of the tendons. Since motion will further stimulate the nociceptors and result in further pain, motion avoidance is indicative of the start of a cumulative trauma disorder and often indicated when workers shorten their motion cycle and move slower. Second, in an attempt to reduce the friction occurring within the tendon, the body can increase its production of lubricants (synovial fluid) within the tendon sheath. However, given the limited space available between the tendon and the tendon sheath, the increased production of synovial fluid often exacerbates the problem by further expanding the tendon sheath. This action further stimulates the surrounding nociceptors. This initiates a viscous cycle where the response of the tendon to the increased friction results in a reaction (inflammation and the increased production of synovial fluid) that exacerbates the problem (see Figure 3). Once this cycle is initiated, it is very difficult to stop and often anti-inflammatory agents are prescribed in order to break this cycle. The process results in chronic joint pain and a series of musculoskeletal reactions such as reduced strength, reduced tendon motion, and reduced mobility. Together, these reactions result in a functional disability.

Cumulative trauma can also affect the muscles. Muscles are overloaded when they become fatigued. Fatigue lowers the tolerance to stress and can result

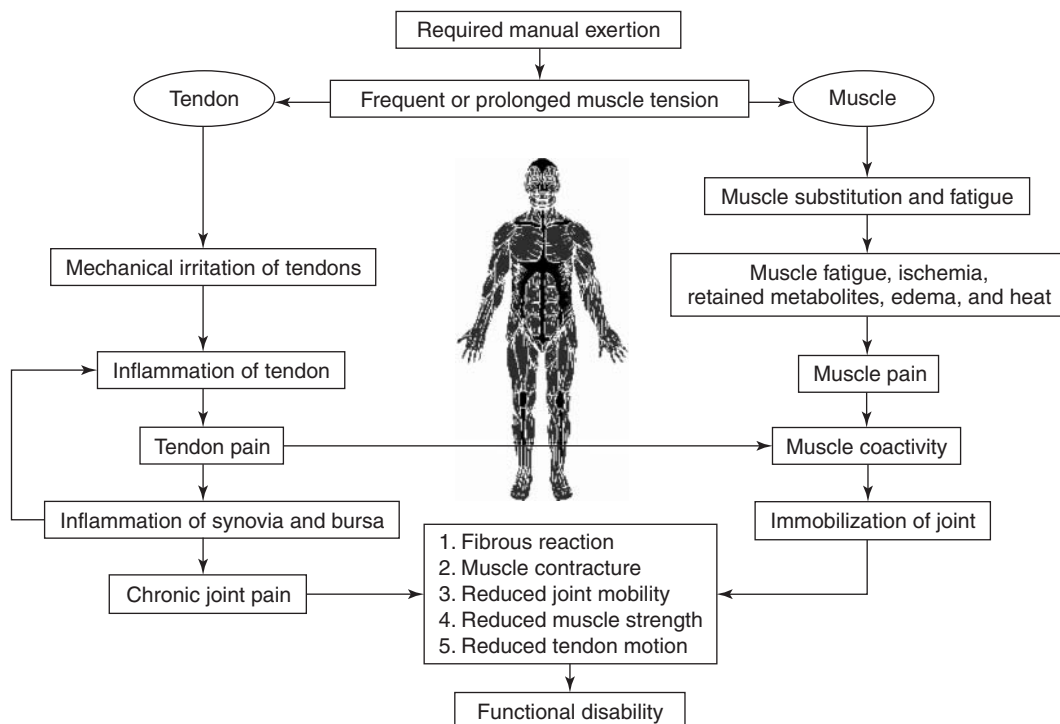

**Figure 3**  Sequence of events in cumulative trauma disorders.

in micro traumato the muscle fibers. This microtrauma typically means the muscle is partially torn, which causes capillaries to rupture and results in swelling, edema, or inflammation near the site of the tear. The inflammation can stimulate nociceptors and result in pain. Once again, the body reacts by cocontracting the surrounding musculature and minimizing the joint motion. However, since muscles do not rely on synovial fluid for their motion, there is no increased production of synovial fluid. However, the end result of this process is the same as that for tendons (i.e., reduced strength, reduced tendon motion, and reduced mobility). The ultimate consequence of this process is, once again, a functional disability.

Although the stimulus associated with the cumulative trauma process is somewhat similar between tendons and muscles there is a significant difference in the time required to heal from the damage to a tendon compared to a muscle. The mechanism of repair for both the tendons and muscles is dependent upon blood flow. Blood flow provides nutrients for repair as well as dissipates waste materials. However, the blood supply to a tendon is a fraction (typically about 5% in an adult) of that supplied to a muscle. Thus, given an equivalent strain to a muscle and a tendon, the muscle will heal rapidly (in about 10 days if not reinjured) whereas the tendon could take months (20 times longer) to accomplish the same level of repair. For this reason, ergonomists must be particularly vigilant in the assessment of workplaces that could pose a danger to the tendons of the body. This lengthy repair process also explains why many ergonomic processes place a high value on identifying potentially risky jobs before a lost-time incident occurs through mechanisms such as discomfort surveys.

### 3.3   Moments and Levers

Biomechanical loads are only partially defined by the magnitude of weight supported by the body. The position of the weight (or mass of the body segment) relative to the axis of rotation of the joint of interest defines the imposed load on the body and is referred to as a *moment*. A moment is defined as the product of force and distance. As an example, a mass of 50 N held at a horizontal distance of 75 cm (0.75 m) from the shoulder joint imposes a moment of 37.5 Nm (50 N × 0.75 m) on the shoulder joint, whereas the same weight held at a horizontal distance of 25 cm from the shoulder joint imposes a moment or load of only 12.5 Nm  (50 N × 0.25 m)  on the shoulder. Thus, the joint load is a function of where the load is held relative to the joint axis and the mass of the weight held. Hence, load is not simply a function of just weight.

As implied in the above example, moments are a function of the mechanical lever systems of the body. In biomechanics, the musculoskeletal system is represented by a system of levers and it is the lever systems that are used to describe the tissue loads with a biomechanical model. Three types of lever systems are common in the human body. First-class levers are those that have a fulcrum placed between the imposed load (on one end of the system) and an opposing force (*internal to the body*)

imposed on the opposite end of the system. The back or trunk is an example of a first-class lever. In this case, the spine serves as the fulcrum. As the human lifts, a moment (*load imposed external to the body*) is imposed anterior to the spine due to the object weight times the distance of the object from the spine. This moment is counterbalanced by the activity of the back muscles; however, they are located in such a way that they are at a mechanical disadvantage since the distance between the back muscles and the spine is much less than the distance between the object lifted and the spine.

A second-class lever system can be seen in the lower extremity. In the second-class lever situation the fulcrum is located at one end of the lever, the opposing force (internal to the body) is located at the other end of the system, and the applied load is in-between these two. The foot is a good example of this lever system. The ball of the foot acts as the fulcrum, the load is applied through the tibia or bone of the lower leg, and the restorative force is applied through the gastrocnemius or calf muscle. The muscle activates and causes the body to rotate about the fulcrum or ball of the foot and moves the body forward.

Finally, a third-class lever is one where the fulcrum is located at one end of the system, the applied load acts at the other end of the system, and the opposing (internal) force acts in between the two. An example of such a lever system in the human body is the elbow joint and is shown in Figure 4.

### 3.4   External versus Internal Loading

Based upon these lever systems, it is evident that two types of forces can impose loads on a tissue during work. *External* loads refer to those forces that are imposed on the body as a direct result of gravity acting upon an external object being manipulated by the worker. For example, Figure 4*a* shows a tool held in the worker's hand that is subject to the forces of gravity. This situation imposes a 44.5-N (10-lb) external load at a distance from the joint of 30.5 cm (12 in.) on the elbow joint. However, in order to maintain equilibrium, this external force must be counteracted by an *internal _force* generated by the muscles of the body. Figure 4*a* also shows that the internal load (muscle) acts at a distance relative to the elbow joint that is much closer to the fulcrum than the external load (tool). Thus, the internal force must be supplied at a biomechanical disadvantage (because of the smaller lever arm) and must be much larger (534 N, or 120 lb) than the external load (44.5 N, or 10 lb) in order to keep the musculoskeletal system in equilibrium. It is not unusual for the magnitude of the internal load to be much greater (often 10 times greater) than the external load. Thus, it is the internal loading that contributes most to cumulative trauma of the musculoskeletal system during work. The net sum of the external load and the internal load defines the total loading experienced at the joint. Therefore, when evaluating a workstation the ergonomist must not only consider the externally applied load but also be particularly sensitive to the magnitude of the internal forces that can load the musculoskeletal system.

**Internal load, F**

$F = 0.0254 \text{ m} = 44.5 \text{ N} = 0.305 \text{ m}$

$= \dfrac{44.5 \text{ N} = 0.305 \text{ m}}{0.0254 \text{ m}}$

$= 534.35 \text{ N (120 lb)}$

### 3.5 Modifying Internal Loads

The previous section has emphasized the importance of understanding the relationship between the external loads imposed upon the body and the internal loads generated by the force-generating mechanisms within the body. The key to proper ergonomic design is based upon the principle of designing workplaces so that the internal loads are minimized. Internal forces can be thought of as both the component that loads the tissue as well as a structure that can be subject to overexertion. Thus, muscle strength or capacity can be considered as a tolerance measure. If the forces imposed on the muscles and tendons as of a result of the task exceed the strength (tolerance) of the muscle or tendon, a potential injury is possible. Generally, three components of the physical work environment (biomechanical arrangement of the musculoskeletal lever system, length−strength relationships, and temporal relationships) can be manipulated in order to facilitate this goal and serve as the basis for many ergonomic recommendations.

### 3.6 Biomechanical Arrangement of the Musculoskeletal Lever System

The posture imposed via the design of the workplace can affect the arrangement of the body's lever system and thus can affect the magnitude of the internal load required to support the external load. The arrangement of the lever system could influence the magnitude of the external moment imposed upon the body as well as dictate the magnitude of the internal forces and the subsequent risk of either acute or cumulative trauma. If one considers the biomechanical arrangement of the

elbow joint (shown in Figure 4a), it is evident that the mechanical advantage of the internal force generated by the biceps muscle and tendon is defined by a posture keeping one's arm bent at a 90° angle. If one palpates the tendon and inserts the index finger between the elbow joint center and the tendon, one can gain an appreciation for the internal moment arm distance. It is also possible to appreciate how this internal mechanical advantage can change with posture. With the index finger still inserted between the elbow joint and the tendon, if the elbow joint is extended, one can appreciate how the distance between the tendon and the joint center of rotation is significantly reduced. If the imposed moment about the elbow joint is held constant (shown in Figure 4b by a heavier tool) under these conditions, the mechanical advantage of the internal force generator is significantly reduced. Thus, the bicep muscle must generate greater force in order to support the external load. This greater force is transmitted through the tendon and can increase the risk of cumulative trauma. Hence, the positioning of the mechanical lever system (which can be accomplished through work design) can greatly affect the internal load transmission within the body. A task can be performed in a variety of ways, but some of these positions are much more costly in terms of loading of the musculoskeletal system than others.

### 3.7 Optimizing the Length−Strength Relationship

Another important relationship that influences the load on the musculoskeletal system is the length−strength relationship of the muscles. This relationship is shown
**Figure 5** Length–tension relationship for a human muscle. [Adapted from Basmajian, J. V., and De Luca, C. J. (1985), *Muscles Alive: Their Functions Revealed by Electromyography*, 5th ed., Williams and Wilkins, Baltimore, MD.]

in Figure 5. The active portion of this figure refers to active force–generating structures such as muscles. When muscles are at their resting length (generally seen in the fetal position) they have the greatest capacity to generate force. However, when the muscle length deviates from this resting position, the muscle's capacity to generate force is greatly reduced because the cross-bridges between the components of the muscle proteins become inefficient. When a muscle stretches or when a muscle attempts to generate force while at a short length, the ability to generate force is greatly diminished. As indicated in Figure 5, passive tissues in the muscle (and ligaments) can also generate tension when muscles are stretched. Thus, the length of a muscle during task performance can greatly influence the force available to perform work and can influence risk by altering the available internal force within the system. Therefore, what might be considered a moderate force for a muscle at the resting length can become the maximum force a muscle can produce when it is

in a stretched or contracted position, thus, increasing the risk of muscle strain. When this relationship is considered in combination with the mechanical load placed on the muscle and tendon (via the arrangement of the lever system), the position of the joint arrangement becomes a major factor in the design of the work environment. Typically, the length–strength relationship interacts synergistically with the lever system. Figure 6 indicates the effect of elbow position on the force generation capability of the elbow. The joint position can have a dramatic effect on force generation and can greatly affect the internal loading of the joint and the subsequent risk of cumulative trauma.

### 3.8  Impact of Velocity on Muscle Force

Motion can also influence the ability of a muscle to generate force and, therefore, load the biomechanical system. Motion can be a benefit to the biomechanical system if momentum is properly employed or it can increase the load on the system if the worker is not taking advantage of momentum. This relationship between muscle velocity and force generation is shown in Figure 7. The figure indicates that, in general, the faster the muscle is moving, the greater the reduction in force capability of the muscle. This reduction in muscle capacity can result in the muscle strain that may occur at a lower level of external loading and a subsequent increase in the risk of cumulative trauma. In addition, this effect is considered in dynamic ergonomic biomechanical models.

### 3.9  Temporal Relationships

### 3.9.1  Strength–Endurance

Strengt h must be considered as both an internal force and a tolerance. However, it is important to realize that strength is transient. A worker may generate a great amount of strength during a one-time exertion; however, if the worker is required to exert his or her strength either repeatedly or for a prolonged period of time, the amount of force that the worker can generate can be reduced

**Figure 6** Position–force diagram produced by flexion of the forearm in pronation. ''Angle'' refers to included angle between the longitudinal axes of the forearm and upper arm. The highest parts of the curve indicate the configurations where the biomechanical lever system is most effective. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, JWiley, New York.]
**Figure 7** Influence of velocity upon muscle force. [Adapted from Astrand and Rodahl (1977), *The Textbook of Work Physiology*, McGraw-Hill, New York.]

dramatically. Figure 8 demonstrates this relationship. The dotted line in this figure indicates the maximum force generation capacity of a static exertion over time.

Maximum force is only generated for a very brief period of time. As time advances, strength output decreases exponentially and levels off at about 20% of maximum after about 7 min. Similar trends occur during repeated dynamic conditions. If a task requires a large portion of a worker's strength, one must consider how long that portion of the strength must be exerted in order to ensure that the work does not strain the musculoskeletal system.

### 3.9.2 Rest Time

As discussed earlier, the risk of cumulative trauma increases when the capacity to exert force is exceeded by the force requirements of the job. Another factor that may influence strength capacity (and tolerance to muscle strain) is rest time. Rest time has a profound effect on a worker's ability to exert force. Figure 9 summarizes how energy for a muscular contraction is regenerated during work. Adenosine triphosphate (ATP) is required to produce a power producing muscular contraction. ATP changes into to adenosine diphosphate (ADP) once a muscular contraction has occurred; however, the ADP is not capable of producing a significant muscular contraction. The ADP must be converted to ATP in order to enable another muscular contraction. This conversion to ATP can occur with the addition of oxygen to the system. If oxygen is not available, then the system goes into oxygen debt and insufficient ATP is available for a muscular contraction. Figure 9 indicates that oxygen is a key ingredient in order to maintain a high level of muscular exertion. Oxygen is delivered to the target muscles via the blood. Under static exertions the blood flow is reduced and there is a subsequent reduction in the blood available to the muscle. This restriction of blood flow and subsequent oxygen deficit

**Figure 8** Forearm flexor muscle endurance times in consecutive static contractions of 2.5 s duration with varied rest periods. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York.]
**Figure 9**   Body's energy system during work. [Adapted from Grandjean, E. (1982), *Fitting the Task to the Man: An Ergonomic Approach*, Taylor & Francis, London.]

are responsible for the rapid decrease in force generation over time, as shown in Figure 8. The solid lines in Figure 8 indicate how the force generation capacity of the muscles increases when different amounts of rest are permitted during a prolonged exertion. As more rest time is permitted, increases in force generation are achieved when more oxygen is delivered to the muscle and more ADP can be converted to ATP. This relationship indicates that any more than about 50 s of rest, under these conditions, does not result in a significant increase in force generation capacity of the muscle. Practically, this relationship indicates that in order to optimize the strength capacity of the worker and minimize the risk of muscle strain a schedule of frequent and brief rest periods would be more beneficial than lengthy, infrequent rest periods.

