hierarchy. Typically, the hierarchy has five separate levels of description, ranging from the physical form of a domain to the higher level purposes it serves. The highest level of constraints refers to the *functional purpose* or design goals for the system. For our simple process these are constraints $K_5$ and $K_6$. For example, consider the relationship between $R$ and $G_1$. When the actual reservoir volume ($R$) equals the goal reservoir volume ($G_1$),

the difference between these two values will assume a constant value (0.00). This process constraint is represented by the equation associated with the higher level property $K_5$ in Figure 12. For an actual work domain, the associated values (costs and benefits) underlying these particular goals might be considered. The *abstract functions* or physical laws that govern system behavior are another important source of constraints. In our

example, $K_4$ reflects the law of conservation of mass. Change of mass in the reservoir ($\Delta R$) should be determined by the difference between the residual mass in ($I_1 + I_2$) and the mass out ($O$). Similar constraints associated with the mass flow are represented as $K_1$, $K_2$, and $K_3$. Flow is proportional to valve setting (this assumes a constant-pressure head). Further constraints arise as a result of the *generalized function* (sources, storage, sink). In our example, there are two sources: a single store and a single sink. The physical processes behind each general function represents another source of constraint, *physical function*. In this case there are two feedwater streams, a single output stream, and a reservoir for storage. Similarly, the moment-to-moment values of each variable ($T$, $V_1$, $V_2$, $V_3$, $I_1$, $I_2$, $O$, and $R$) should be considered at the level of physical function. Finally, the level of *physical form* provides information concerning the physical configuration of the system, including information related to causal connections, length of pipes, position of valves on pipes, and size of the reservoir. All of these constraints will be satisfied if the process is being controlled in a proper fashion.

To summarize, an abstraction hierarchy analysis provides information about the hierarchically nested constraints that constitute the semantics of a domain and therefore defines the information that must be present in the interface for a person to perform successfully. The product of this analysis (interrelated categories of information) provides a structured framework for display development, as we will demonstrate shortly. It should be emphasized that this analysis and description is independent of the interface and therefore differs from traditional task analysis. Although space limitations do not permit a complete discussion, we view abstraction hierarchy analysis and task analysis (traditional or cognitive) as complementary processes that are necessary for the development of effective displays.

## 5.2   Coherence and Correspondence: Alternative Mappings

In this section we provide six examples that illustrate alternative mappings between domain semantics and representations (displays) for our simple process (Figure 13). The discussion is organized in terms of the distinction between integral, configural, and separable dimensions that was outlined in Section 3.3. One goal is to illustrate what these terms, originally coined in the attention literature, mean in the context of display design for complex systems. A second goal is to focus on the quality of the mapping that each display provides, especially with respect to the ability of each display to convey information at various levels of abstraction (see Sections 4.1.1 and 5.1.1). To illustrate the quality of the mapping explicitly, we have provided a summary listing (at the right of each display in Figure 13) that sorts the associated process constraints into two categories (P and D). Process constraints that are represented directly in the display (i.e., which can be "seen") have been placed in the P category (*P*erceived). Process constraints that are not represented directly and must be computed or inferred are placed in the D category (*D*erived). Process constraints that are related to physical structure are

represented by the theta symbol ($\phi$); process constraints related to the functional structure are represented by the integration symbol ($\int$).

***Separable Displays***   Figure 13*a* represents a separable display that contains a single display for each individual process variable present. Each display is represented in the figure by a circle, but no special significance should be attached to the symbology: The circles could represent digital displays, bar graphs, and so on. For example, four instantiations of this display are shown in Figures 10*a*, *b*, *e*, and *f*. In Figures 10*a* and *b* the display constraints are the relative heights of the bars in response to changes in the underlying variables.

In terms of the abstraction hierarchy, the class of displays represented by Figure 13*a* provides information only at the level of physical function: Individual variables are represented directly. Thus, there is not likely to be a focused-attention cost for low-level data. However, there is likely to be a divided-attention cost, because the observer must derive the high-level properties. To do so, the observer must have an internalized model of the functional purpose, the abstract functions, the general functional organization, and the physical process. For example, to determine the direction (and cause) of $\Delta R$ would require detailed internal knowledge about the process, since no information about physical relationships ($\phi$) or functional properties ($\int$) is present in the display.

Simply adding information about high-level properties does not change the separable nature of the display. In Figure 13*b* a second separable display has been illustrated. In this display the high-level properties (constraints) have been calculated and are displayed directly, including information related to functional purpose ($K_5$ and $K_6$) and abstract function ($K_1$, $K_2$, $K_3$, and $K_4$). This does off-load some of the calculational requirements (e.g., $\Delta R$). However, there is still a divided-attention cost. Even though the high-level properties have been calculated and incorporated into the display, the relationships among and between levels of information in the abstraction hierarchy are still not apparent. The underlying cause of a particular system state still must be derived from the separate information that is displayed. Thus, although some low-level integration is accomplished in the display, the burden for understanding the causal structure still rests in the observer's stored knowledge.

***Configural Displays***   The first configural display, illustrated in Figure 13*c*, provides a direct representation of much of the low-level data that are present in the display in Figure 13*a*. However, it also provides additional information that is critical to completing domain tasks: information about the physical structure of the system ($\phi$). This "mimic" display format was introduced in STEAMER (Hollan et al., 1984), and issues in the animation of these formats have been investigated more recently (Bennett, 1993; Bennett and Madigan, 1994; Bennett and Nagy, 1996; Bennett and Malek, 2000).