### 3.10   Load Tolerance

Biomechanical analyses must consider not only the loads imposed upon a structure but also the ability of the structure to withstand or tolerate a load during work. This section will briefly review the knowledge base associated with human structure tolerances.

#### 3.10.1   Muscle, Ligament, Tendon, and Bone Capacity

The precise tolerance characteristics of human tissues such as muscles, ligaments, tendons, and bones loaded under various working conditions are difficult to estimate. Tolerances of these structures vary greatly under similar loading conditions. In addition, tolerance depends upon many other factors, such as strain rate, age of the structure, frequency of loading, physiological influences, heredity, conditioning, as well as other, unknown factors. Furthermore, it is not possible to measure these tolerances under in vivo conditions. Therefore, most of the estimates of tissue tolerance have been derived from various animal and/or theoretical sources.

#### 3.10.2   Muscle and Tendon Strain

The muscle is the structure within the musculoskeletal system that has the lowest tolerance. The ultimate strength of a muscle has been estimated to be 32 MPa

(Hoy et al., 1990). In general, it is believed that the muscle will rupture prior to the (healthy) tendon (Nordin and Frankel, 1989) since tendon stress has been estimated at between 60 and 100 MPa (Hoy et al., 1990; Nordin and Frankel, 1989). It is commonly believed that there is a safety margin between the muscle failure point and the failure point of the tendon of about two- (Nordin and Frankel, 1989) to threefold (Hoy et al., 1990). Thus, tendon failure it generally thought to occur at around 60–100 MPa.

#### 3.10.3   Bone Tolerance

Bone tolerances have also been estimated in the literature (Ozkaya and Nordin, 1991). The ultimate stress of bone depends upon the direction of loading. Bone tolerance can range from 51 MPa in transverse tension to over 133 MPa in transverse compression and from 133 MPa in longitudinal loading tension to 193 MPa in longitudinal compression and 68 MPa in shear.

#### 3.10.4   Ligament Tolerance

In general, ultimate ligament stress has been estimated to be approximately 20 MPa. However, ligament properties vary greatly depending on their location within the body. Table 1 shows an overview of these properties as a function of their location. Note the much greater tolerances associated with greater body load bearing.

A strong temporal component to ligament recovery has also been identified. Solomonow found that ligaments require long periods of time to regain structural integrity during which compensatory muscle activities are observed (Solomonow, 2004; Solomonow et al., 1998, 1999, 2000, 2002; Stubbs et al, 1998; Gedalia et al, 1999; Wang et al., 2000). Recovery time has been observed to be several times the loading duration and can easily exceed the typical work–rest cycles observed in industry.

#### 3.10.5   Disc/End-Plate and Vertebrae Tolerance

The mechanism of cumulative trauma to the vertebral disc is thought to be associated with repeated trauma

**Table 1  Range of Ligament Tolerance Characteristics for Different Parts of Body**

to the vertebral end plate. The end plate is a very thin (about 1-mm-thick) structure that facilitates nutrient flow from the vertebrae to the disc fibers (annulus fibrosis). The disc has no direct blood supply so it relies heavily on this nutrient flow for disc viability. Repeated microfracture of this vertebral end plate is thought to lead to the development of scar tissue which can impair the nutrient flow to the disc fibers. This, in turn, leads to atrophy of the fiber and fiber degeneration. Since the disc contains few nociceptors, the development of microfractures is typically unnoticed by the individual. Given this process, if one can determine the level at which the end plate experiences a microfracture, one can then minimize the effects of cumulative trauma and disc degeneration within the spine.

Several studies of in vitro disc end-plate tolerance have been reported in the literature. Figure 10 indicates the levels of end-plate compressive loading tolerance that have been used to establish safe lifting situations at the worksite [National Institute for Occupational Safety and Health (NIOSH), 1981]. This figure shows the compressive force mean (column value) as well as the compression force distribution (thin line and normal distribution curve) that would result in vertebral end-plate microfracture. The figure indicates that, for those under 40 years of age, end-plate microfracture

damage begins to occur at about 3432 N of compressive load on the spine. If the compressive load is increased to 6375 N, approximately 50% of those exposed will experience vertebral end-plate microfracture. Finally, when the compressive load on the spine reaches a value of 9317 N, almost all of those exposed to the loading will experience a vertebral end-plate microfracture. It is also obvious from this figure that the tolerance distribution shifts to lower levels with increasing age (Adams et al., 2000). In addition, it should be recognized that this tolerance is based upon compression of the vertebral end plate alone. Shear and torsional forces in combination with compressive loading would further lower the tolerance of the end plate.

This vertebral end-plate tolerance distribution has been widely used to set limits for spine loading and define risk. It should also be noted that others have identified different limits of vertebral end-plate tolerance. Jager et al. (1991) have reviewed the spine tolerance literature and suggested different compression value limits. Their spine tolerance summary is shown in Table 2. They have also been able to describe vertebral compressive strength based upon an analysis of 262 values collected from 120 samples. According to their data, the compressive strength of the lumbar spine can
**Figure 10**   Mean and range of disc compression failures by age. [Adapted from National Institute for Occupational Safety and Health (NIOSH) (1981), ''Work Practices Guide for Manual Lifting,'' Publication No. 81-122, Department of Health and Human Services (DHHS), NIOSH, Washington, DC.]

**Table 2  Lumbar Spine Compressive Strength**

| Population | $n$ | Strength, kN | |
| --- | --- | --- | --- |
| | | Mean | s.d. |
| Females | 132 | 3.97 | 1.50 |
| Males | 174 | 5.81 | 2.58 |
| Total | 507 | 4.96 | 2.20 |

*Source*: Jager et al., 1991

be described according to a regression equation:

$$\text{Compressive Strength (kN)} = (7.26 + 1.88G) - 0.494 \\ + 0.468G) \times A + (0.042 + 0.106G) \times C - 0.145 \\ \times L - 0.749 \times S$$

where

$A$ = age in decade
$G$ = gender coded as 0 for female or 1 for male
$C$ = cross-sectional area of vertebrae, cm$^2$
$L$ = lumbar level unit, where 0 is the L5/S1 disc, 1 represents the L5 vertebrae, etc., through 10. which represents the T10/L1 disc
$S$ = structure of interest, where 0 is a disc and 1 is a vertebrae

This equation suggests that the decrease in strength within a lumbar level is about 0.15 kN of that of the adjacent vertebrae and that the strength of the vertebrae is about 0.8 kN lower than the strength of the discs (Jager et al., 1991). This equation can account for 62% of the variability among the samples.

It has also been suggested that spine tolerance limits vary as a function of frequency of loading (Brinkmann et al., 1988). Figure 11 indicates how spine tolerance varies as a function of spine load level and frequency of loading.

Finally, more recent investigations have shown that disc and end-plate tolerances vary greatly with flexion angle of the spine (Callahan and McGill, 2001; Gallagher et al., 2005). These studies have indicated that risk increases sharply at extreme spine flexion. This information suggests that tolerances to mechanical loading drop sharply at the end of the flexion range, especially under dynamic loading conditions.

### 3.10.6  Pain Tolerance

Over the past decade we have learned that there are numerous pathways to pain perception associated with musculoskeletal disorders (Khalsa, 2004; Cavanaugh et al, 1997; Cavanaugh, 1995). It is important to understand these pathways since these pathways may be able to be used as tissue tolerance limits as opposed to tissue damage limits. Hence, one might be able to consider the quantitative limits above which a pain pathway is initiated as a tolerance limit for ergonomic purposes. While none of these pathways have been defined quantitatively, they represent an appealing approach since they represent biologically plausible mechanisms that complement the view of injury association derived from the epidemiological literature.

Several categories of pain pathways are believed to exist that might be used as tolerance limits in the design of the workplace. These categories are (1) structural disruption, (2) tissue stimulation and proinflammatory response, (3) physiological limits, and (4) psychophysical acceptance. Each of these pathways is expected to respond differently to mechanical loading of the tissue and thus serve as tolerance limits. Although many of these limits have yet to be quantitatively defined, current biomechanical research is attempting to define these tolerances, and it is expected that one will be able to one day use these limits to identify the characteristics of a dose–response relationship.
**Figure 11** Probability of a motion segment to be fractured in dependence on the load range and the number of load cycles. [Adapted from Brinckmann, P., Biggemann, M., and Hilweg, D. (1988), ''Fatigue Fracture of Human Lumbar Vertebrae,'' *Clinical Biomechanics*, Vol. 3, Suppl. 1, pp. S1–S23.]

## 4 APPLICATION OF BIOMECHANICAL PRINCIPLES TO REDUCING STRESS IN THE WORKPLACE

These basic concepts and principles of biomechanics can now be applied to workplace design situations. Different body parts, due to differences in structure, are affected by work design in different ways. This section will discuss, in general, how the established biomechanical principles relate to biomechanical loading of the parts of the body often affected by work.

### 4.1 Shoulder

Shoulder pain is believed to be one of the most under-recognized occupationally related musculoskeletal disorders. Shoulder disorders are increasingly being recognized as a major workplace problem by those organizations that have reporting systems sensitive enough to detect such trends. The shoulder is one of the more complex structures of the body with numerous muscles and ligaments crossing the shoulder joint girdle complex. Because of this biomechanical complexity, surgical repair can be problematic. During shoulder surgeries it is often necessary to damage much of the surrounding tissue in an attempt to reach the structure in need of repair. The target structure is often small (e.g., a joint capsule) and difficult to reach. Thus, often damage is done to surrounding tissues that may offset the benefit surgery. Hence, the best course of action is to ergonomically design workstations so that risk of initial injury is minimized.

Since the shoulder joint is biomechanically complex, much of our biomechanical knowledge is derived from empirical evidence. The shoulder represents a statically indeterminate system in that we can typically measure six external moments and forces acting about the point of rotation, yet there are far more internal forces (over 30 muscles and ligaments) that are capable of counteracting the external moments. Thus, quantitative estimates of shoulder joint loading are not common for ergonomic purposes.

When shoulder intensive work is considered, optimal workplace design is typically defined in terms of preferred posture during work. Shoulder *abduction*, defined as the elevation of the shoulder in the lateral direction, is often a problematic posture when work is performed overhead. Figure 12 indicates shoulder performance measures in terms of both available strength and perceived fatigue when the shoulder is held at varying degrees of abduction. The figure indicates that the shoulder can produce a considerable amount of force throughout shoulder abduction angles of between 30° and 90°. However, when comparing reported fatigue at these same abduction angles, it is apparent that fatigue increases rapidly as the shoulder is abducted above 30°. Thus, even though strength is not an issue at shoulder abduction angles up to 90°, fatigue becomes the limiting factor. Therefore, the only position of the shoulder that is acceptable from both a strength and fatigue standpoint is a shoulder abduction of at most 30°.

Shoulder *flexion* has been examined almost exclusively as a function of reported fatigue. Chaffin (1973) has shown that even slight shoulder flexion can influence fatigue of the shoulder musculature. Figures 13 and 14 indicate the effects of vertical and horizontal positioning of the work, respectively, during shoulder flexion while seated, upon fatigability of the shoulder musculature. Fatigue occurs more rapidly as the worker's arm becomes more elevated (Figure 13). This trend is most likely due to the fact that the muscles are deviated from the neutral position as the shoulder becomes more elevated, thus affecting the length–strength relationship (Figure 5) of the shoulder muscles. Figure 14 indicates that as the horizontal distance between the work and the body is increased the time to reach significant fatigue is decreased. This is due to the fact that as a load is held
**Figure 12** Shoulder abduction strength and fatigue time as a function of shoulder abducted from the torso. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York.]

**Figure 13** Expected time to reach significant shoulder muscle fatigue for varied arm flexion postures. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York.]
**Figure 14** Expected time to reach significant shoulder muscle fatigue for different forward arm reach postures. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York.]

further from the body more of the external moment (force × distance) must be supported by the shoulder. Thus, the shoulder muscles must produce a greater internal force when the load is held further from the body. With this increased force they fatigue quicker. Elbow supports can significantly increase the endurance time in these postures. In addition an elbow support changes the biomechanical situation by providing a fulcrum at the elbow. Thus, the axis of rotation becomes the elbow instead of the shoulder, and this makes the external moment much less. This not only increase the time one can maintain a posture but also significantly increases the external load one can hold in the hand (Figure 15).

### 4.2 Neck

Neck disorders may also be associated with sustained work postures. Generally, the more upright the posture of the head, the less muscle activity and neck strength are required to maintain the posture. Upright neck positions also have the advantage of reducing the extent of fatigue experienced in the neck (Figure 16). This figure indicates that when the head is tilted forward by $30°$ or more from the vertical position, the time to experience significant neck fatigue decreases rapidly. From a biomechanical standpoint, as the head is flexed, the center of mass of the head moves forward relative to
**Figure 15** Expected time to reach significant shoulder and arm muscle fatigue for different arm postures and loads with the elbow supported. The greater the reach, the shorter the endurance time. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York.]

the base of support of the head (spine). Therefore, as the head is moved forward, more of a moment is imposed about the spine and this necessitates increased activation of the neck musculature and greater probability of fatigue (since a static posture is maintained by the neck muscles). On the other hand, when the head is not flexed forward and is relatively upright, the neck can be positioned in such a way that minimal muscle activity is required of the neck muscles and thus fatigue is minimized.

### 4.3 Trade-Offs in Work Design

The key to proper ergonomic design of a workplace from a biomechanical standpoint is to consider the biomechanical trade-offs associated with a particular work situation. These trade-offs are necessary because it is often the case that a situation that is advantageous for one part of the body is disadvantageous for another part of the body. Thus, many biomechanical considerations in the ergonomic design of the workplace require one to consider the various trade-offs and rationales for various design options.

One of the most common trade-off situations encountered in ergonomic design is the trade-off between accommodating the shoulders and accommodating the neck. This trade-off is often resolved by considering the hierarchy of needs required by the task. Figure 17 illustrates this logic. It shows the recommended height of the work as a function of the type of work that is to be performed. Precision work requires a high level of visual acuity that is of utmost importance in order to accomplish the work task. If the work is performed at too low of a level, the head must be flexed in order to accommodate the visual requirements of the job. This situation could result in significant neck discomfort. Therefore, in this situation, visual accommodation is at the top of the hierarchy of task needs and the work is typically raised to a relatively high level (95–110 cm above the floor). This position accommodates the neck but creates a problem for the shoulders since they must be abducted when the work level is high. Thus, a trade-off must be considered. In this instance, ideal shoulder posture is sacrificed in order to accommodate the neck since the visual requirements of the job are great while the shoulder
**Figure 16** Neck extensor fatigue and muscle strength required vs. head tilt angle. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York.]

strength required for precision work is low. Thus, visual accommodation is given a higher priority in the hierarchy of task needs. In addition, shoulder disorder risk can be minimized by providing wrist or elbow supports.