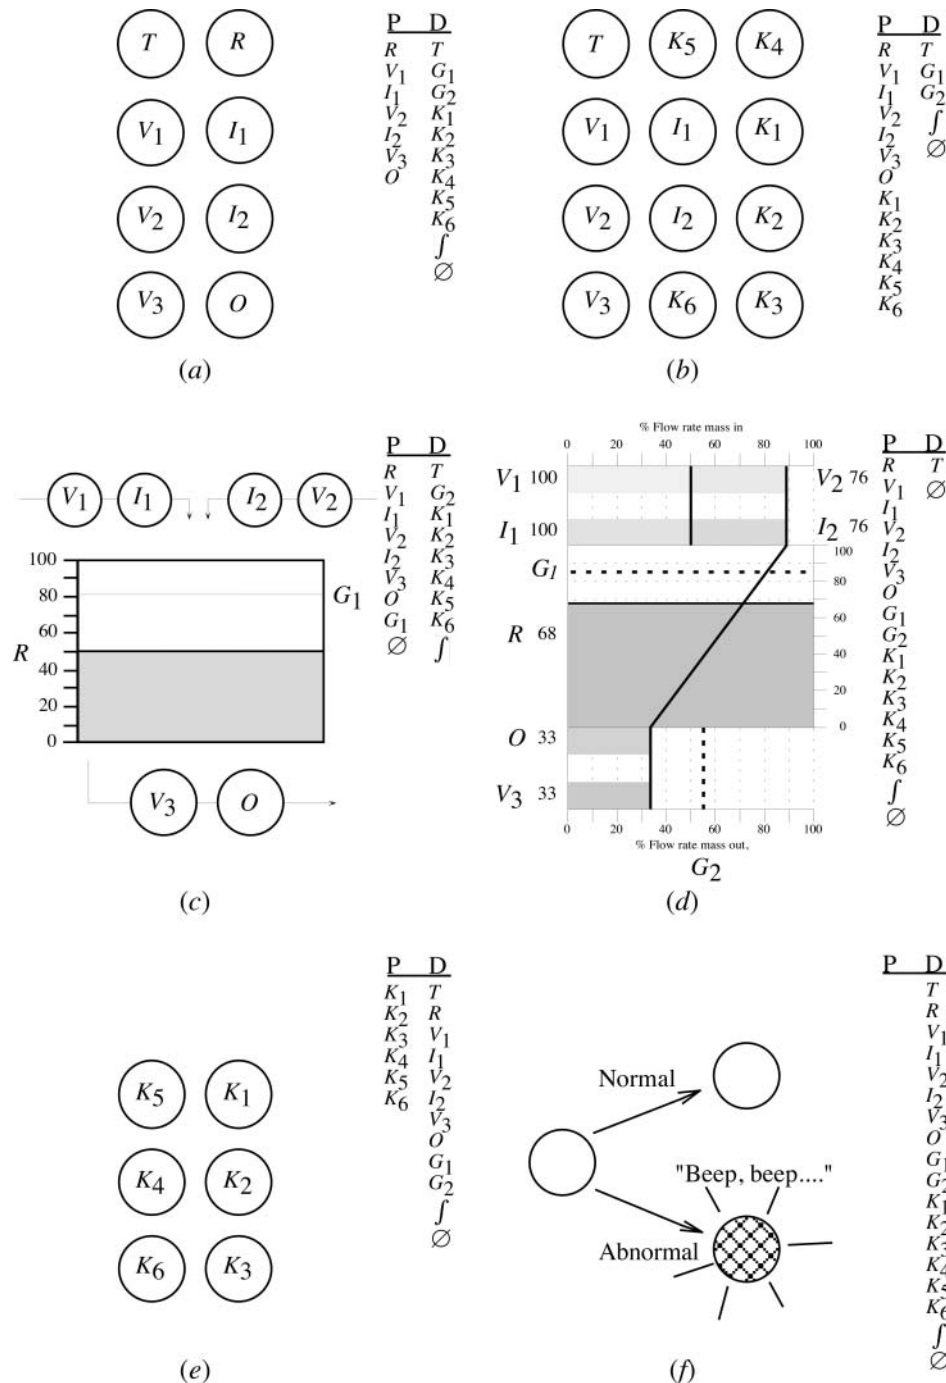
The mimic display is an excellent format for representing the generalized functions in the process. It


**Figure 13** Six alternative mappings for the domain constraints described in Figure 12. The circles represent generic separable displays, which could be bar graphs, pie charts, or digital displays. The data and properties outlined in Figure 12 have been placed in two categories for each mapping: P for data that can be perceived directly from the display and D for data that must be derived from the display by the observer. Parts (*a*) and (*b*) represent separable mappings, (*c*) and (*d*) represent configural mappings, and (*e*) and (*f*) represent integral mappings. These mappings illustrate how the terms *separable, configural*, and *integral* have different meanings when applied to display design (as opposed to their meaning in the attention literature).

has many of the properties of a functional flow diagram or flowchart. The elements can represent physical processes (e.g., feedwater streams), and by appropriately scaling the diagram, relations at the level of physical form can be represented (e.g., relative positions of valves). Also, the moment-to-moment values of the process variables can easily be integrated within this representation. Not only does this display include information with respect to generalized function, physical function, and physical form, but also the organization provides a visible model illustrating the relations across these levels of abstraction. This visual model allows the observer to "see" some of the logical constraints that link the low-level data. Thus, the current value of $I_2$ can be seen in the context of its physical function (feedwater stream 2) and its generalized function (source of mass); in fact, its relation to the functional purpose in terms of $G_1$ is also readily apparent from the representation.

Just as in the displays listed in Figures 13a and b, there is not likely to be a cost in selective attention with respect to the low-level data. However, although information about physical structure illustrates the causal factors that determine higher level system constraints, the burden of computing these constraints (e.g., determining mass balance) rests with the observer. Thus, what is missing in the mimic display is information about abstract function (information about the physical laws that govern normal operation).