The other extreme of the working height situation involves heavy work. The greatest demand on the worker in heavy work is for a high degree of arm strength, whereas visual requirements in this type of work are typically minimal. Thus, the shoulder position is higher on the hierarchy of task needs in this situation. Therefore, in this situation ideal neck posture is typically sacrificed in favor of more favorable shoulder and arm postures. Hence, heavy work is performed at a height of 70–90 cm above floor level. With the work set at this height, the position the elbow angles are close to 90°, which maximizes strength (Figure 6), and the shoulders are close to 30° of abduction, which minimizes fatigue. In this situation, the neck is not in an optimal position,

but the logic dictates that the visual demands of a heavy task would not be substantial and, thus, the neck should not be flexed for prolonged periods of time.

A third work height situation involves light work. Light work is a mix of moderate visual demands with moderate strength requirements. In such a situation, work is a compromise between shoulder position and visual accommodation and neither the visual demands of the job nor the strength requirements dominate the hierarchy of job demands. Both are important considerations. The solution is to minimize the negative aspects of both the strength and neck posture situations by "splitting the difference" between extreme situations. Thus, the height of the work is set at a height between those of the precision work height level and the heavy-work height level. This situation leads to a situation where the work is performed at a level of between 85 and 95 cm off the floor under light-work conditions.
**Figure 17**   Recommended heights of bench for standing work. The reference line (+0) is the height of the elbows above the floor. [From Grandjean, E. (1982), *Fitting the Task to the Man: An Ergonomic Approach*, Taylor & Francis, London. With permission.]

## 4.4  The Back

Low-back disorders (LBDs) have been identified as one of the most common and significant musculoskeletal problems in the United States that results in substantial amounts of morbidity, disability, and economic loss (Hollbrook et al., 1984; Praemer et al., 1992; Guo et al., 1999). Low-back disorders are one of the most common reasons for missing work. Back disorders were responsible for the loss of more than 100 million lost workdays in 1988 with 22 million cases reported that year (Guo et al., 1999; Guo, 1993). Among those under 45 years of age, LBD is the leading cause of activity limitations and it can affect up to 47% of workers with physically demanding jobs (Andersson, 1997). The prevalence of LBD is also on the rise. It has been reported to have increased by 2700% since 1980 (Pope, 1993). Costs associated with LBD are also significant with health care expenditures incurred by individuals with back pain in the United States exceeding $90 billion per year in 1998 (Luo et al., 2004).

It is clear that the risk of LBD is associated with occupational tasks [National Research Council (NRC), 1999, 2001]. Thirty percent of occupation injuries in the United States are related to overexertion, lifting, throwing, holding, carrying, pushing, and/or pulling objects that weigh 50 lb or less. Around 20% of all workplace injuries and illnesses are back injuries which account for up to 40% of compensation costs. Estimates of occupational annual LBD prevalence vary from 1 to 15% depending upon occupation and, over a career, can seriously affect 56% of workers.

Manual materials handling (MMH) activities, specifically lifting, are most often associated with occupationally related LBD risk. It is estimated that lifting and MMH account for up to two-thirds of work-related back injuries (NRC, 2001). Biomechanical assessments target disc-related problems since disc problems are the most serious and costly type of back pain and have

a mechanical origin (Nachemson, 1975). The literature reports increased degeneration in the spines of cadaver specimens who had previously been exposed to physically heavy work (Videman et al., 1990). These findings suggest that occupationally related LBDs are closely associated with spine loading.

### 4.4.1  Significance of Moments

The most important component of occupationally related LBD risk is that of the external moments imposed about the spine (Marras et al., 1993, 1995). As with most biomechanical systems, loading is influenced greatly by the external moment imposed upon the system. However, because of the biomechanical disadvantage at which the torso muscles operate relative to the trunk fulcrum during lifting, very large loads can be generated by the muscles and imposed upon the spine. Figure 18 shows an idealized biomechanical arrangement of lever system. The back musculature is at a severe biomechanical disadvantage in many manual materials-handling situations. Supporting an external load of 222 N (about 50 lb) at a distance of 1 m from the spine imposes a 222-Nm external moment load about the spine. However, since the spine's supporting musculature is at a relatively close proximity relative to the external load, the trunk musculature must exert extremely large forces (4440 N, or 998 lb) to simply hold the external load in equilibrium. The internal loads can increase greatly if dynamic motion of the body is considered (since force is a product of mass and acceleration). Thus, this moment concept dominates risk interpretation in workplace design from a back protection standpoint. Thus, a fundamental issue is to keep the external load's moment arm at a minimum.

A recent study in distribution centers has shown that exposure to large sagittal bending moments when combined with greater lateral spine velocity and exposure to peak moments occurring late in the lift cycle are associated with a significant decrease in spine function over

Internal muscle force, F

$$F \cdot 5 \text{ cm} = 222 \text{ N} \cdot 1 \text{ m}$$

$$= \frac{222 \text{ N} \cdot \text{m}}{0.05 \text{ m}}$$

$$= 4440 \text{ N (998 lb)}$$
**Figure 18** Internal muscle force required to counterbalance an external load during lifting.

time (Marras et al., 2010). This effort emphasizes the importance of multiple dimensions of risk factors and the interaction of risk factors associated with moment exposure. It is clear from this work that exposure to high load moments in conjunction with dynamic loading factors greatly increases the chances of LBDs due to work tasks.

The concept of minimizing the external moment during lifting has major implications for lifting styles or the best "way" to lift. Since the externally applied moment during a lift significantly influences the internal loading, the lifting style is of far less concern compared to the magnitude of the applied moment. Some have suggested that proper lifting involves lifting "using the legs" or using the "stoop" lift method (bending from the waist). In addition, research has shown that spine load is a function of anthropometry as well as lifting style (Chaffin et al., 2006). Hence, biomechanical analyses (van Dieen et al., 1999; Park and Chaffin, 1974) have demonstrated that no one lift style is correct for all body types. For this reason, the NIOSH (1981) has concluded that lift style need not be a consideration when assessing risk due to materials handling. Some have suggested that the internal moment within the torso is optimized when lumbar lordosis is preserved during the lift (NIOSH, 1981; McGill et al., 2000; McGill, 2002; Anderson et al., 1985). However, from a practical, biomechanical standpoint, the primary indicator of spine loading and, thus, the correct lifting style is whatever style permits the worker to bring the center of mass of the load as close to the spine as possible.

### 4.4.2 Seated versus Standing Workplaces

Seated workplaces have become more prominent with modern work, especially with the aging of the workforce and the introduction of service-oriented and data-processing jobs. It has been documented that loads on the lumbar spine are greater when a worker is seated

compared to standing (Andersson et al., 1975). This is true since the posterior (bony) elements of the spine form an active load path when one is standing. However, when seated these elements are disengaged and more of the load passes through the intervertebral disc. Thus, work performed in a seated position puts the worker at greater risk of spine loading and, therefore, greater risk of damaging the disc. Given this mechanism of spine loading, it is important to consider the design features of a chair since it may be possible to influence disc loading through chair design. Figure 19 shows the results of a study involving pressure measurements taken within the intervetebral disc of individuals as the back angle of the chair and magnitude of lumbar support were varied (Andersson et al., 1975). It is infeasible to directly measure the forces in the spine in vivo. Therefore, disc pressure measures have traditionally been used as a rough approximation of loads imposed upon the spine. This figure indicates that both the seat back angle and lumbar support features have a significant impact on disc pressure. Disc pressure decreases as the backrest angle is increased. However, increasing the backrest angle in the workplace is often not practical since it can also move the worker farther away from the work and thereby increase external moment. Figure 19 also indicates that increasing lumbar support can significantly reduce disc pressure. This reduction in disc pressure is due to the fact that as lumbar curvature (lordosis) is reestablished (with lumbar support) the posterior elements play more of a role in providing an alternative load path, as is the case when standing in the upright position.

Less is known about risk to the low back relative to prolonged standing. The trunk muscles may experience low-level static exertion conditions and may be subject to the static overload through the muscle static fatigue process described in Figure 9. Muscle fatigue can result in lowered muscle force generation capacity and can, thus, initiate the cumulative trauma sequence of events (Figure 3). The fatigue and cumulative trauma sequence can be minimized through two actions. First, foot rails can provide a mechanism to allow relaxation of the large back muscles and thus increased blood flow to the muscle. This reduces the static load and subsequent fatigue in the muscle by the process described in Figure 9. When a leg is rested on the foot rest, the large back muscles are relaxed on one side of the body and the muscle can be supplied with oxygen. Alternating legs placed on the foot rest provides a mechanism to minimize back muscle fatigue throughout the day. Second, floor mats can decrease the fatigue in the back muscles provided that the mats have proper compression characteristics (Kim et al., 1994). Floor mats are believed to facilitate body sway, which enhances the pumping of blood through back muscles, thereby minimizing fatigue.

Knowledge of when standing workplaces are preferable to seated workplaces is dictated mainly by work performance criteria. In general, *standing* workplaces are preferred when (1) the task required a high degree of mobility (when reaching and monitoring in positions that exceed the employee's reach envelope or performing tasks at different heights or different locations), (2) precise manual control actions are not required, (3) leg room is not available (when leg room is not available the moment arm distance between the external load and
**Figure 19** Disc pressures measured with different backrest inclinations and different-size lumbar supports. [From Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York. With permission.]

the back is increased and thus greater internal back muscle force and spinal load result), and (4) heavy weights are handled or large forces are applied. When jobs must accommodate both sitting and standing postures, it is important to ensure that the positions and orientations of the body, especially the upper extremity, are in the same location under both standing and sitting conditions.

### 4.5  Wrists

The Bureau of Labor Statistics reports that repetitive trauma had increased in prevalence from 18% of occupational illnesses in 1981 to 63% of occupational illnesses in 1993. Based upon these figures repetitive trauma has been described as a growing occupationally related problem. Although these numbers and statements appear alarming, one must realize that occupational illnesses represent only 6% of all occupational injuries and illnesses. Furthermore, the statistics for illness include illnesses unrelated to musculoskeletal disorders such as noise-induced hearing loss. Thus, the magnitude of the cumulative trauma problem should not be overstated. Nonetheless, there are specific industries (i.e., meat packing, poultry processing, etc.) where cumulative trauma to the wrist is a major problem and the problem has reached epidemic proportions within these industries.

#### 4.5.1  Wrist Anatomy and Loading

In order to understand the biomechanics of the wrist and how cumulative trauma occurs, one must appreciate the anatomy of the upper extremity. Figure 20 shows a simplified anatomical drawing of the wrist joint complex. The hand has few power-producing muscles in the hand itself. The thenar muscle, which activates

**Figure 20**  Important anatomical structures in the wrist.

the thumb, is one of the few power-producing muscles located in the hand. The vast majority of the power-producing muscles are located in the forearm. Force is

transmitted from these forearm muscles to the fingers through a series of tendons (tendons attach muscles to bone). The tendons originate at the muscles in the forearm, transverse the wrist (with many of them passing through the carpal canal), pass through the hand, and culminate at the fingers. These tendons are secured, or "strapped down," at various points along this path with ligaments that keep the tendons in close proximity to the bones, forming a pulley system around the joints. This results in a system (the hand) that is very small and compact yet capable of generating large amounts of force. However, the price the musculoskeletal system pays for this design is friction. The forearm muscles must transmit force over a long distance in order to supply internal forces to the fingers. Thus, a great deal of tendon travel must occur and this tendon travel can result in tendon friction under repetitive-motion conditions, thereby initiating the events outlined in Figure 3. The key to controlling wrist cumulative trauma is embedded in an understanding of those workplace factors that adversely affect the internal force generating (muscles) and transmitting (tendons) structures.

### 4.5.2 Biomechanical Risk Factors

A number of risk factors for upper extremity cumulative trauma disorders have been documented in the literature. Most of these risk factors have a biomechanical basis for their risk. First, deviated wrist postures reduce the volume of the carpal tunnel and, thus, increase tendon friction. In addition, grip strength is dramatically reduced once wrist posture is deviated from the neutral position. Figure 21 demonstrates the magnitude of grip strength decrement due to any deviation from the wrist's neutral position. The reduction in strength is caused by a change in the length–strength relationship (Figure 5) of the forearm muscles when the wrist is deviated from the neutral posture. Hence, the muscles must work at level lengths that are nonoptimal when the wrist is

bent. This reduced strength associated with deviated wrist positions can, therefore, more easily initiate the sequence of events associated with cumulative trauma (Figure 3). Therefore, deviated wrist postures not only increase tendon travel and friction but also increase the amount of muscle strength necessary to perform the gripping task.

Second, increasing the frequency or repetition of the work cycle has also been identified as a risk factor for cumulative trauma disorders (CTDs) (Silverstein et al., 1996, 1997). Studies have shown that increased frequency of wrist motions increases the risk of cumulative trauma disorder reporting. Repeated motions requiring a cycle time of less than 30 s are considered candidates for cumulative trauma. Increased frequency is believed to increase the friction within the tendons, thereby accelerating the cumulative trauma progression described in Figure 3.

Third, the force applied by the hands and fingers during a work cycle has been identified as a cumulative trauma risk factor. In general, the greater the force required by the work, the greater the risk of CTD. Greater hand forces result in greater tension within the tendons and greater tendon friction and tendon travel. Another factor related to force is that of wrist acceleration. Industrial surveillance studies report that repetitive jobs resulting in greater wrist acceleration are associated with greater CTD incident rates (Schoenmarklin et al., 1994; Marras and Schoenmarklin, 1993). Force is a product of mass and acceleration. Thus, jobs that increase the angular acceleration of the wrist joint result in greater tension and force transmitted through the tendons. Therefore, wrist acceleration can be another mechanism to impose force on the wrist structures.

Finally, as shown in Figure 20, the anatomy of the hand is such that the median nerve becomes very superficial at the palm. Direct impacts to the palm through pounding or striking an object (with the palm)

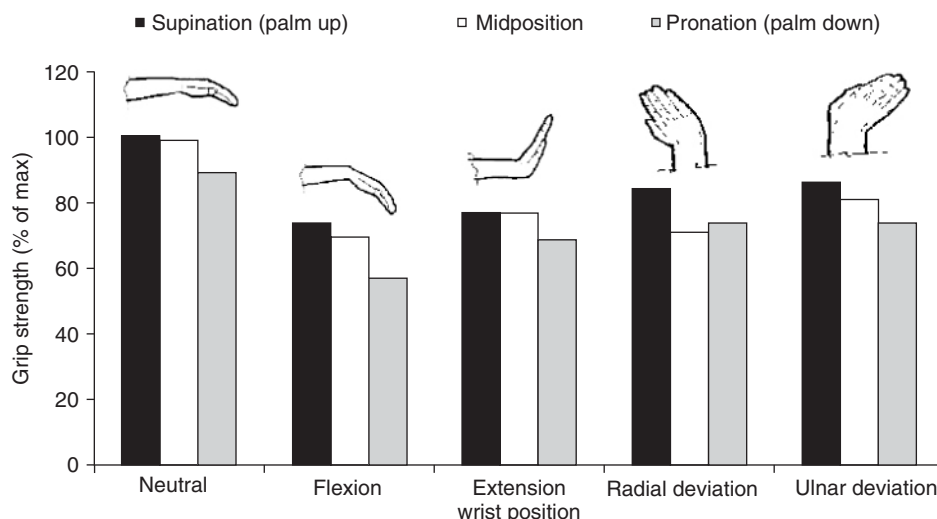

**Figure 21** Grip strength as a function of wrist and forearm position. [Adapted from Sanders, M. S., and McCormick, E. F. (1993), *Human Factors in Engineering and Design*, McGraw-Hill, New York.]
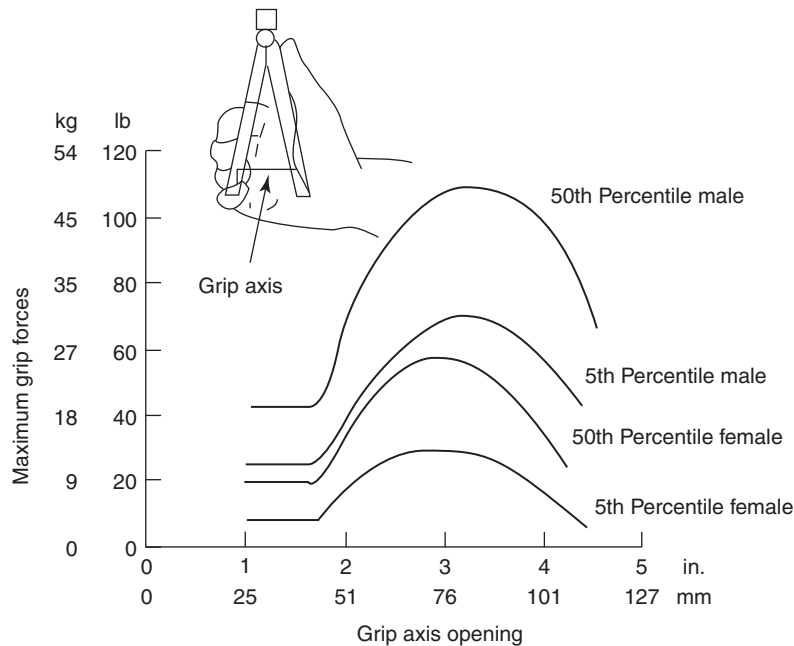

**Figure 22**  Grip strength as a function of grip opening and hand anthropometry. [Adapted from Sanders, M. S., and McCormick, E. J. (1993), *Human Factors in Engineering and Design*, McGraw-Hill, New York.]

can directly assault the median nerve and initiate symptoms of cumulative trauma even though the work may not be repetitive.