The second configural display, illustrated in Figure 13d, is slightly more complex [the logic is similar to that of Vicente (1991)] and will be described in detail before discussing the quality of the mapping that it provides. The valve settings $V_1$ and $V_2$ are represented as back-to-back horizontal bar graphs that increase or decrease in horizontal extent with changes in settings. The measured flow rates ($I_1$ and $I_2$) have the same configuration of graphical elements and are located below the valve settings in the display. The horizontal bar graphs depicting valve settings and flow rates for a particular pipe (e.g., $V_1$ and $I_1$) are connected with a bold vertical line (in Figure 13d both of the lines are perpendicular because the settings and flow rates are equal in both input streams). The volume of the reservoir ($R$) is represented by a bold horizontal line and as the filled portion of the rectangle inside the reservoir. The value of $R$ can be read from the scale on the right side of the display and the associated digital value on the left; in Figure 13d the value of $R$ is 68. The associated reservoir volume goal ($G_1$) is represented by the bold horizontal dashed line (approximately 85). The flow rate of the mass leaving the reservoir is represented by the horizontal bar graph labeled $O$ at the bottom of the display; the corresponding valve setting is represented by the bar graph labeled $V_3$. These two bar graphs are also connected by a bold vertical line. The mass output goal ($G_2$) is represented by the bold vertical dashed line (approximately 55). The relationship between mass in ($I_1 + I_2$) and mass out ($O$) is highlighted by the bold angled line that connects the corresponding bar graphs.

Unlike the displays discussed previously, this configural display integrates information from all levels of the abstraction hierarchy in a single representation, making extensive use of emergent features that include equality, parallel lines, and collinearity. The general functions are related through a graphical "flow chart" with input (source) at the top, storage in the center, and output (sink) on the bottom. The abstract functions are related using the emergent features of equality and the resulting collinearity across the bar graphs. For example, the constraints on mass flow ($K_1$, $K_2$, $K_3$) are represented by a salient emergent feature (i.e., equality of the horizontal extent of the bars labeled $V_1/I_1$, $V_2/I_2$, and $V_3/O$). In addition, the constraints relating rate of volume change and mass balance ($K_4$) are represented by the horizontal extent of $I_1 + I_2$ relative to the horizontal extent of $O$, and these relationships are highlighted by the bold line connecting these bars. Thus, the mass balance is represented by the symmetry between the input bar graphs and the output bar graphs; the orientation of the line connecting them constitutes an additional emergent feature that should be proportional to rate of change of mass in the reservoir. Constraints at the level of functional purpose are illustrated by the difference between the goal and the relevant variable. For example, the constraint on mass inventory ($K_5$) is shown using the relative position between the hatched area representing volume within the reservoir and the bold horizontal dashed line representing the goal level $G_1$.

Although not a direct physical analog, this configural display preserves important physical relations from the process (e.g., volume and filling). In addition, it uses a variety of emergent features that provide a direct visual representation of the process constraints and that connect these constraints so as to make the functional logic of the process visible within the geometric form. In short, the visual properties of this display, most notably emergent features, provide a set of geometric constraints that specify the domain constraints directly (note that when we use the term geometric constraints we will be primarily referring to these emergent features). As a result, performance for both focused- and divided-attention tasks is likely to be facilitated substantially.

**Integral Displays** Figure 13e shows an integral mapping in which each of the process constraints are shown directly, providing information at the higher levels of abstraction. However, the low-level data must be derived. In addition, there is absolutely no information about the functional processes behind the display, and therefore the display does not aid the observer in relating the higher level constraints to the physical variables. Because there would normally be a many-to-one mapping from physical variables to the higher order constraints, it would be impossible for the observer to recover information from this display at lower levels of abstraction.

Figure 13f shows the logical extreme of this continuum. In this display the process variables and constraints are integrated into a single "bit" of information that indicates whether or not the process is working properly (all constraints are at their designed value). It should be obvious that although these displays may have no divided-attention costs, they do have selective-attention

costs and provide little support for problem solving when the system fails.

**Summary** This section has focused on issues related to the quality of mapping between process constraints and display constraints. Even the simple domain that we chose for illustrative purposes has a nested structure of domain constraints: There are multiple constraints that are organized hierarchically both within and between levels of abstraction. The six alternative displays achieved various degrees of success in mapping these constraints. The principle of correspondence is illustrated by the fact that these formats differ in terms of the amount of information about the underlying domain that is present. The display in Figure 13*f* has the lowest degree of correspondence; the displays in Figures 13*b* and *d* have the highest degree of correspondence. These two displays are roughly equivalent in correspondence, with the exception of the two goals that are present in Figure 13*d* but absent in Figure 13*b*. Although these two displays are roughly equivalent in correspondence, it should be clear from the prior discussion that they are definitely not equivalent in terms of coherence. Figure 13*d* allows a person to perceive information concerning the physical structure, functional structure, and hierarchically nested constraints in the domain directly, a capability that is not supported by the format in Figure 13*b*. The coherence of Figure 13*d* will be explored in greater detail in the following section. This section has also illustrated the duality of meaning for the terms *integral, configural*, and *separable*. In attention, these terms refer to the relationship between perceptual dimensions, as described in Section 3.3; in display design, these terms refer more appropriately to the nature of the mapping between the domain and the representation.

### 5.3 Meaning Processing: Normal and Abnormal Operating Conditions

In Section 10 we outlined differences in correspondence and coherence that resulted from six alternative mappings for our simple domain. In this section we explore issues related to coherence in greater detail, focusing on Figure 13*d* and the implications of the mapping for performance under both normal and abnormal or emergency operating conditions. To begin, we discuss the facilitating role that graphical constraints (i.e., emergent features) representing information in the abstraction hierarchy (in particular, abstract function—the physical laws that govern normal operation) can play under normal conditions. Properly designed configural displays will provide a powerful representation for control: breaks in the domain constraints will generally be seen as breaks in display constraints (e.g., nonsymmetries) and will suggest appropriate control inputs. This information is, perhaps, even more important for detecting faults (e.g., a leak). The possibility that these types of displays can change the fundamental nature of the behavior that is required on the part of the operator will also be entertained. Finally, the implications for the reduction of errors (more likely to occur under abnormal or emergency conditions) will be discussed.

The mapping between domain constraints and geometric constraints that is provided in the configural display shown in Figure 13*d* provides a powerful representation for control under normal operating conditions. In Figure 14*a* the display is shown with values for system variables indicating that all constraints are satisfied. The figure indicates that the flow rate is larger for the first mass input valve ($I_1$, $V_1$) than for the second ($I_2$, $V_2$) but that the two flow rates added together match the flow rate of the mass output valve ($O$, $V_3$). In addition, the two system goals ($G_1$ and $G_2$) are being fulfilled.

In contrast, Figures 14*b–d* illustrate failures to achieve system goals. In these displays not only is the violation of the goal easily seen, but each system variable is seen in the context of the control requirements. Thus, in Figure 14*b* it is apparent that the $K_5$ constraint is not being met (the actual level of the reservoir is higher than the goal). It is also apparent that the $K_4$ constraint is broken. The orientation of the line connecting mass in ($I_1 + I_2$) and the mass out ($O$) specifies that a positive net inflow for mass exists (mass in is greater than mass out). In essence, the deviation in orientation of this line from perpendicular is an emergent feature corresponding to the size of the difference. Under these circumstances control input is required immediately: An adjustment at valve 1 and/or valve 2 will be needed to avoid overflow from the reservoir. The observer can see these valves in the context of the two system goals; the representation makes it clear that these are the appropriate control inputs to make. For example, although adjusting valve 3 from 54 to a value greater than 70 would also cause the reservoir volume to drop, it is an inappropriate control input because goal 2 would then be violated.

In Figure 14*c* the situation is exactly the same, with one exception: There is a negative net inflow for mass, as indicated by the reversed orientation of the connecting line. Under these circumstances the operator can see that no immediate control input is required. Because mass in is less than mass out, the reservoir volume is falling, and this is exactly what is required to meet the $G_1$ reservoir volume goal. Of course, a control input will be required at some point in the future (mass will need to be balanced when the reservoir level approaches the goal). Similarly, in Figure 14*d* the observer can see that the $K_5$ and $K_6$ constraints are broken and that an adjustment to valve 3 (a decrease in output) is needed to meet the output requirements ($G_2$) and the volume goal ($G_1$).

Thus, in complex dynamic domains it is the pattern of relationships between variables, as reflected in the geometric constraints, that determines the significance of the data that are presented. It is this pattern that ultimately provides the basis for action, even when the action hinges on the value of an individual variable. When properly designed, configural displays will directly reflect these critical data relationships via emergent features and suggest the appropriate control input.

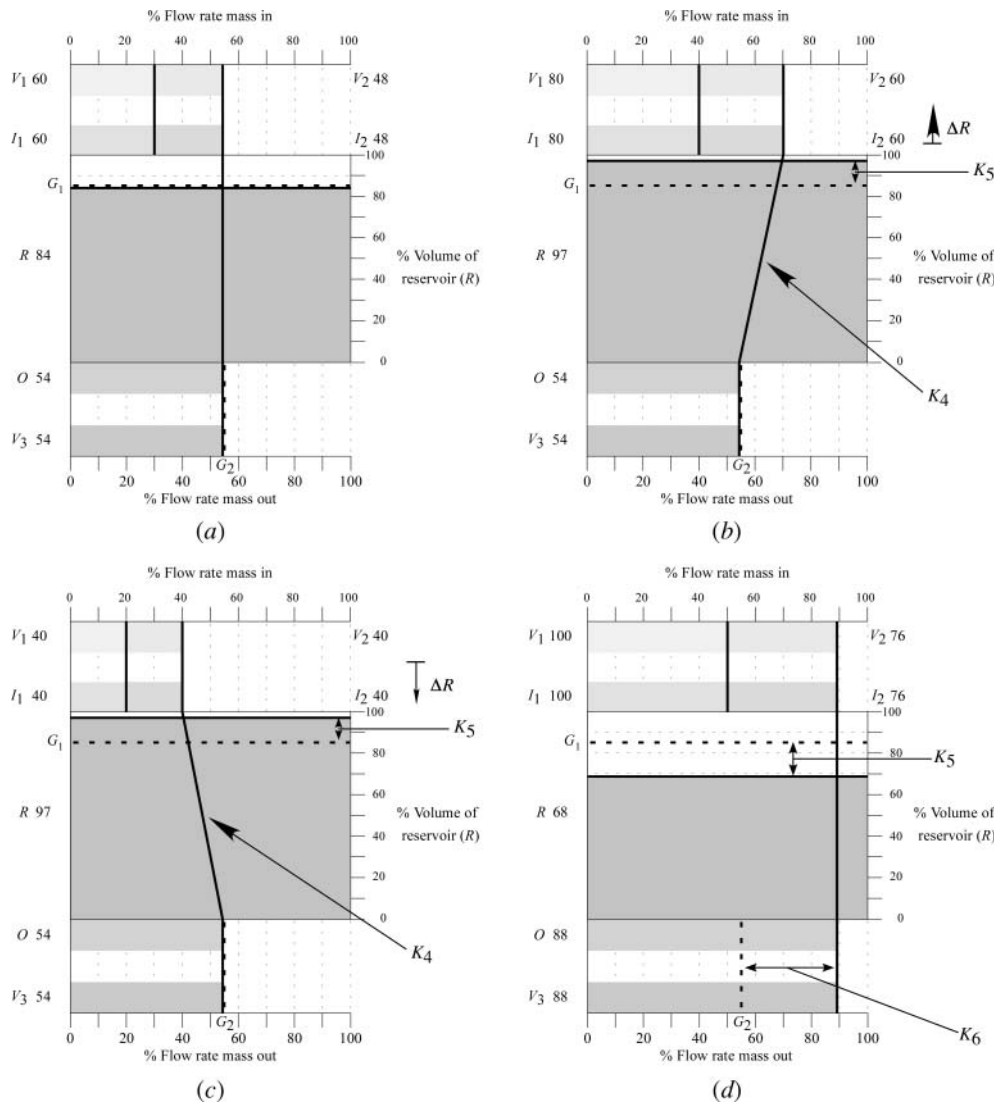
A similar logic applies for operational support under abnormal or emergency conditions. As in Figure 14, Figure 15*a* represents a configuration with all system