### 4.5.3  Grip Design

The design of a tool's gripping surface can impact the activity of the internal force transmission system (tendon travel and tension). Grip opening and shape have a major influence on the available grip strength. Figure 22 indicates how grip strength capacity changes as a function of the separation distance of the grip opening. This figure indicates that maximum grip strength occurs within a very narrow range of grip span. If the grip opening deviates from this ideal range by as little as an inch (a couple of centimeters), then grip strength is markedly reduced. This reduction in strength is, once again, due to the length–strength relationship of the forearm muscles. Also indicted in Figure 22 are the effects of hand size. The worker's hand anthropometry as well as hand preference can influence grip strength and risk. Therefore, proper design of tool handles is crucial in optimizing ergonomic workplace design.

Handle shape can also influence the strength of the wrist. Figure 23 shows how changes in the design of screwdriver handles can impact the maximum force that can be exerted on the tool. The biomechanical origin of these differences in strength capacity is believed to be related to the length–strength relationship of the forearm muscles as well as contact area with the tool. The handle designs resulting in diminished strength permit the wrist to twist or the grip to slip, resulting in a deviation from the ideal length–strength position in the forearm muscles.

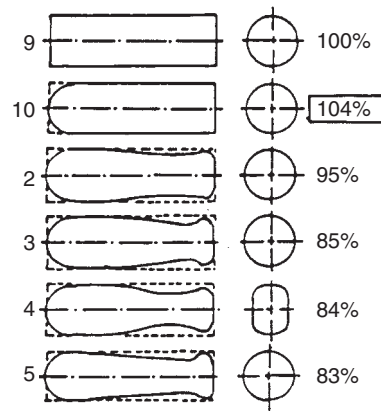

**Figure 23**  Maximum force which could be exerted on a screwdriver as a function of handle shape. [From Konz, S. A. (1983), *Work Design: Industrial Ergonomics*, 2nd ed., Grid Publishing, Columbus, OH. With permission.]

### 4.5.4  Gloves

The use of gloves can also significantly influence the generation of grip strength and may play a role in the development of cumulative trauma disorders. When gloves are worn during work, three factors must be considered. First, the grip strength that is generated is often reduced. Typically, a 10–20% reduction in grip strength is noted when gloves are worn. Gloves reduce the coefficient of friction between the hand and the tool, which in turn permit some slippage of the hand upon the

tool surface. This slippage may result in a deviation from the ideal muscle length and thus a reduction in available strength. The degree of slippage and the subsequent degree of strength loss depend upon how well the gloves fit the hand as well as the type of material used in the glove. Poorly fitting gloves are likely to result in greater strength loss. Figure 24 indicates how the glove material and the glove fit can influence grip force potential.

Second, while wearing gloves, even though the externally applied force (grip strength) is often reduced, the internal forces are often very large relative to a bare-hand condition. For a given grip force application, the muscle activity is significantly greater when using gloves compared to a bare-handed condition (Kovacs et al., 2002). Thus, the musculoskeletal system is less efficient when wearing a glove due to the fact that the hand typically slips within the glove, thereby altering the length–strength relationship of the muscle.

Third, the ability to perform a task is significantly affected when wearing gloves. Figure 25 shows the

**Figure 24**  Peak grip force shown as a function of type of glove. Different letters above the columns indicate statistically significant differences.

**Figure 25**  Performance (time to complete) on a maintenance-type task while wearing gloves constructed of five different materials. [From Sanders, M. S., and McCormick, E. J. (1993), *Human Factors in Engineering and Design*, McGraw-Hill, New York. With permission.]

increase in time required to perform work tasks when wearing gloves composed of different materials compared to performing the same task bare handed. The figure indicates that task performance can increase up to 70% when wearing certain types of gloves.

These effects have indicated that there are biomechanical costs associated with the use of gloves. Less strength capacity is available to the worker, more internal force is generated, less force output is available, and worker productivity is reduced when wearing gloves. These negative effects of glove use do not mean that gloves should never be worn at work. When hand protection is required, gloves should be considered as a potential solution. However, protection should only be provided to the parts of the hand that are at risk. For example, if the palm of the hand requires protection but not the fingers, fingerless gloves might provide an acceptable solution. If the fingers require protection but there is little risk to the palm of the hand, then grip tape wrapped around the fingers might be considered as a potential solution. Additionally, different styles, materials, and sizes of gloves will fit workers differently. Thus, gloves produced by different manufacturers and of different sizes should be available to the worker to minimize the negative effects mentioned above.

### 4.5.5 Design Guidelines

This discussion has indicated that there are many factors that can impact the biomechanics of the wrist and the subsequent risk of cumulative trauma disorders. Proper ergonomic design of a work task cannot be accomplished by simply providing the worker with an "ergonomically designed" tool. Ergonomics is associated with matching the workplace design to the worker's capabilities and it is not possible to design an "ergonomic tool" without considering the workplace design and task requirements simultaneously. What might be an "ergonomic" tool for one work condition may be improper for use while a worker is assuming another work posture. For example, an *in-line* tool may keep the wrist straight when inserting a bolt into a horizontal surface. However, if the bolts are to be inserted into a vertical surface, a *pistol grip* tool may be more appropriate. Using the in-line tool in this situation (inserting a bolt into a vertical surface) may cause the wrist to be deviated. This illustrates that there are no ergonomic tools, there are just ergonomic *situations*. A tool that is considered ergonomically correct in one situation may be totally incorrect in another work situation. Thus, workplace design should be performed with care and one should be alert to the trade-offs between different parts of the body that must be considered by taking into consideration the various biomechanical trade-offs.

Given these considerations, the following components of the workplace should be considered when designing a workplace to minimize cumulative trauma risk. First, keep the wrist in a neutral posture. A neutral posture is a relaxed wrist posture with a slight extension (which optimizes the forearm's length–strength relationship), not a rigid linear posture. Second, minimize tissue compression on the hand. Third, avoid tasks and actions that repeatedly impose force on the internal structures. Fourth, minimize required wrist accelerations and motions through the design of the work. Fifth, be sensitive to the impact of glove use, hand size, and left-handed workers.

## 5 BIOMECHANICAL MODELING AS A MEANS OF ASSESSING AND CONTOLLING RISK

Several models of joint and tissue loads have been created over the years with the intent of using model output for job risk analysis and control. Many modeling techniques have been employed that embrace various degrees of modeling sophistication. Based upon these assessments control measures have been developed to evaluate and control biomechanical loading of the body during work tasks. A model is nothing more than a way to organize one's logic when considering all the interacting risk factors discussed earlier. Since LBDs are often associated with spine-loading magnitude, most analysis methods have focused on risk to the back. Many biomechanical models have been developed and they all vary in the degree of complexity included in the analyses. Models range from very simple models with a great number of simplifying assumptions to very sophisticated models that monitor the precise motions of the body and recruitment of the muscles in their estimation of spinal tissue loads. While most of these models are focused upon risk assessment of the low back, several of the measures also include analyses of risk to other body parts.

### 5.1 NIOSH Lifting Guide and Revised Equation

The NIOSH has developed two assessment tools or guides to help determine the risk associated with manual materials-handling tasks. This guide was intended to be a simple representation of risk to the low back that could be employed by most people with little need for measurement or analysis equipment. The lifting guide was originally developed in 1981 (NIOSH, 1981) and applied to lifting situations where the lifts were performed in the sagittal plane and to motions that are slow and smooth. Two benchmarks or limits were defined by this guide. The first limit is called the *action limit* (AL) and represents a magnitude of weight in a given lifting situation which would impose a spine load corresponding to the beginning of LBD risk along a risk continuum. The AL was associated with the point at which people under 40 years of age just begin to experience a risk of vertebral end-plate microfracture (3400 N of compressive load) (See Figure 10). The guide estimates the force imposed upon the spine of a worker as a result of lifting a weight and compares the spine load to the AL. If the weight of the object results in a spine load that is below the AL, the job is considered safe. If the weight lifted by the worker is larger than the AL, there is some level of risk associated with the task. The general form of the AL formula is defined according to the equation

$$AL = k \, (HF)(VF)(DF)(FF) \qquad (1)$$

where

AL = action limit, kg or lb

$k$ = load constant (40 kg, or 90 lb), which is the greatest weight a subject can lift if all lifting conditions are optimal

HF = horizontal factor defined as horizontal distance from point bisecting ankles to center of gravity of load at lift origin, defined algebraically as 15/$H$ (metric units) or 6/$H$ (U.S. units)

VF = vertical factor or height of load at lift origin, defined algebraically as (0.004) $|V - 75|$ (metric) or $1 - (.01)|V - 30|$(U.S.).

DF = distance factor or vertical travel distance of load, defined algebraically as $0.7 + 7.5/D$ (metric) or $0.7 + 3/D$ (U.S.).

FF = frequency factor or lifting rate, defined algebraically as $1 - F/F_{max}$

$F$ = average frequency of lift, $F_{max}$ is shown in Table 3

This equation assumes that if the lifting conditions are ideal a worker could safely hold (and implies lift) the load constant $k$ (40 kg, or 90 lb). However, if the lifting conditions are not ideal, the allowable weight is discounted according to the four factors HF, VF, DF, and FF. These four discounting factors are shown in monogram form in Figures 26–29 and relate to many of the biomechanical principles discussed earlier. According to the relationships indicated in these figures, the HF, which is associated with the external moment, has the most dramatic effect on acceptable lifting conditions. Both VF and DF are associated with the back muscle's length–strength relationship. Finally, FF attempts to account for the cumulative effects of repetitive lifting.

The second benchmark associated with the 1981 lifting guide is the *maximum permissible limit* (MPL). The MPL represents the point at which significant risk, defined in part as a significant risk of vertebral end-plate microfracture (Figure 10), occurs. The MPL is associated with a compressive load on the spine of 6400 N, which corresponds to the point at which 50% of the people would be expected to suffer a vertebral end-plate microfracture. The MPL is a function of the AL and is defined as

$$MPL = 3(AL) \qquad (2)$$

The weight that the worker is expected to lift in a work situation is compared to the AL and MPL. If the magnitude of weight falls below the AL, the work is

**Table 3** $F_{max}$ **Table**

| | Average Vertical Location (cm) (in.) | |
|---|---|---|
| Period | Standing $V > 75$ (3) | Stooped $V \le 75$ (3) |
| 1 h | 18 | 15 |
| 8 h | 15 | 12 |

Reprinted from NIOSH, 1981.

**Figure 26** Horizontal factor (HF) varies between the body interference limit and the limit of functional reach. [Adapted from National Institute for Occupational Safety and Health (NIOSH) (1981), ''Work Practices Guide for Manual Lifting,'' Publication No. 81-122, Department of Health and Human Services (DHHS), NIOSH, Washington, DC.]

**Figure 27** Vertical factor (VF) varies both ways from knuckle height. [Adapted from National Institute for Occupational Safety and Health (NIOSH) (1981), ''Work Practices Guide for Manual Lifting,'' Publication No. 81-122, Department of Health and Human Services (DHHS), NIOSH, Cincinnati, OH.]

considered safe and no work adjustments are necessary. If the magnitude of the weight falls above the MPL, then the work is considered to represent a significant risk and engineering changes involving the adjustment of HF, VF, and/or DF are required to reduce the AL and MPL.
**Figure 28**  Distance factor (DF) varies between a minimum vertical distance moved of 25 cm (10 in.) to a maximum distance of 200 cm (80 in.). [Adapted from National Institute for Occupational Safety and Health (NIOSH) (1981), ''Work Practices Guide for Manual Lifting,'' Publication No. 81-122, Department of Health and Human Services (DHHS), NIOSH, Cincinnati, OH.]

**Figure 29**  Frequency factor (FF) varies with lifts/minute and the $F_{max}$ curve. The $F_{max}$ depends upon lifting posture and lifting time. [Adapted from National Institute for Occupational Safety and Health (NIOSH) (1981), ''Work Practices Guide for Manual Lifting,'' Publication No. 81-122, Department of Health and Human Services (DHHS), NIOSH, Cincinnati, OH.]

If the weight falls between the AL and MPL, then either engineering changes or administrative changes, defined as selecting workers who are less likely to be injured or rotating workers, would be appropriate.

The AL and MPL were also indexed to relative to nonbiomechanical benchmarks. The NIOSH (1981) states that these limits also correspond to strength, energy expenditure, and psychophysical acceptance points.

The 1993 NIOSH revised lifting equation was introduce in order to address those lifting jobs that violate the sagittally symmetric lifting assumption of the original 1981 lifting guide (Waters et al., 1993). The concepts of

AL and MPL were replaced with a concept of a *lifting index* (LI) defined as

$$LI = \frac{L}{RWL} \tag{3}$$

where

$L$ = load weight or weight of object to be lifted
RWL = recommended weight limit for particular lifting situation
LI = lifting index used to estimate relative magnitude of physical stress for a particular job

If the LI is greater than 1.0, an increased risk of suffering a lifting-related LBD exists. The RWL is similar in concept to the NIOSH1(981) AL equation (equation 1) in that it contains factors that discount the allowable load according to the horizontal distance, vertical location of the load, vertical travel distance, and frequency of lift. However, the form of these discounting factors was adjusted. In addition, two discounting factors have been included. These additional factors include a lift asymmetry factor which accounts for asymmetric lifting conditions and a coupling factor that accounts for whether or not the load lifted has handles. The RWL is represented in equations (4) (metric units) and (5) (U.S. units):

$$RWL(kg) = 23(25/H)[1 - (0.003|V - 75|)][0.82$$
$$+ (4.5/D)](FM)[1 - (0.0032A)](CM)$$
$$(4)$$

$$RWL(lb) = 51(10/H)[1 - (0.0075|V - 30|)][0.82$$
$$+ (1.8/D)](FM)[1 - (0.0032A)](CM)$$
$$(5)$$

where

$H$ = horizontal location forward of midpoint between ankles at origin of lift; if significant control is required at destination, then $H$ should be measured at both origin and destination of lift
$V$ = vertical location at origin of lift
$D$ = vertical travel distance between origin and destination of lift

$FM$ = frequency multiplier shown in Table 4
$A$ = angle between midpoint of ankles and midpoint between hands at origin of lift
$CM$ = coupling multiplier ranked as good, fair, or poor and described in Table 5

In this revised equation the load constant has been significantly reduced relative to the 1981 equation. The discounting adjustments for load moment, muscle length–strength relationships, and cumulative loading are still integral parts of this equation. However, these adjustments relationships have been changed (compared to the 1981 guide) to reflect the most conservative value of the biomechanical, physiological, psychophysical, or strength data upon which they are based. Effectiveness studies report that the 1993 revised equation yields a more conservative (protective) prediction of work-related LBD risk (Marras et al., 1999).