**Figure 14** Mapping between the domain constraints (data, properties, goals) and the geometric constraints (visual properties of the display, including emergent features such as symmetry and parallelism) under relatively normal operating conditions.

constraints being met. In Figure 15b the first constraint ($K_1$) is broken. There are two aspects of the display geometry indicating that the flow rate ($I_1$) does not match the commanded flow or valve setting ($V_1$). First, the horizontal extent of the two bar graphs in the top left portion of the display are not equal, and this relationship is emphasized by the orientation of the bold line connecting the two graphs (similar to the emergent feature for mass balance). There are a number of potential causes for this discrepancy, which include (1) a leak in the valve, (2) a leak in the pipe prior to the point at which the flow rate is measured, or (3) an obstruction in the pipe. In contrast, the fact that the line connecting $V_2$ and $I_2$ is not perpendicular

(but is parallel to the first connector line) does not indicate that the $K_2$ constraint is broken. Instead, this is an indication that the commanded and actual mass flows in the second mass input stream are equal (and therefore that the discrepancy is isolated in the first mass input stream). A similar mapping between geometric constraints and domain constraints represents a fault in the $K_3$ constraint, as illustrated in Figure 15c.

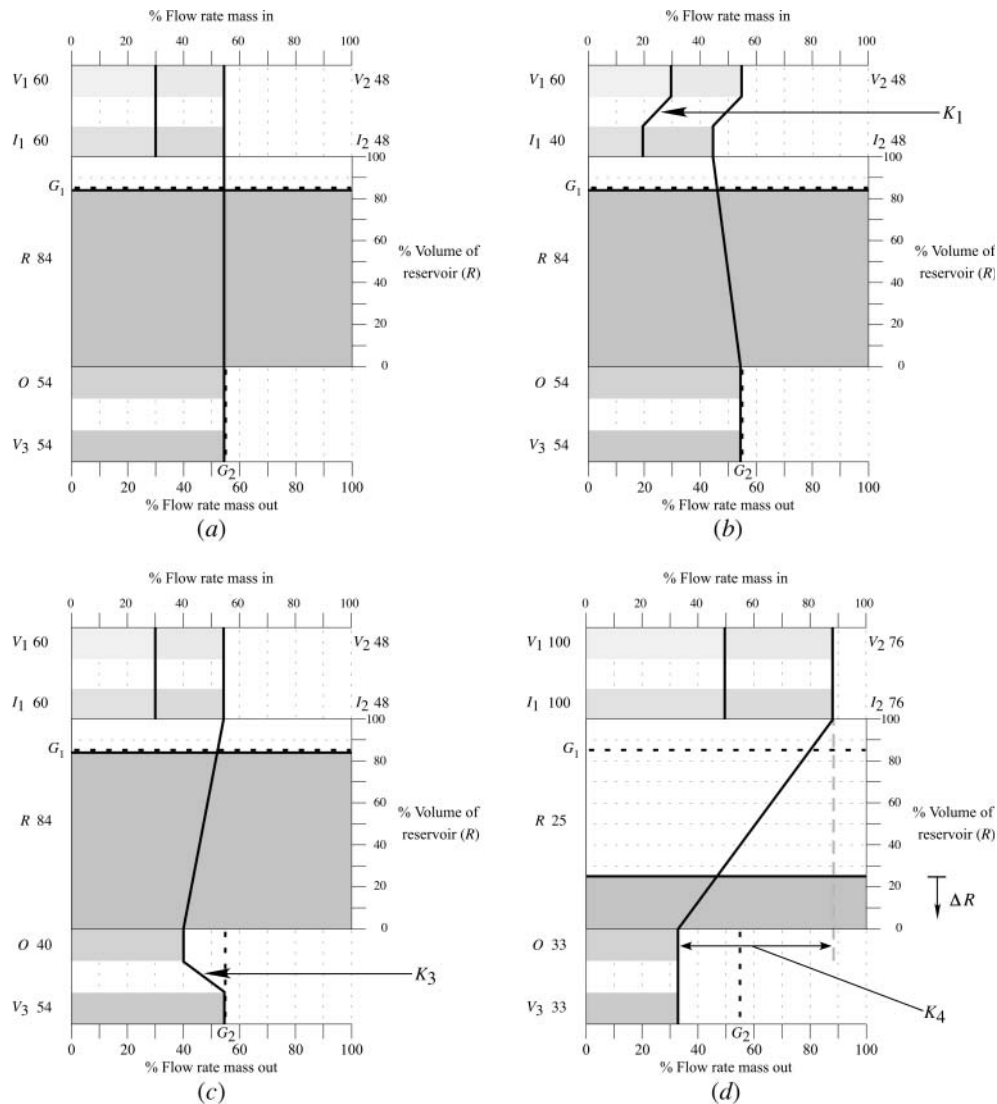
Figure 15d illustrates changes in the visual display (breaks in the geometric constraints) that are associated with a fault in the system (a break in the mass balance constraint, $K_4$). In this example, there is a positive net inflow of mass which is normally associated with an increase in the volume of the reservoir (again, specified


**Figure 15** Mapping between the domain constraints (data, properties, goals) and the geometric constraints (visual properties of the display, including emergent features such as symmetry and parallelism) under abnormal or emergency operating conditions.

by the emergent feature of orientation). However, in this case the mass inventory is falling, as we have indicated in the diagram by the downward-pointing arrow located near the $\Delta R$ symbol (this is difficult to represent in a static diagram but would be seen clearly on a dynamic display). Again, there are several potential explanations for this fault. The most likely explanation is that there is a leak in the reservoir itself; however, there could be a leak in the pipe between the reservoir and the point at which the flow measurement is taken. It should be noted that while the nature of the fault can be seen (e.g., leak or blockage in feedwater line) this representation would not be very helpful in physically locating the leak within the plant (e.g., locating valve 1).