**Table 5 Coupling Multiplier**

| Coupling Type | Coupling Multiplier | |
|---|---|---|
| | $V < 30$ in. (75 cm) | $V \geq 30$ in. (75 cm) |

## 5.2  Static Single Equivalent Muscle Biomechanical Models

Biomechanically based spine models have been developed to assess occupationally related manual materials-handling tasks. These models assess the task based upon both spine-loading criteria and a strength assessment of task requirements. One of the early static assessment models was developed by Don Chaffin at the University of Michigan (Chaffin, 1969). The original two-dimensional (2D) model has been expanded to a three-dimensional (3D) static model (Chaffin et al, 2006; Chaffin and Muzaffer, 1991). In this model, the moments imposed upon the various joints of the body due to the object lifted are evaluated assuming that a static posture is representative of the instantaneous loading of the body. These models compare the imposed moments about each joint with the static strength capacity derived from a working population. The static strength capacity required of the major joint articulations used in this model have been documented in a database of over 3000 workers. In this manner the proportion of the population capable of performing a particular static exertion is estimated. The joint that limits the capacity to perform the task can be identified via this method. The model assumes that a single equivalent muscle (internal force) supports the external moment about each joint. By considering the contribution of the externally applied load and the internally generated single muscle equivalent,

spine compression at the lumbar discs is predicted. The predicted compression can then be compared to the tolerance limits for the vertebral end plate (Figure 10). Two important assumptions of this model are that (1) no significant motion occurs during the exertion since it is a static model (postures must be considered as a freeze frame in time) and (2) one "equivalent muscle" counter balances the external loads imposed upon the body (thus, coactivation of the muscle is not represented). Figure 30 shows the output screen for this computer model where the lifting posture, lifting distances, strength predictions, and spine compression are shown.

## 5.3  Multiple Muscle System Models

One significant simplifying assumption form a biomechanical standpoint in most static models is that one internal force counteracts the external moment. In reality a great deal of coactivity (simultaneous recruitment of multiple muscles) occurs in the trunk muscles during an exertion, and the more complex the exertion, the greater the coactivity. Hence, the trunk is truly a multiple-muscle system with many major muscle groups supporting and loading the spine (Schultz and Andersson, 1981). This arrangement can be seen in the cross section of the trunk shown in Figure 31. Significant coactivation also occurs in many of the major muscle groups in the trunk during realistic *dynamic* lifting (Marras and

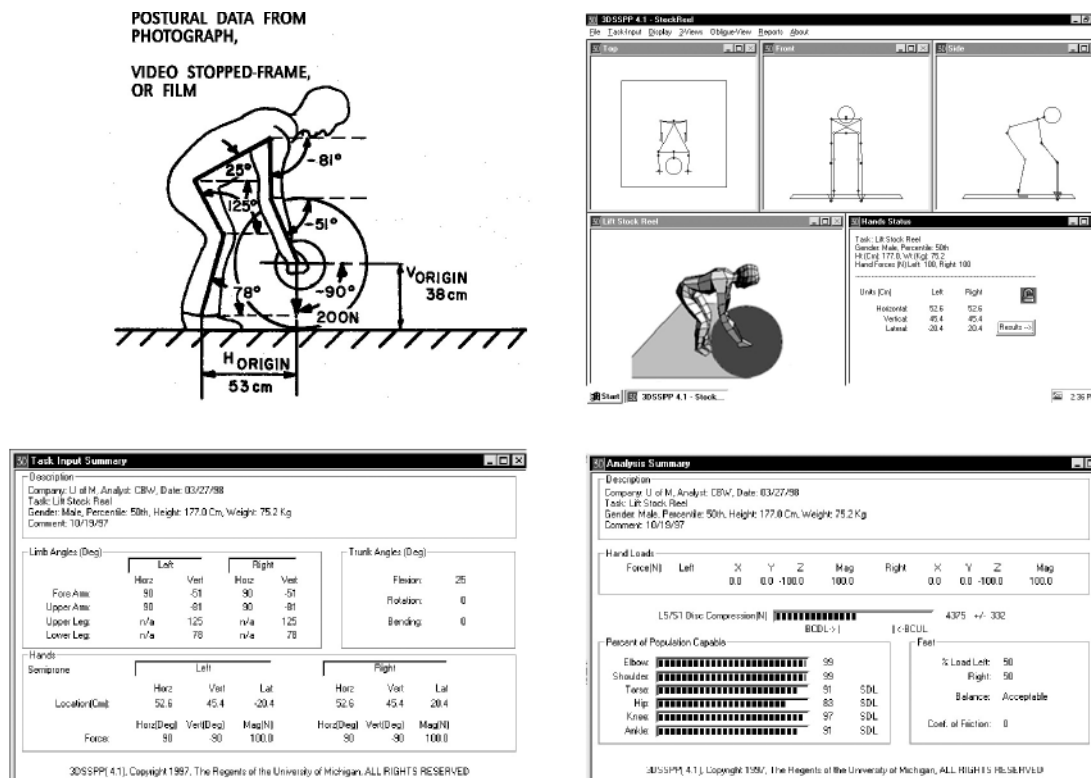

**Figure 30**  The 2D static strength prediction model. [Adapted from Chaffin, D. B., and Andersson, G. B. (1991), *Occupational Biomechanics*, Wiley, New York. With permission.]
**Figure 31** Bomechanical model of a pushing-and-pulling task.

Mirka, 1993). Accounting for coactivation in these models is important because all the trunk muscles have the ability to load the spine since antagonist muscles can oppose each other during occupational tasks, thereby increasing the total load on the spine. Ignoring the coactivation of the trunk muscles during dynamic lifting can misrepresent spine loading by 45–70% (Granata and Marras, 1995a; Thelen et al., 1995). In order to more accurately estimate the loads on the lumbar spine, especially under complex, changing (dynamic) postures, multiple-muscle-system models of the trunk have been developed. However, predicting the activity of the muscles is the key to accurate low-back loading assessments.

## 5.4 Biologically Assisted Models of the Spine

One way of assessing the degree of activation of the trunk muscles during a task is to monitor the muscle force contribution by directly measuring the muscle activity within the human biological system and use this information as input to a biomechanical model. These biologically driven models typically monitor muscle activities via electromyography or EMG and use this information to directly account for muscle coactivity. EMG-assisted models take into account the individual recruitment patterns of the muscles during a specific lift for a specific individual. By directly monitoring muscle activity the EMG-assisted model is capable of

determining individual muscle force and the subsequent spine loading. These models have been developed and tested under bending and twisting dynamic motion conditions and have been validated (McGill and Norman, 1985, 1986; Marras and Reilly 1988; Reilly and Marras, 1989; Marras and Sommerich, 1991a,b; Granata and Marras, 1993,1995b). These models are the only biomechanical models that can predict the *multidimensional loads* on the lumbar spine under many three-dimensional complex dynamic lifting conditions.

Traditionally, models used for ergonomic purposes were only able to predict loads imposed on the lumbosacral junction (L5/S1). However, recently EMG-assisted models have been expanded so that they are able to predict loads on the entire lumbar spine (Knapik and Marras, 2009). This has become a particularly important development in order to assess risk during pushing and pulling since the load on the mid to upper lumbar vertebrae are much greater than those at L5/S1. These models have enabled us, for the first time, to realistically determine risk associated with pushing-and-pulling tasks in occupational environments (Marras et al., 2009a,b). While these models have become very sophisticated and accurate, their disadvantage is that they require significant instrumentation of the worker in order to generate accurate predictions of spinal loading. Figure 31 shows a graphical representation of a model used to assess a pushing-and-pulling task.

### 5.5   Finite-Element Spine Models

Finite-element models (FEMs) of the lumbar spine have been used for some time, particularly to assess the loading of the spine for clinical assessment purposes (Arjmand and Shirazi-Adl, 2005; Bowden et al., 2008; Goel and Gilbertson, 1995; Goel and Pope, 1995; Shirazi-Adl et al., 1986; Suwito et al., 1992; Zander et al., 2004). FEMs are valuable techniques to consider how loads imposed upon a structure cause deformation and damage to the structure. The idea behind FEMs is that the structure is represented by many small elements that are representative of the underlying structural strength of the material. When loads are imposed on the structure, the FEM will predict how the elements rearrange themselves and provide information about how the structure will fail.

FEMs appear to be valuable tools to assess load tolerance of a structure if they are properly modeled. These models have been used often to assess the impact of spinal instrumentation (Bowden et al., 2008; Goel and Pope, 1995; Bono et al., 2007; Dooris et al., 2001). However, these models do little to help assess how loads are imposed upon the spine during task performance due to muscle recruitment since they do not include the coactive influence of spine-loading muscles in their analyses.

### 5.6   Personalized Hybrid Spine Models

Recently hybrid EMG-driven/FEM models have been developed to take advantage of the strengths of both EMG-assisted models and FEMs. In these hybrid models EMG-assisted techniques are used to assess the forces imposed upon the spine during a task, whereas FEM techniques are used to determine the impact of these

forces on spine tolerance. Some of the latest improvements in these models have enabled the ability to import anatomic images of a specific individual into the model. This has facilitated the development of a "personalized" hybrid model of specific persons. With this enhancement one can assess spinal loads and consider the effects of degeneration upon spine loading. These models have been used to assess clinical interventions such as surgery (Marras et al., 2008) as well as occupational tasks (Marras, 2008). These personalized models represent the future of biomechanical assessments and should become more readily available for applications as computer processing power continues to improve. An example of one of these models is shown in Figure 32.

### 5.7   Stability-Driven Models of the Spine

Stability of a system refers to the ability of the system to return to a state of equilibrium after a perturbation to the system. This concept is key to predicting system "balance" and has been traditionally used to predict force experienced by joints such as the knee during sports. The idea is that when a simple joint (e.g., knee) is unstable the ligaments will become stretched or torn and damage will occur.

While this concept is generally accepted for the assessment of risk for simple joints, particularly during sporting activities, it has also been proposed that similar concepts may apply to the much more complex system of the low back (Panjabi, 1992a,b, 2003). However, muscle involvement in the spine is much more difficult to predict than that of a simple joint.

From a biomechanical standpoint, the concept of stability is important for two reasons. First, if instability

**Figure 32**  Example of a personalized hybrid EMG-driven/FEM of the lumbar spine.

can be predicted, then it might be able to pinpoint the tissues at risk due to occupational task performance. Second, instability might "drive" the muscular recruitment system, making it possible to predict muscle activity so that one might be able to understand when overexertion occurs. In addition, prediction of muscle recruitment patterns might eliminate the need for equipment-intensive EMG measurements during work, thereby making EMG-driven modeling easier. Several researchers have attempted to model the spine via stability-driven principles (Cholewicki et al., 2000, 2005; Cholewicki and VanVliet, 2002; Granata and England, 2006; Granata and Marras, 2000; Granata and Orishimo, 2001). Unfortunately, thus far these techniques have been successful only when applied to static conditions and have not yet been able to assess dynamic task activities. Thus, these approaches have not been able to represent realistic risk at the workplace. The principal problem with this approach is that the stability principle does not appear to predict trunk muscle recruitment accurately because of its inability to predict dynamic cocontraction of the trunk muscles. The torso's muscle recruitment system appears to be driven by an individual's own mental model that they develop over their lifetime (Marras, 2008; Erlandson and Fleming, 1974) and is unique to an individual.

## 5.8 Predicting Muscle Recruitment for Spine Model Use

It is obvious from the preceding discussion regarding biomechanical modeling that a critical requirement for accurate biomechanical modeling of spinal tissues is the ability to accurately assess the behavior of the power-producing muscles of the trunk. Since these muscles have short moment arms relative to the externally applied moments, their influence upon spine tissue loading is immense. This is why biologically (EMG-)assisted models are currently the most accurate and precise means to assess spine loading during occupational task performance. Unfortunately, EMG requires significant equipment and is sometimes impractical at the worksite and therefore could require task simulation in a laboratory environment.

In an effort to minimize the need for EMG collection several researchers have attempted to predict muscle activities during task performance. Several techniques have been attempted. Optimization techniques have been attempted for some time (Bean et al., 1988; Brown et al., 2005; Cholewicki and McGill, 1994; Hughes and Chaffin, 1995; Li et al., 2006; van Dieen and Kingma, 2005; Zhang et al., 1998). Some of these attempts have been able to predict muscle activity under steady-state static loading conditions. However, these conditions are not representative of realistic work situations and can dramatically underestimate spine tissue loading (Granata and Marras, 1995a. These optimization-based assessments have not been able to accurately predict loading under realistic dynamic task performance conditions.

Several efforts have attempted to employ neural network and fuzzy logic techniques to predict trunk muscle coactivation under occupational task performance conditions (Hou et al., 2007; Lee et al., 2000, 2003; Nussbaum and Chaffin, 1997). These efforts have employed

databases of EMG responses to various kinematic and kinetic spine-loading conditions to train neural network models of trunk muscle responses. Given a specific peak moment exposure and velocity of trunk motion, these models appear able to relatively accurately predict muscle behavior for a wide range of subjects. While these models show promise, it is unfortunate that they require a large volume of training data so that a variety of activities can be represented. It is not expected that such a large database will be available for comprehensive modeling of the muscle activities of the trunk.

## 5.9 Dynamic Motion Assessment at the Workplace

It is clear that that dynamic activity may significantly increase the risk of LBD, yet there are few assessment tools available to quickly and easily assess the biomechanical demands associated with workplace dynamics and the risk of LBD. In order to assess this biomechanical situation at the worksite, one must know the type of motion that increases biomechanical load and determine "how much motion exposure is too much motion exposure" from a biomechanical standpoint. These issues were the focus of several industrial studies performed over a six-year period in 68 industrial environments. Trunk motion and workplace conditions were assessed in workers exposed to high-risk of LBD jobs and compared to trunk motions and workplace conditions associated with low-risk jobs (Marras et al., 1993, 1995). A trunk goniometer (lumbar motion monitor, or LMM) has been used to document the trunk motion patterns of workers at the workplace and is shown in Figure 33. Based upon this study, a five-factor multiple logistic

**Figure 33**   The LMM.

regression model was developed that is capable of discriminating between task exposure that indicates the probability of high-risk group membership. These risk factors include (1) frequency of lifting, (2) load moment (load weight multiplied by the distance of the load from the spine), (3) average twisting velocity (measured by the LMM), (4) maximum sagittal flexion angle through the job cycle (measured by the LMM), and (5) maximum lateral velocity (measured by the LMM). This LMM risk assessment model is the only model capable of assessing the *risk* associated with three-dimensional trunk motion on the job. This model has a high degree of predictability (odds ratio 10.7) compared to previous attempts to assess work-related LBD risk. The advantage of such an assessment is that the evaluation provides information about risk that would take years to derive from historical accounts of incidence rates. The model has also been validated prospectively (Marras et al., 2000).

## 5.10 Threshold Limit Values

Threshold limit values (TLVs) have been recently introduced as a means for controlling biomechanical risk to the back in the workplace. TLVs have been introduced through the American Conference of Governmental Industrial Hygienists (ACGIH) and provide lifting weight limits as a function of lift origin "zones" and repetitions associated with occupational tasks. Lift origin zones are defined by the lift height off the ground and lift distance from the spine associated with the lift origin. Twelve zones are defined that relate to lifts within $+/-30°$ of asymmetry from the sagittal plane. These zones are represented in a series of figures with each figure corresponding to different lift frequency and time exposures. Within each zone weight-lifting limits are specified based upon the best information available from several sources which include (1) EMG-assisted biomechanical models, (2) the 1993 revised lifting

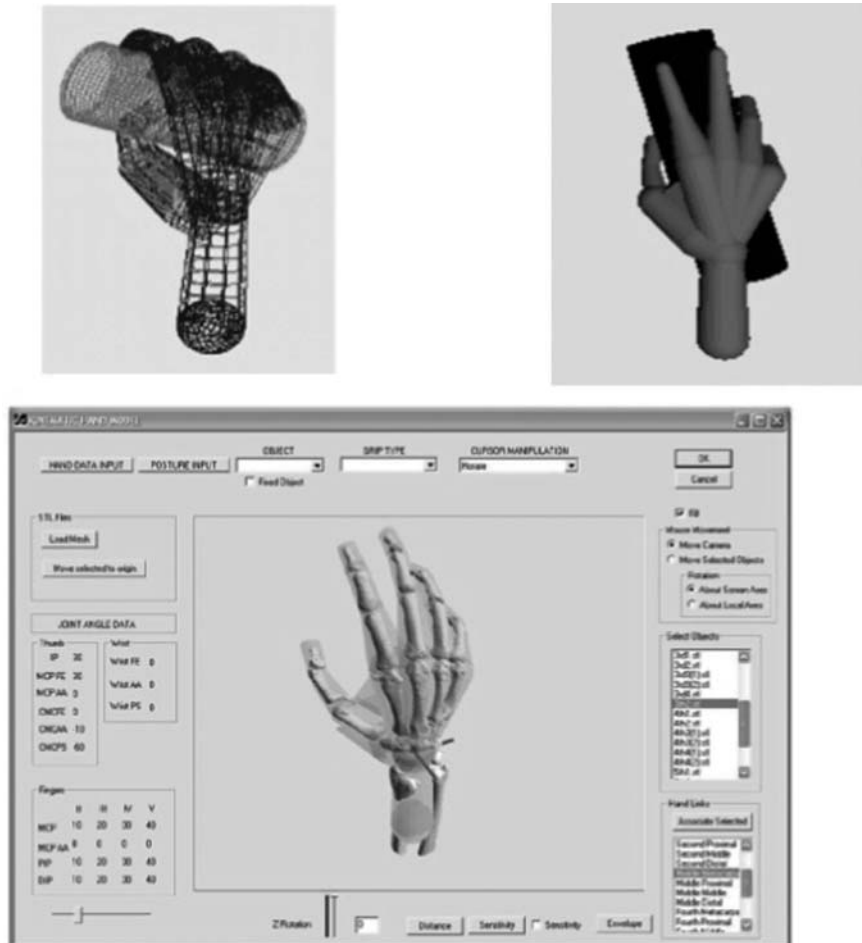

**Figure 34**  Upper extremity biomechanical model used for ergonomics assessments. (Courtesy of T. Armstrong.)

equation, and (3) the historical risk data associated with the LMM database. The weight lifted by the worker is compared to these limits. Weights exceeding the zone limit are considered hazards.

## 5.11 Upper Extremity Models

Recently, the Center for Ergonomics at the University of Michigan has developed a kinetic model of the upper extremity that is intended to be used to assess hand-intensive tasks (Armstrong et al., in press). This model consists of a link system that represents the joints of the hand and cone shapes are used to represent finger surfaces. The model estimates hand postures and finger movements. The model has been used to determine how workers grasp objects in the workplace and assesses how much space will be required for the hand and the required tendon forces and hand strength necessary to perform a task. The model has recently been used to evaluate hose insertion tasks. Figure 34 illustrates the graphical nature of this model.

## 6 SUMMARY

This chapter has shown that biomechanics provides a means to *quantitatively* consider the implications of workplace design. Biomechanical design considerations are important when a particular job is suspected of imposing large or repetitive forces on the structures of the body. It is particularly important to recognize that the internal structures of the body, such as muscles, are the primary generators of force within the joint and tendon structures. In order to evaluate the risk of injury due to a particular task, one must consider the contribution of both the external loads and internal loads upon a structure and how they relate to the tolerance of the structure. Armed with an understanding of some general biomechanical concepts (presented in this chapter) and how they apply to different parts of the body (affected by work), one can logically reason through the design considerations and trade-offs so that musculoskeletal disorders are minimized due to the design of the work.

# PART 3
# DESIGN OF TASKS AND JOBS

# CHAPTER 13

# TASK ANALYSIS: WHY, WHAT, AND HOW

**Erik Hollnagel**
**University of Southern Denmark**
**Odense, Denmark**

## 1 THE NEED TO KNOW

The purpose of task analysis, as it is commonly practiced, is to describe tasks and more particularly to identify and characterize the fundamental characteristics of a specific activity or set of activities. According to the *Shorter Oxford Dictionary*, a *task* is "any piece of work that has to be done," which is generally taken to mean one or more functions or activities that must be carried out to achieve a specific goal. Task analysis can therefore be defined as the study of what people, individually and collectively, are required to do in order to achieve a given goal or objective.

Since a task by definition is a directed activity because it has a purpose or an objective, there is little or no methodological merit in speaking simply of activities and tasks without taking into account both their goals and the context in which they occur. Task analysis can therefore basically be defined as the study of what people, individually and collectively, are required to do to achieve a specific goal, or, simply put, as *who* does *what* and *why*.

**Who**    *Who* refers to the people who carry out a task. In the case where this is a single person, task analysis is a description of individual work. It is, however, far more common that people have to work together, in pairs, as a team, or in an organization, in which case task analysis is a description of the collective effort of what the team does. Whereas a description of individual work can focus on the activities, a description of collective work must also include how the collaboration is accomplished, that is, the organization and coordination of what the individuals do. Moving from the realm of human work to artifacts or agents (such as robots), task

analysis becomes the analysis of functions (e.g., movements) that an artifact must carry out to achieve a goal.

In industrialized societies, tasks are in most cases accomplished by people using some kind of technological artifact or system: in other words, a human–machine system. Task analysis is therefore often focused on the *what* of the human–machine system as such should do: for instance, as task analysis for human–computer interaction (e.g., Diaper and Stanton, 2003). More generally, humans and machines working together can be described as *cognitive systems* or *joint cognitive systems* (Hollnagel and Woods, 2005). Indeed, at the time of writing (2010) the main issues are no longer human work with technology, or human interaction with technology, but the *coagency* of multiple functions, providers, stakeholders, and so on. Human work with technology is no longer a question of human–technology interaction but rather a question of how complex sociotechnical systems function. The human–machine dyad and the focus on human–machine interaction are relics from the early days of human factors and are no longer adequate—if they have not already become irrelevant.

The built-in assumptions about the nature of who carries out the task have important consequences for task analysis, as will be clear from the following. The use of the pronoun *who* should not be taken to mean that task analysis is only about what humans do, although that was the original objective. In contemporary terms it would probably be more appropriate to refer to the *system* that carries out the task.

**What**    *What* refers to the contents of the task and is usually described in terms of the activities that constitute the task. Task analysis started by focusing on physical

tasks (i.e., manifest work) but has since the 1970s enlarged its scope to include cognitive or mental tasks. The content of the task thus comprises a systematic description of the activities or functions that make up the task, either in terms of observable actions (e.g., grasping, holding, moving, assembling) or in terms of the usually unobservable functions that may lie behind these actions, commonly referred to as *cognition* or *cognitive functions*.

**Why**    Finally, *why* refers to the purpose or goal of the task: for instance, the specific system state or condition that is to be achieved. A goal may be something that is objective and physically measurable (a product) but also something that is subjective: for instance, a psychological state or objective, such as "having done a good job." The task analysis literature has usually eschewed the subjective and affective aspects of tasks and goals, although they clearly are essential for understanding human performance as well as for designing artifacts and work environments.

Task analysis is supposed to provide concrete answers to the *practical* questions of how things should be done or are done. When dealing with work, and more generally with how people use sociotechnical artifacts to do their work, it is necessary to know both what activities (functions) are required to accomplish a specified objective and how people habitually go about doing them, particularly since the latter is usually different—and sometimes significantly different—from the former. Such knowledge is necessary to design, implement, and manage sociotechnical systems, and task analysis looks specifically at how work takes place and how it can be facilitated. Task analysis therefore has applications that go well beyond interface and interaction design and may be used to address issues such as training, performance assessment, event reporting and analysis, function allocation and automation, procedure writing, maintenance planning, risk assessment, staffing and job organization, personnel selection, and work management.

The term *task analysis* is commonly used as a generic label. A survey of task analysis methods shows that they represent many different meanings of the term (Kirwan and Ainsworth, 1992). A little closer inspection, however, reveals that they fall into a few main categories:

- The analysis and description of tasks or working situations that do not yet exist or are based on hypothetical events
- The description and analysis of observations of how work is carried out or of event reports (e.g., accident investigations)
- The representation of either of the above, in the sense of the notation used to capture the results (of interest due to the increasing use of computers to support task analysis)
- The various ways of further analysis or refinement of data about tasks (from either of the foregoing sources)

- The modes of presentation of results and the various ways of documenting the outcomes

Methods of task analysis should in principle be distinguished from methods of task description. A task description produces a generalized account or summary of activities as they have been carried out. It is based on empirical data or observations rather than on design data and specifications. A classical example is link analysis or even hierarchical task analysis (Annett et al., 1971). Properly speaking, task description or performance analysis deals with actions rather than with tasks. This distinction, by the way, is comparable to the French ergonomic tradition where the described task is seen as different from the effective task. The described task (*tâche prévue* or simply *tâche*) is the intended task or what the organization assigns to the person, what the person should do. The effective task (*tâche effective* or *activité*) is the actual task or the person's response to the prescribed task, what the person actually does (Daniellou, 2005). Understanding the task accordingly requires an answer to the question of *what* the person does, while understanding the activity requires an answer regarding *how* the person performs the task. (In practice, it is also necessary to consider *when* and *where* the task is carried out.) An important difference between tasks and activities is that the latter are dynamic and may change depending on the circumstances, such as fluctuations in demands and resources, changing physical working conditions, the occurrence of unexpected events, and so on. The distinction between the task described and the effective task can be applied to both individual and collective tasks (Leplat, 1991).

## 1.1   Role of Task Analysis in Human Factors

Task analysis has over the years developed into a stable set of methods that constitute an essential part of human factors and ergonomics as applied disciplines. The focus of human factors engineering or ergonomics is humans at work, more particularly the human use of technology in work, although it sometimes may look more like technology's use of humans. The aim of *human factors* (which in the following is used as a common denominator for human factors engineering and ergonomics) is to apply knowledge about human behavior, abilities, and limitations to design tools, machines, tasks, and work environments to be as productive, safe, healthy, and effective as possible. From the beginning, ergonomics was defined broadly as the science of work (Jastrzebowski, 1857). At that time work was predominantly manual work, and tools were relatively few and simple. Human factors, which originally was called human factors engineering, came into existence around the mid-1940s as a way of solving problems brought on by emerging technologies such as computerization and automation. Ergonomics and human factors thus started from different perspectives but are now practically synonymous. At the present time, literally every type of work involves the use of technology, and the difference between ergonomics and human factors engineering is rather nominal.

Throughout most of history, people have depended on tools or artifacts to do their work, such as the

painter's brush or the blacksmith's hammer. As long as users were artisans rather than workers and work was an individual rather than a collective endeavor, the need of prior planning, and therefore of anything resembling task analysis, was limited or even nonexistent. The demand for task analysis arose when the use of technology became more widespread, especially when tools changed from being simple to being complex. More generally, the need of a formal task analysis arises when one or more of the following three conditions are met:

1. The accomplishment of a goal requires more effort than one person can provide or depends on a combination of skills that goes beyond what a single individual can be expected to master. In such cases task analysis serves to break down a complex and collective activity to descriptions of a number of simpler and more elementary activities. For example, building a ship, in contrast to building a dinghy or a simple raft, requires the collaboration of many individuals and the coordination of many different types of work. In such cases people have to collaborate and must therefore adjust their own work to match the progress and demands of others. Task analysis is needed to identify the task components that correspond to what a person can achieve or provide over a reasonable period of time as well as to propose a way to combine and schedule the components to an overall whole.

2. Tasks become so complex that one person can no longer control or comprehend them. This may happen when the task becomes so large or takes so long that a single person is unable to complete it (i.e., the transition from individual to collective tasks). It may also happen when the execution of the task depends on the use of technological artifacts and where the use of the artifact becomes a task in its own right (cf. below). This is the case, for instance, when the artifacts can function in an independent or semiautonomous way (i.e., they begin partially to regulate themselves rather than passively carry out an explicit function under the user's control).

3. A similar argument goes when technology itself—machines—becomes so complex that the situation changes from simply being one of *using* the technology to one learning how to *understand*, *master*, or *control* the technology. In other words, being in control of the technology becomes a goal in itself, as a means to achieve the original goal. Examples are driving a car in contrast to riding an ordinary bicycle, using a food processor instead of a knife, using a computer (as in writing this chapter) rather than paper and pencil, and so on. In these cases, and of course also in cases of far more complex work, use of the technology is no longer straightforward but requires preparation and prior thought either by the person who does the task or work or by those who prepare tasks or tools for others. Task analysis can in these cases be used to describe situations where the task itself is very complex because it involves interaction and dependencies with other people. It can similarly be used to describe situations where use of the technology is no longer straightforward but requires mastery of the system to such a degree that not everyone can apply it directly as intended and designed.

In summary, task analysis became necessary when work changed from something that could be done by an unaided individual to something requiring the collective efforts of either people or joint cognitive systems. Although collective work has existed since the beginning of history, its presence became more conspicuous after the Industrial Revolution about 250 years ago. In this new situation the work of the individual became a mere part of the work of the collective, and individual control of work was consequently lost. The worker became part of a larger context, a cog in complex social machinery that defined the demands and constraints to work. One important effect of that was that people no longer could work at a pace suitable for them and pause whenever needed but instead had to comply with the pace set by others—and increasingly the pace set by machines.

## 1.2  Artifacts and Tools

It is common to talk about humans and machines, or humans and technology, and to use expressions such as *human−machine systems* or, even better, *human−technology systems*. In the context of tasks and task analysis, the term *technological artifact*, or simply *artifact*, will be used to denote that which is being applied to achieve a goal. Although it is common to treat computers and information technology as primary constituents of the work environment, it should be remembered that not all tools are or include computers, and task analysis is therefore far more than human−computer interaction. That something is an artifact means that it has been constructed or designed by someone, hence that it expresses or embodies a specific intention or purpose. In contrast to that, a natural object does not have an intended use, but is the outcome of evolution—or happenstance—rather than design. Examples of natural objects are stones used to hammer or break something and sticks used to poke for something.

A natural object may be seen as being instrumental to achieve something, hence used for that purpose. In the terminology of Gibson (1979), the natural object is perceived as having an actionable property (an affordance), which means that it is seen as being useful for a specific purpose. An artifact is designed with a specific purpose (or set of uses) in mind and should ideally offer a similar perceived affordance. To the extent that this is the case, the design has been successful. Task analysis (i.e., describing and understanding in advance the uses of artifacts) is obviously one of the ways in which that can be achieved. Although there is no shortage of examples of failure to achieve this

noble goal, it is of course in the best interest of the designer—and the producer—to keep trying.

When a person designs or constructs something for himself or herself an artifact or a composite activity, there is no need to ask what the person is capable of, what the artifact should be used for, or how it should be used. But the need is there in the case of a single but complex artifact where the use requires a series of coordinated or ordered actions. It is also there in the case of more complex, organized work processes where the activities or tasks of an individual must fit into a larger whole. Indeed, just as the designer of a complex artifact considers its components and how they must work together for the artifact to be able to provide its function, so must the work process designer consider the characteristics of people and how they must collaborate to deliver the desired end product or result. It is, indeed, no coincidence that the first task analyses were made for organized work processes rather than for the single users working with artifacts or machines.