These examples illustrate that properly designed displays can change the fundamental type of behavior that is required of an operator under both normal and abnormal operating conditions. With separable displays (e.g., the separable configurations illustrated in Figure 13) the operators are required to engage in knowledge-based behaviors: They must rely on internal models of system structure and function (and therefore use limited capacity resources—working memory) to detect, diagnose, and correct faults. As a result, the potential for errors is increased dramatically. In contrast, properly designed configural displays present externalized models of system structure and function through geometric constraints. This allows operators to

utilize skill-based behaviors (e.g., visual perception and pattern recognition) that do not require limited capacity resources. As a result, the potential for errors will be decreased dramatically. As Rasmussen and Vicente (1989) have noted, changing the required behavior from knowledge-based behavior to rule- or skill-based behavior is a goal for display design.

Properly designed configural displays will also reduce the possibility of *underspecified action errors* (Rasmussen and Vicente, 1989). In complex, dynamic domains people can form incorrect hypotheses about the nature of the existing problem if they do not consider the relevant subsets of data (Woods, 1988). Observers may focus on these incorrect hypotheses and ignore disconfirming evidence, showing a kind of tunnel vision (Moray, 1981). Observers may also exhibit *cognitive hysteresis* and fail to revise hypotheses as the nature of the problem changes over time (Lewis and Norman, 1986). Configural displays that reflect the semantics of a domain directly can reduce the probability of these types of errors by forcing an observer to consider relevant subsets of data.

One final point needs to be made in closing this section. It is important to note that, even though multiple variables may testify with regard to higher level domain properties, configural displays that use geometric forms are *not* always the appropriate design solution. Ultimately, the design decision hinges on the relationships and interactions between variables. Consider the case of a mobile army commander engaged in tactical battlefield operations (Bennett et al., 2008). There are five combat resources that are the primary determinants of the higher level property of combat power: tanks, personnel carriers, ammunition, fuel, and personnel. The key design criterion is that these resources are essentially independent; there is no physical law or causal relationship that explicitly defines higher order patterns between variables. It is true that the combat resources can be correlated: A unit engaged in an intense offensive battle might suffer equipment and personnel losses while expending substantial amounts of fuel and ammunition. However, any number of factors can change the relationship between them. For example, ammunition is likely to be expended more quickly than fuel in a defensive mission.

The use of a highly configural representation, such as a polar graphic display (e.g., Woods et al., 1981) for the five combat resources, is a tempting, but inappropriate, design choice. This display would produce numerous, salient, and hierarchically nested emergent features that highlighted the relationships and interactions between combat resources. This produces a poor mapping between display and domain: The display constraints (i.e., the particular asymmetries and other distortions of the polar graphic) would not uniquely specify underlying domain constraints (i.e., higher level domain properties arising from the interaction of variables). Many, if not most, of the emergent features produced by the display would be essentially meaningless and would therefore need to be ignored (an extremely difficult, if not impossible, task for actors to accomplish). Bennett et al. (2008) chose a separable format similar to that

portrayed in Figure 10*b*. This representation maintains the independence of the individual combat resources while still providing limited configurality (Sanderson et al., 1989).

## 5.4   Practical Guidelines

In conclusion, we believe that the application of this approach to display design will improve overall human machine performance through the development of configural displays that support normal control as well as fault detection, diagnosis, and repair. The potential for errors will be decreased dramatically, because the critical information for control is represented directly in the interface. This, in turn, dramatically reduces the requirement for knowledge-based reasoning on the basis of internalized models. Recent applications of this approach include aviation displays (e.g., Amelink et al., 2005), anesthesiology (e.g., Drews and Westenskow, 2006), and process control (Lau et al., 2008). To summarize, we offer three general heuristics for analog, configural displays designed for law-driven domains:

1. Each relevant process variable should be represented by a distinct element within the display. If precise information about this variable is desirable, a reference scale and supplemental digital information should be provided.
2. The display elements should be organized so that the emergent properties (symmetries, closure, parallelism) that arise from their interaction correspond to higher order constraints within the process. Thus, when process constraints are broken (i.e., a fault occurs), the corresponding geometric constraints are also broken (the display symmetry is broken).
3. The symmetries within the display should be nested (from global to local) in a way that reflects the hierarchical structure of the process. High-order process constraints (e.g., at the level of functional purpose or abstract function) should be reflected in global display symmetries; lower order process constraints (e.g., functional organization) should be reflected in local display symmetries.

## 6   CHALLENGES OF COMPLEX SYSTEMS

The simple process described above is convenient for a tutorial introduction to some of the important decisions that must be made when designing a graphical representation. However, this example greatly underestimates the complexity seen in many advanced human–technological systems (e.g., nuclear power, air traffic control, advanced tactical aviation, command and control centers for managing military and space operations, minimally invasive and remote surgery). These systems typically have multiple modes of operation (each with different constraints and boundary conditions) and require multiple windows into the process. In these systems, the goal remains the same, to make the real constraints of the work process (at all levels of

abstraction) visible to the human operator. The designer must still address the problems of correspondence (so that all relevant process constraints are represented in the interface) and coherence (so that the representation is comprehensible to the human operator). For these complex systems, however, it will not be possible to achieve both correspondence and coherence with a single graphic display. Thus, the added problem of navigating through multiple views (i.e., windows, screens, pages) must be addressed.

A principal threat to these complex systems is *mode error* (Woods, 1984), which occurs when the operator loses track of dynamic changes in the operating constraints governing a process. The operator responds to one set of constraints (i.e., mode) when a different set of constraints is, in fact, governing the process. The design challenge is to coordinate the multiple windows necessary for complete representation with the changing operational modes. In simple terms, the problem is how the interface can be designed to ensure that the appropriate window is always coupled with the appropriate mode, that is, to ensure that the important information is salient at the appropriate times.

Two classes of solutions might be considered for dealing with the navigation problems that typically lead to mode errors, computational and graphical. Computational solutions or adaptive interfaces include an inference engine that manages the representation automatically. This computational engine adjusts the representation automatically based on inferences about the state of the system and the state of the operator. Projects such as the "pilot's associate" are examples of attempts to design automatic systems to aid operators to navigate through the representations associated with a complex work domain. However, the focus of this chapter is on graphical solutions. For this reason we use the remaining space to consider briefly some graphical approaches to this problem.

Woods (1984) introduced the term *visual momentum* to refer to the cognitive costs associated with switching from one reference frame to another. If visual momentum is high, the cost of switching views is low. In this case, the new display is consistent with expectations created by the prior display. If visual momentum is low, there is a high cost of switching. That is, the new display is not consistent with expectations and the cognitive system must effectively recalibrate before information can be extracted from the new display. To ensure high visual momentum, the design of each graphical display must be considered relative to the other displays that operators may be using. Are the graphical conventions [e.g., coordinates, scales, directions, motions, colors, stimulus–response (S-R) mappings] used in one display consistent with those in another?

A graphical device that Woods (1984) has suggested to increase visual momentum is the use of *landmarks*, graphical elements that provide an orientation point that relates one display to another. Just as a tall building or mountain that is visible from many different parts of the landscape might help a person to orient to the geography, graphical landmarks can be designed with the objective of aiding the operator to orient within the functional landscape of the work domain. For example, Aretz (1991) used a shaded wedge within an electronic map display as a landmark to specify the region within the map that corresponded to the head-up forward view of the pilot.

Another graphical device to help operators navigate across multiple display pages is a map or overview display. This display can be implemented as a separate window or as an embedded landmark in all windows. This overview might use a flow diagram or hierarchical tree structure to show functional links among the multiple display pages.

The concrete examples we have provided involve law-driven work domains and configural displays. We provide one brief description of an intent-driven domain and a metaphorical display. The BookHouse interface designed by Pejtersen (1980, 1992) uses a spatial metaphor in which rooms in a "house" are set up for various categories of users. This spatial metaphor allows the operator to apply natural abilities for navigating in three-dimensional spaces to the task of navigating in the more abstract space of a library database. For a more detailed treatment of intent-driven domains and metaphorical displays, consider Flach et al. (2011), who discuss ecological interface design for the Web. For a more detailed treatment of visual momentum, consider Bennett and Flach (2011), who provide additional discussion and concrete examples from several different work domains.

In the BookHouse, the three-dimensional space is implemented in a two-dimensional display. Virtual reality systems now offer the possibility for effective three-dimensional representations. With these systems, designers have the opportunity to maximize the transfer of natural human ability to orient and navigate in three-dimensional environments to more abstract environments and to combine natural three-dimensional representations with imagery obtained by advanced sensor systems. For example, virtual displays for minimally invasive surgery are being designed that integrate the three-dimensional image of a patient's anatomy with information obtained by magnetic resonance imaging (MRI) scans and other advanced imaging technologies. Thus, virtual three-dimensional spatial metaphors might provide another technique for integrating complex information from distributed sensors into a coherent representation.

The central theme of this chapter is that problem solving can be critically influenced by the nature of visual representations. Building effective representations requires designers to go beyond the simple psychophysical questions of data availability to the more complex questions of information availability, where information refers to the specification of domain constraints and boundary conditions. This specification depends both on the mapping from display to human (i.e., coherence) and that from display to domain (i.e., correspondence).

# CHAPTER 43

# INFORMATION VISUALIZATION

**Chris North**
**Virginia Polytechnic Institute and State University**
**Blacksburg, Virginia**

## 1 INTRODUCTION

The information revolution is changing the way that many people live and think. Vast quantities and diverse types of information are being generated, stored, and disseminated, raising serious issues about how to make such information usable. The need to understand and extract knowledge from stored information is becoming a ubiquitous task. As examples, in everyday life people must sort through a variety of personal information, such as e-mail communications, schedules, news, finances, and social media. Students can access countless digital libraries of educational materials. Online shoppers must make decisions among dozens of alternative products, models, vendors, and prices. New disciplines such as bioinformatics are leading the revolution in information-intensive science using high-throughput data collection technologies such as microarrays and online data repositories. Government intelligence analysts must sift through massive collections of information gathered on a daily basis from sensor networks and other sources.

*Information visualization* has evolved as an approach to make large quantities of complex information intelligible. An information visualization is a visual user interface to information, with the goal of providing users with information *insight* (Spence, 2001). The basic method is to generate interactive visual representations of the information that exploit the perceptual capabilities of the human visual system and the interactive capabilities of the cognitive problem-solving loop (Ware, 2004).

The goal of this chapter is to highlight the critical high-level design decisions in the information visualization design process. Lower level details of visual display and human perception can be found elsewhere in this book. Other aspects of the design process that apply to the design of user interfaces in general, such as evaluation methods, are also covered in other chapters. While other major references focus on the "what" and "why" of information visualization (Card et al., 1999; Chen, 1999; Wickens and Hollands, 2000; Spence, 2001; Ware, 2004; Shneiderman and Plaisant, 2005), here we emphasize the "how."