From an analytical perspective, the person's knowledge of what he or she can do can be seen as corresponding to the designer's assumptions about the user, while the person's knowledge of how the artifact should be used can be seen as corresponding to the user's assumptions about the artifact, including the designer's intentions. As long as the artifact or the work processes are built around the person, there is little need to make any of these assumptions explicit or indeed to produce a formal description of them: The user and the designer are effectively the same person. There is also little need of prior thought or prior analysis since the development is an integral part of work rather than an activity that is separated in time and space. But when the artifact is designed by one person to be used by someone else, the designer needs to be very careful and explicit in making assumptions and to consider carefully what the future user may be able to do and will do. In other words, it is necessary in these cases to analyze how the artifact will be used or to perform a task analysis.

## 2   TASK TYPES AND TASK BREAKDOWN

Task analysis is in the main a collection of methods which describe (or prescribe) how the analysis will be performed, preferably by describing each step of the analysis as well as how they are organized. Each method should also describe the *stop rule* or criterion (i.e., define the principles needed to determine when the analysis has come to an end, for instance, that the level of elementary tasks has been reached).

An important part of the method is to name and identify the main constituents of a task and how they are organized. As described later in this chapter, task analysis has through its development embraced several different principles of task organization, of which the main ones are the sequential principle, the hierarchical principle, and the functional dependency principle. To do so, the method must obviously refer to a classification scheme or set of categories that can be used to describe and represent the essential aspects of a task.

The hallmark of a good method is that the classification scheme is applied consistently and uniformly, thereby limiting the opportunities for subjective interpretations and variations. Task analysis should depend not on personal experience and skills but on generalized public knowledge and common sense. A method is also important as a way of documenting how the analysis has been done and of describing the knowledge that was used to achieve the results. It helps to ensure that the analysis is carried out in a systematic fashion so that it, if needed, can be repeated, hopefully leading to the same results. This reduces the variability between analysts and hence improves the reliability.

The outcome of the task analysis accounts for the organization or structure of constituent tasks. A critical issue is the identification or determination of elementary activities or task components. The task analysis serves among other things to explain how something should be done for a user who does not know what to do or who may be unable to remember it (in the situation). There is therefore no need to describe things or tasks that the user definitely knows. The problem is, however, how that can be determined.

Task analysis has from the very start tried to demarcate the basic components. It would clearly be useful if it was possible to find a set of basic tasks—or activity atoms—that could be applied in all contexts. This is akin to finding a set of elementary processes or functions from which a complex behavior can be built. Such endeavors are widespread in the behavioral and cognitive sciences, although the success rate usually is quite limited. The main reason is that the level of an elementary task depends on the person as well as on the domain. Even if a common denominator could be found, it would probably be at a level of detail as to have little practical value (e.g., for training or scheduling).

### 2.1   Changing Views of Elementary Tasks

Although the search for all-purpose task components is bound to fail, it is nevertheless instructive to take a brief look at three different attempts to do so. Probably the first—and probably also the most ambitious—attempt was made by Frank Bunker Gilbreth, one of the pioneers of task analysis. The categorization, first reported about 1919, evolved from the observation by trained motion-and-time specialists of human movement, specifically of the fundamental motions of the hands of a worker. Gilbreth found that it was possible to distinguish among the following 17 types of motion: search, select, grasp, reach, move, hold, release, position, pre-position, inspect, assemble, disassemble, use, unavoidable delay, wait (avoidable delay), plan, and rest (to overcome fatigue). (The basic motions are known as *therbligs*, using an anagram of the developer's name.)

A more contemporary version is a list of typical process control tasks suggested by Rouse (1981). This comprises 11 functions, which are in alphabetical order: communicating, coordinating tasks, executing procedures, maintaining, planning, problem solving, recognizing, recording, regulating, scanning, and steering. In contrast to the *therbligs*, it is possible to organize these functions in several ways: for instance, in relation

to an input–output model of information processing, in relation to a control model, and in relation to a decision-making model. The functions proposed by Rouse are characteristically on a higher level of abstraction than the *therbligs* and refer to cognitive functions, or cognitive tasks, rather than to physical movements.

A final example is the GOMS model proposed by Card et al. (1983). The purpose of GOMS, which is an acronym that stands for "goals, operators, methods, and selection rules," was to provide a system for modeling and describing human task performance. Operators, one of the four components of GOMS, denote the set of atomic-level operations from which a user can compose a solution to a goal, while methods represent sequences of operators grouped together to accomplish a single goal. For example, the manual operators of GOMS are: Keystroke key_name, Type_in string_of_characters, Click mouse_button, Double_click mouse_button, Hold_down mouse button, Release mouse_button, Point_to target_object, and Home_to destination. These operators refer not to physical tasks, such as the *therbligs*, but rather to mediating activities for mental or cognitive tasks.

The definition of elementary tasks in scientific management could comfortably refer to what people did, hence to what could be reported by independent observers. The problem with defining elementary cognitive or mental tasks is that no such independent verification is possible. Although GOMS was successful in defining elementary tasks on the keystroke level, it was more difficult to do the same for the cognitive or mental aspects (i.e., the methods and selection rules). The physical reality of elementary tasks such as *grasp, reach, move*, and *hold* has no parallel when it comes to cognitive functions. The problems in identifying elementary mental tasks are not due to a lack of trying. This has indeed been a favorite topic of psychology from Donders (1969; orig. 1868) to Simon (1972). The problems come about because the "smallest" unit is defined by the theory being used rather than by intersubjective reality. In practice, this means that elementary tasks must be defined relative to the domain at the time of the analysis (i.e., in terms of the context rather than as absolutes or context-free components).

## 3  BRIEF HISTORY OF TASK ANALYSIS

Task analysis has a relatively short history starting around the beginning of the twentieth century. The first major publications were Gilbreth (1911) and Taylor (1911), which introduced the principles of scientific management. The developments that followed reflected both the changing view of human nature, for instance, in McGregor's (1960) theory X and theory Y, and the changes in psychological schools, specifically the models of the human mind. Of the three examples of a classification system mentioned above, Gilbreth (1911) represents the scientific management view, Rouse (1981) represents the supervisory control view (human–machine interaction), and Card et al. (1983) represents the information-processing

view (human–computer interaction). These views can be seen as alternative ways of describing the same reality: namely, human work and human activities. One standpoint is that human nature has not changed significantly for thousands of years and that different descriptions of the human mind and of work therefore only represent changes in the available models and concepts. Although this undoubtedly is true, it is also a fact that the nature of work has changed due to developments in technology. Gilbreth's description in terms of physical movements would therefore be as inapplicable to today's work as a description of cognitive functions would have been in 1911.

### 3.1  Sequential Task Analysis

The dawn of task analysis is usually linked to the proposal of a system of scientific management (Taylor, 1911). This approach was based on the notion that tasks should be specified and designed in minute detail and that workers should receive precise instructions about how their tasks should be carried out. To do so, it was necessary that tasks could be analyzed unequivocally or "scientifically," if possible in quantitative terms, so that it could be determined how each task step should be done in the most efficient way and how the task steps should be distributed among the people involved.

One of the classical studies is Taylor's (1911) analysis of the handling of pig iron, where the work was done by men with no "tools" other than their hands. A pig-iron handler would stoop down, pick up a pig weighing about 92 pounds, walk up an inclined plank, and drop it on the end of a railroad car. Taylor and his associates found that a gang of pig-iron handlers was loading on the average about $12\frac{1}{2}$ long tons per man per day. The aim of the study was to find ways in which to raise this output to 47 tons a day, not by making the men work harder but by reducing the number of unnecessary movements. This was achieved both by careful motion-and-time studies and by a system of incentives that would benefit workers as well as management.

Scientific management was based on four elements or principles, which were used in studies of work.

1. The development of the science of work with *rigid* rules for each motion of every person and the perfection and *standardization* of all implements and working conditions

2. The careful *selection* and subsequent *training* of workers into first-class people and the elimination of all people who refuse to or are unable to adopt the best methods

3. Bringing the first-class workers and the science of working together through the constant help and watchfulness of management and through paying each person a large daily bonus for working fast and doing what he or she is told to do

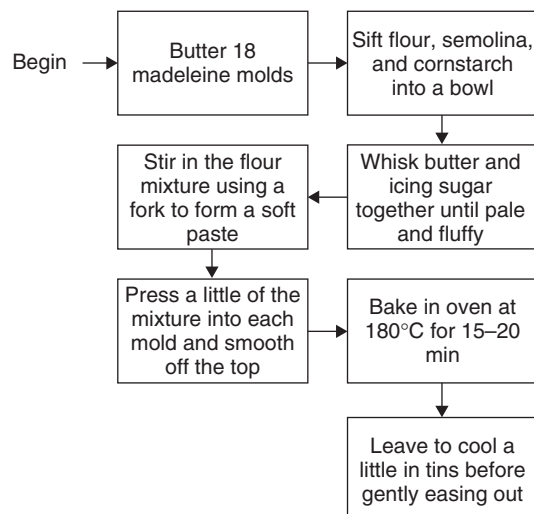
4. An almost equal division of the work and responsibility between workers and management

Of these four elements, the first (the development of the science of work) is the most interesting and

spectacular. It was essentially an analysis of a task into its components, using, for example, the list of *therbligs* mentioned above. In the case of manual work this was entirely feasible, since the task could be described as a single sequence of more detailed actions or motions. The motion-and-time study method was, however, unable to cope with the growing complexity of tasks that followed developments in electronics, control theory, and computing during the 1940s and 1950s. Due to the increasing capabilities of machines, people were asked—and tasked—to engage in multiple activities at the same time, either because individual tasks became more complex or because simpler tasks were combined into larger units. An important consequence of this was that tasks changed from being a sequence of activities referring to a single goal to an organized set of activities referring to a hierarchy of goals. The use of machines and technology also became more prevalent, so that simple manual work such as pig-iron handling was taken over by machines, which in turn were operated or controlled by workers.

Since the use of technology has made work environments more complex, relatively few tasks today are sequential tasks. Examples of sequential tasks are therefore most easily found in the world of cooking. Recipes are typically short and describe the steps as a simple sequence of actions, although novice cooks sometimes find that recipes are underspecified. As an example of a sequential task analysis, Figure 1 shows the process for baking Madeleines.

### 3.2 From Sequential to Hierarchical Task Organization

The technological development meant that the nature of work changed from being predominantly manual and became more dependent on mental capabilities (comprehension, monitoring, planning). After a while, human factors engineering, or classical ergonomics,


recognized that traditional methods of breaking the task down into small pieces, where each could be performed by a person, were no longer adequate. Since the nature of work had changed, the human capacity for processing information became decisive for the capacity of the human–machine system. This capacity could not be extended beyond its "natural" upper limit, and it soon became clear that the human capacity for learning and adaptation was insufficient to meet technological demands.

To capture the more complex task organization, Miller (1953) developed a method for human–machine task analysis in which main task functions could be decomposed into subtasks. Each subtask could then be described in detail, for instance, by focusing on information display requirements and control actions. This led to the following relatively simple and informal procedure for task analysis:

1. Specify the human–machine system criterion output.
2. Determine the system functions.
3. Trace each system function to the machine input or control established for the operator to activate.
4. For each respective function, determine what information is displayed by the machine to the operator whereby he or she is directed to appropriate control activation (or monitoring) for that function.
5. Determine what indications of response adequacy in the control of each function will be fed back to the operator.
6. Determine what information will be available and necessary to the operator from the human–machine "environment."
7. Determine what functions of the system must be modulated by the operator at or about the same time, or in close sequence, or in cycles.
8. In reviewing the analysis, be sure that each stimulus is linked to a response and that each response is linked to a stimulus.

The tasks were behavior groups associated with combinations of functions that the operator should carry out. These were labeled according to the subpurpose they fulfilled within the system. Point 8 reflects the then-current psychological thinking, which was that of stimulus-and-response couplings. The operator was, in other words, seen as a transducer or a machine that was coupled to the "real" machine. For the human–machine system to work, it was necessary that the operator interpret the machine's output in the proper way and that he or she respond with the correct input. The purpose of task analysis was to determine what the operator had to do to enable the machine to function as efficiently as possible.

#### 3.2.1 Task–Subtask Relation

The task–subtask decomposition was a significant change from sequential task analysis and was necessitated by the growing complexity of work. The

**Figure 1** Sequential task description.

development was undoubtedly influenced by the emerging practice—and later science—of computer programming, where one of the major innovations was the subroutine. Arguably the most famous example of a task–subtask relation is the TOTE (test–operate–test–exit), which was proposed as a building block of human behavior (Miller et al., 1960). This introduced into the psychological vocabulary the concept of a plan, which is logically necessary to organize combinations of tasks and subtasks. Whereas a subroutine can be composed of motions and physical actions, and hence in principle can be found even in scientific management, a plan is obviously a cognitive or mental component. The very introduction of the task–subtask relation, and of plans, therefore changed task analysis from describing only what happened in the physical world to describing what happened in the minds of the people who carried out the work.

Miller's task–subtask analysis method clearly implied the existence of a hierarchy of tasks and subtasks, although this was never a prominent feature of the method. As the technological environments developed further, the organization of tasks and subtasks became increasingly important for task analysis, culminating with the development of hierarchical task analysis (HTA) (Annett and Duncan, 1967; Annett et al., 1971). Since its introduction HTA has become the standard method for task analysis and task description and is widely used in a variety of contexts, including interface design.

The process of HTA is to decompose tasks into subtasks and to repeat this process until a level of elementary tasks has been reached. Each subtask or operation is specified by its goal, the conditions under which the goal becomes relevant or "active," the actions required to attain the goal, and the criteria that mark the attainment of the goal. The relationship between a set of subtasks and the superordinate task is governed by plans expressed as, for instance, procedures, selection rules, or time-sharing principles. A simple example of HTA is a description of how to get money from a bank account using an ATM (see Figure 2). In this description, there is an upper level of tasks (marked, 1, 2, 3), which describe the order of the main segments, and

a lower level of subtasks (marked 1.1, 1.2, etc.), which provide the details. It is clearly possible to break down each of the subtasks into further detail, for instance, by describing the steps comprised by *1.2 Enter PIN code*. This raises the nontrivial question of when the HTA should stop (i.e., what the elementary subtasks or task components are; cf. below).

The overall aim of HTA is to describe a task in sufficient detail, where the required level of resolution depends on the specific purposes (e.g., interaction design, training requirements, interface design, risk analysis). HTA can be seen as a systematic search strategy adaptable for use in a variety of different contexts and purposes within the field of human factors (Shepherd, 1998). In practice, performing HTA comprises the following steps. (Note, by the way, that this is a sequential description of hierarchical task analysis!)

1. Decide the purpose of the analysis.
2. Get agreement between stakeholders on the definition of task goals and criterion measures.
3. Identify sources of task information and select means of data acquisition.
4. Acquire data and draft a decomposition table or diagram.
5. Recheck the validity of the decomposition with the stakeholders.
6. Identify significant operations in light of the purpose of the analysis.
7. Generate and, if possible, test hypotheses concerning factors affecting learning and performance.

Whereas Miller's description of human–machine task analysis concentrated on how to analyze the required interactions between humans and machines, HTA extended the scope to consider the context of the analysis, in particular which purpose it served. Although this was a welcome and weighty development, it left the actual HTA somewhat underspecified. Indeed, in the description above it is only the fourth step that is the actual task analysis.

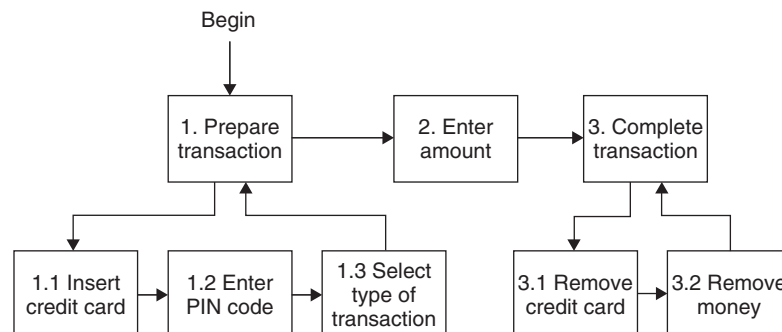


**Figure 2** Hierarchical task description.

### 3.2.2  Tasks and Cognitive Tasks

In addition to the change that led from sequential motion-and-time descriptions to hierarchical task organization, a further change occurred in the late 1980s to emphasize the cognitive nature of tasks. The need to consider the organization of tasks was partly a consequence of changing from a sequential to a hierarchical description, as argued above. The changes in the nature of work also meant that "thinking" tasks became more important than "doing." The need to understand the cognitive activities of the human–machine system, first identified by Hollnagel and Woods (1983), soon developed a widespread interest in cognitive task analysis, defined as the extension of traditional task analysis techniques to yield information about the knowledge, thought processes, and goal structures that underlie observable task performance (e.g., Schraagen et al., 2000). As such, it represents a change in emphasis from overt to covert activities. An example is the task analysis principles described by Miller et al. (1960), which refer to mental actions as much as to motor behavior. Since many tasks require a considerable amount of mental functions and effort, in particular in retrieving and understanding the information available and in planning and preparing what to do (including monitoring of what happens), much of what is essential for successful performance is covert. Whereas classical task analysis relies very much on observable actions or activities, the need to find out what goes on in other peoples' minds requires other approaches.

One consequence of the necessary extension of task analysis from physical to cognitive tasks was the realization that both the physical and the cognitive tasks were affected by the way the work situation was designed. Every artifact we design has consequences for how it is used. This goes for technological artifacts (gadgets, devices, machines, interfaces, complex processes) as well as social artifacts (rules, rituals, procedures, social structures and organizations). The consequences can be seen in the direct and concrete (physical) interaction with the artifact (predominantly manual work) as well as in how the use of the artifact is planned and organized (predominantly cognitive work). Introducing a new "tool" therefore affects not only how work is done but also how it is conceived of and organized. Yet interface design and instruction manuals and procedures typically describe how an artifact should be used but not how we should plan or organize the use of it even though the latter may be affected as much—or even more—than the former. The extension of task analysis to cognitive task analysis should therefore be matched by a corresponding extension of task design to cognitive task design (Hollnagel, 2003).

### 3.2.3  Elementary Task

All task analysis methods require an answer to what the elementary task is. As long as task analysis was occupied mainly with physical work, the question could be resolved in a pragmatic manner. But when task analysis changed to include the cognitive aspects of work, the answer became more contentious. This is obvious from the simple example of a HTA shown in Figure 2. For a person living in a developed or industrialized society, entering a PIN code can be assumed to be an elementary task. It can nevertheless be broken down into further detail by, for example, a motion-and-time study or a GOMS-type interaction analysis. The determination of what an elementary task is clearly cannot be done separately from assumptions about who the users are, what the conditions of use (or work) are, and what the purpose of the task analysis is. If the purpose is to develop a procedure or a set of instructions such as the instructions that appear on the screen of an ATM, there may be no need to go further than "enter PIN code" or possibly "enter PIN code and press ACCEPT." Given the population of users, it is reasonable for the system designer to take for granted that they will know how to do this. If, however, the purpose is to design the physical interface itself or to perform a risk analysis, it will be necessary to continue the analysis at least one more step. GOMS is a good example of this, as would be the development of instructions for a robot to use an ATM.

In the contexts of work, assumptions about elementary tasks can be satisfied by ensuring that users have the requisite skills (e.g., through training and instruction). A task analysis may indeed be performed with the explicit purpose of defining training requirements. Designers can therefore, in a sense, afford themselves the luxury of dictating what an elementary task is as long as the requirements can be fulfilled by training. In the context of artifacts with a more widespread use, typically in the public service domain, greater care must be taken in making assumptions about an elementary task, since users in these situations often are "accidental" (Marsden and Hollnagel, 1996).

### 3.3  Functional Dependency and Goals–Means Task Analysis

Both sequential and hierarchical task analyses are structural in the sense that they describe the order in which the prescribed activities are to be carried out. A hierarchy is by definition the description of how something is ordered, and the very representation of a hierarchy (as in Figure 2) emphasizes the structure. As an alternative, it is possible to analyze and describe tasks from a functional point of view (i.e., in terms of how tasks relate to or depend on each other). This changes the emphasis from how tasks and activities are ordered to what the tasks and activities are supposed to achieve.

Whereas task analysis in practice stems from the beginning of the twentieth century, the principle of functional decomposition can be traced back at least to Aristotle (Book III of the *Nicomachean Ethics).* This is not really surprising, since the focus of a functional task analysis is the reasoning about tasks rather than the way in which they are carried out (i.e., the physical performance). Whereas the physical nature of tasks has changed throughout history, and especially after the beginning of the Industrial Revolution, thinking about how to do things is largely independent of how things are actually done.

In relation to task analysis, functional dependency means thinking about tasks in terms of goals and means. The strength of a goals–means, or means–ends, decomposition principle is that it is ubiquitous, important, and powerful (Miller et al., 1960, p. 189). It has therefore been used widely, most famously as the basis for the General Problem Solver (Newell and Simon, 1961).

The starting point of a functional task analysis is a goal or an end, defined as a specified condition or state of the system. A description of the goal usually includes or implies the criteria of achievement or acceptability (i.e., the conditions that determine when the goal has been reached). To achieve the goal, certain means are required. These are typically one or more activities that need to be carried out (i.e., a task). Yet most tasks are possible only if specific conditions are fulfilled. For instance, you can work on your laptop only if you have access to an external power source or if the batteries are charged sufficiently. When these conditions are met, the task can be carried out. If not, bringing about these preconditions becomes a new goal, denoted a subgoal. In this way goals are decomposed recursively, thereby defining a set of goal–subgoal dependencies that also serves to structure or organize the associated tasks.

An illustration of the functions or tasks needed to start up an industrial boiler is shown in Figure 3

(see Lind and Larsen, 1995). The diagram illustrates how the top goal, "St1 established," requires that a number of conditions have been established, where each of these in turn can be described as subgoals. Although the overall structure is a hierarchical ordering of goals and means, it differs from a HTA because the components of the diagram are goals rather than tasks. The goals–means decomposition can be used as a basis for identifying the tasks that are necessary to start the boiler, but this may not necessarily fit into the same representation.

## 4 PRACTICE OF TASK ANALYSIS

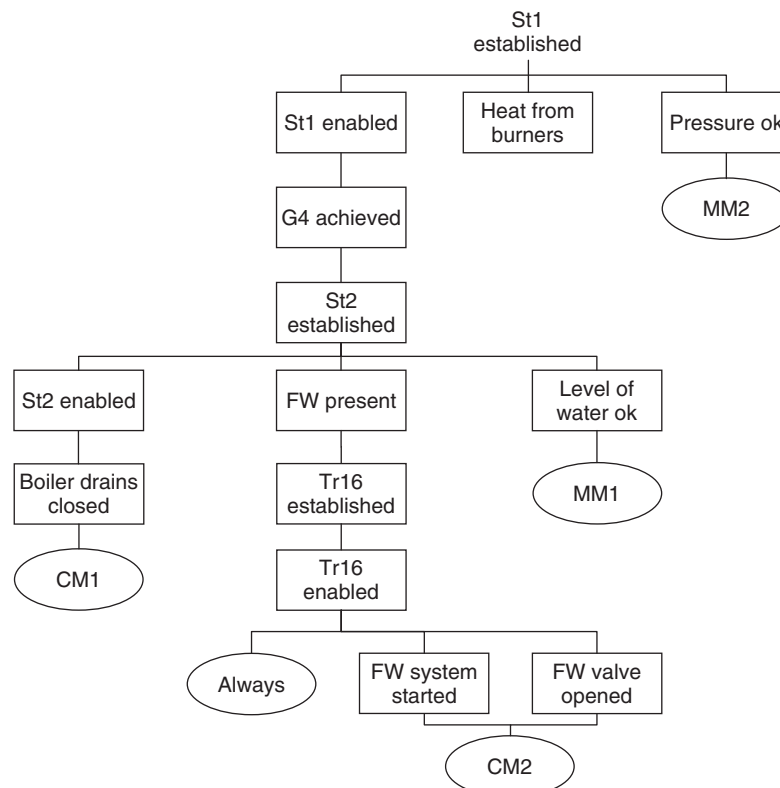
As already mentioned, task analysis can be used for a variety of purposes. Although the direct interaction between humans and computers got the lion's share of attention in the 1990s, task analysis is necessary for practically any aspect of a human–machine system's functioning. Task analysis textbooks, such as Kirwan and Ainsworth (1992), provide detailed information and excellent descriptions of the many varieties of task analysis. More recent works, such as Hollnagel (2003), extend the scope from task analysis to task design, emphasizing the constructive use of task knowledge. Regardless of which method an investigator decides to


**Figure 3** Goals–means task description.

use, there are a number of general aspects that deserve consideration.

## 4.1  Task Data Collection Techniques

The first challenge in task analysis is to know where relevant data can be found and to collect them. The behavioral sciences have developed many ways of doing this, such as activity sampling, critical incident technique, field observations, questionnaire, structured interview, and verbal protocols. In many cases, data collection can be supported by various technologies, such as audio and video recording, measurements of movements, and so on, although the ease of mechanical data collection often is offset by the efforts needed to analyze the data.

As task analysis extended its scope from physical work to include cognitive functions, methods were needed to get data about the unobservable parts of a task. The main techniques used to overcome this were "think-aloud" protocols and introspection (i.e., extrapolating from one's own experience to what others may do). The issue of thinking aloud has been hotly debated, as has the issue of introspection (Nisbett and Wilson, 1977). Other structured techniques rely on controlled tasks, questionnaires, and so on. Yet in the end the problem is that of making inferences from some set of observable data to what goes on behind, in the sense of what is sufficient to explain the observations. This raises interesting issues of methods for data collection to support task analysis and leads to an increasing reliance on models of the tasks. As long as task analysis is based on observation of actions or performance, it is possible to establish some kind of objectivity or intersubjective agreement or verification. As more and more of the data refer to the unobservable, the dependence on interpretations, and hence on models, increases.

## 4.2  Task Description Techniques

When the data have been collected, the next challenge is to represent them in a suitable fashion. It is important that a task analysis represent the information about the task in a manner that can easily be comprehended. For some purposes, the outcome of a task analysis may simply be rendered as a written description of the tasks and how they are organized. In most cases this is supplemented by some kind of graphical representation or diagram, since this makes it considerably easier to grasp the overall relations. Examples are the diagrams shown in Figures 1–3. Other staple solutions are charting and networking techniques, decomposition methods, HTA, link analysis, operational sequence diagrams (OSDs), and timeline analyses.

## 4.3  Task Simulation Methods

For a number of other purposes, such as those that have to do with design, it is useful if the task can be represented in other ways, specifically as some kind of description or model that can be manipulated. The benefit is clearly that putative changes to the task can be implemented in the model and the consequences can be explored. This has led to the development of a range of methods that rely on some kind of symbolic model of the task or activity, going from the production rule systems to task networks (e.g., Petri nets). This development often goes hand in hand with user models (i.e., symbolic representation of users that can be used to simulate responses to what happens in the work environment). In principle, such models can carry out the task as specified by the task description, but the strength of the results depends critically on the validity of the model assumptions. Other solutions, which do not require the use of computers, are mock-ups, walk-throughs, and talk-throughs.

## 4.4  Task Behavior Assessment Methods

Task analyses are in many cases used as a starting point to look at a specific aspect of the task execution, usually risk or consequences for system safety. One specific type of assessment looks at the possibility for humans to carry out a task incorrectly (i.e., the issue of "human error" and human reliability). Approaches to human reliability analysis that are based on structural task descriptions are generally oversimplified not only because humans are not machines but also because there is an essential difference between described and effective tasks or between "work as imagined" and "work as done." Task descriptions in the form of event trees or as procedural prototype models represent an idealized sequence or hierarchy of steps. Tasks as they are carried out or as they are perceived by the person are more often series of activities whose scope and sequence are adjusted to meet the demands—perceived or real—of the current situation (Hollnagel, 2010a). It can be argued that task descriptions used for risk and reliability analyses on the whole are inadequate and unable to capture the real nature of human work. The decomposition principle has encouraged—or even enforced—a specific form of task description (the event tree), and this formalism has been self-sustaining. It has, however, led human reliability analysis into a cul-de-sac.

## 4.5  Future of Task Analysis

We started this chapter by pointing out that task analysis is the study of *who* does *what* and *why*, where the *who* should be broadened to include individual work, collective work, and joint cognitive systems. The future of task analysis is bright in the sense that there will always be a practical need to know how things should be done. The question is whether task analysis as it is currently practiced is capable of meeting this need in the long run. There are several reasons why the reply need not be unequivocally positive:

1. Task analysis has from the beginning been concerned mostly with individuals, whether as single workers or single users, despite the fact that most work involves multiple users (collaboration, distributed work) in complex systems (Hutchins, 1995). Although the importance of distributed cognition and collective work is generally acknowledged, only few methods are capable of analyzing that, over and above

**Table 1 Tractable and Intractable Systems**

| | Tractable System | Intractable System |
|---|---|---|
| Number of details | Descriptions are simple with few details | Descriptions are elaborate with many details |
| Comprehensibility | Principles of functioning are known | Principles of functioning are partly unknown |
| Stability | System does not change while being described | System changes before description is completed |
| Relationship to other systems | Independence | Interdependence |
| Organization of tasks and activities | Stable, work is highly regular and tasks can be prescribed | Unstable, work must be adjusted to match the conditions, tasks cannot be prescribed |

representing explicit interactions such as in link analysis and OSDs.

2. Many task analysis methods are adequate for describing single lines of activity. Unfortunately, most work involves multiple threads and timelines. Although HTA represents a hierarchy of tasks, each subtask or activity is carried out on its own. There is little possibility of describing two or more simultaneous tasks, even though that is often what people have to cope with in reality. Another shortcoming is the difficulty of representing temporal relations other than simple durations of activities.

3. There is a significant difference between described and effective tasks. Work in practice is characterized by ongoing adaptations and improvisations rather than the straightforward carrying out of a procedure or an instruction. The reasons for this are that demands and resources rarely correspond to what was anticipated when the task was developed and the actual situation may differ considerably from that which is assumed by the task description, thereby rendering the latter unworkable.

The problem in a nutshell is that task analysis was developed to deal with linear work environments, where effects were proportional to causes and where orderliness and regularity on the whole could be assured. Sociotechnical systems have, however, since the 1980s become steadily more complex due to rampant technological and societal developments. The scope of task analysis must therefore be extended in several directions. A "vertical" extension is needed to cover the entire system, from technology to organization. A "horizontal" extension is needed to increase the scope to include both design and maintenance. A second horizontal extension is needed to include both upstream and downstream processes. The latter in particular means that previously separate functions no longer can be treated as separate. There are important dependencies to what went before (upstream) and what comes after (downstream).

Today's task analysis must therefore address systems that are larger and more complex than the systems of yesteryear. Because there are many more details to consider, some modes of operation may be incompletely known, there are tight couplings among functions, and systems may change faster than they can be described,

the net result is that many systems today are underspecified or intractable. For these systems it is clearly not possible to prescribe tasks and actions in every detail. This means that performance must be variable or flexible rather than rigid. In fact, the less completely the system is described, the more performance variability is needed.

It is useful to make a distinction between tractable and intractable systems (Hollnagel, 2010b). Tractable systems can be completely described or specified, while intractable systems cannot. The differences between the two types of systems are summarized in Table 1.