### 1.1 Insight

Human vision contains millions of photoreceptors and is capable of rapid parallel processing and pattern recognition (Ware, 2004). The impressive bandwidth of vision as a mode of communication leads to the efficient transfer of data from digital storage to human mind. Yet a more important benefit is the human ability to reason visually about the data and extract higher level

knowledge, or insight, beyond simple data transfer (Card et al., 1999). This enables people to infer new mental models of the real phenomena represented by the data.

For example, Figure 1 demonstrates the mapping of a database of census demographics. From the visual representation in scatterplot form, one can readily recognize the approximate proportional relationship between education and income, various outliers, such as New York, NY, and the predominance of large population counties in high income and education. These insights are not explicitly stored within the data set but are inferred through visual pattern recognition. These insights are not so readily identifiable from the textual spreadsheet representation. Clearly, appropriate design choices in

the visual representation are important to enabling this insight. A poorly designed visualization can hide this insight or even mislead with incorrect insight.

Researchers increasingly recognize that the benefit of visualization goes beyond tapping into human visual abilities to human interactive abilities (Thomas and Cook, 2005; Fekete et al., 2008). Visualizations provide humans with a medium for interacting with information. Cognitive psychology theories of embodied interaction (Wilson, 2002) and distributed cognition (Liu et al., 2008) suggest that insight is gained through the interactive dialogue that takes place between the user and the visualization. In the example in Figure 1, the perceived relationship between income and education might

(a)

(b)

(c)  (d)  (e)  (f)

**Figure 1** Census demographics data set of 3140 U.S. counties shown in (a) spreadsheet form and (b) scatterplot form using Spotfire. The plot shows counties by income per capita vs. percentage of adult population that has college degree, with dots sized by population, and labels for some outliers. The plot is interactive and reveals details of a county when the user clicks on a dot. Dots can be filtered by other county attributes, such as median rental cost of housing, using the dynamic query slider widgets on the right. The plots at bottom show the result when filtering median rent to (c) low, (d) medium–low, (e) medium–high, and (f) high. [From Ahlberg and Wistrand (1995). Courtesy of Spotfire.]

prompt one to investigate how cost of living relates. Interactive filtering reveals an interesting animated trend on the median cost of rental housing. Low rent is limited to areas that are low income and low education. Increasing rent first extends to high-income, low-education areas, then to low-income, high-education areas, then finally to high-income, high-education areas. This additional insight was enabled by the interactive affordances of the visualization. The design of the interaction is important to allow users to selectively pursue many possible lines of investigation, depending on new questions that arise from discoveries made, in accordance with their thought processes.

Visualization can enable a broad range of information insight, and several categories of such insights are listed below (see also Wehrend and Lewis, 1990; Zhou and Feiner, 1998; Wickens and Hollands, 2000; Shneiderman and Plaisant, 2005; Amar et al., 1995). The first two are simplistic and can be supported readily by textual or query-based user interfaces such as spreadsheets or search forms, because they are precisely defined and have solutions consisting of a single data entity. However, the latter are more complex and are well supported by visualization. These involve open-ended questions with complex answers that require seeing the whole. A strength of visualization is the capacity for discovery, the recognition of new insights unexpected by the users and potentially unforeseen by the visualization designers.

Simple insights:

- *Summaries:* minimum, maximum, average, percentages
- *Find:* known item search

Complex insights:

- *Patterns:* distributions, trends, frequencies
- *Relationships:* correlations, multiway interactions
- *Trade-offs:* balance, combined minimum/maximum
- *Comparisons:* choices (1:1), context ($1 : M$), sets ($M : N$)
- *Clusters:* groups, similarities
- *Structures:* breadth, depth, decompositions, order
- *Paths:* distance, multiple routes, connectedness
- *Outliers:* exceptions
- *Anomalies:* data errors

## 1.2 Design

Like any user interface, effective information visualizations are difficult to design. Fundamentally, information visualizations make *abstract information* perceptible. Abstract information has no inherent perceptual form, as in the case of databases or computer directories. Hence, there are no natural constraints on the types of visual representations and interactions that creativity can produce for abstract information, and the possibilities are limitless. As a result, there is significant

challenge, excitement, and opportunity both in creating novel visual representations and in identifying the most effective representations among the endless possibilities. In contrast, *scientific visualization* (Rosenblum et al., 1994) typically emphasizes the visualization of data that represent physical three-dimensional phenomena, which offer some natural constraints on visual representations and focus the challenges on realism.

The two most challenging characteristics of information that make designing effective information visualizations difficult are (1) the *complexity* of diverse abstract information that may have multiple interrelated data types and structures and (2) the *scalability* to very large quantities of information. Because of these characteristics, visual representations alone are not sufficient, and interactive techniques must also be designed. Although the design principles of static graphs and illustrations are fundamental to visualization design (Cleveland, 1993; Gillan et al., 1998; Wilkinson, 1999; Tufte, 2001), new human–computer interaction issues related to these two challenging characteristics come to the forefront in information visualization design.

As an overview, the visualization design process involves iterative requirements analysis, design, and evaluation (e.g., Rosson and Carroll, 2001). In the requirements analysis phase, it is important to identify the two primary inputs to design: (1) the characteristics of the information to be visualized and (2) the types of insights that the visualization should enable. Characteristics of the information include the data schema, underlying information structures, and data quantity. Since the number of data attributes and desired insights may be large, identifying a prioritization of attributes and insights will be helpful in balancing design trade-offs. Other elements of requirements analysis include broader user tasks, users' domain knowledge, data semantics, and computer system requirements. In the design phase, major design decisions (presented in this chapter) include the visual mapping of the information, the representation of information structures, visual overview strategies, navigation strategies, and interaction techniques.

The evaluation phase must be considered continually during the design process (Plaisant, 2004). A claims analysis identifies the positive and negative impacts of a visualization design's features on its insight capability and seeks to overcome or balance these trade-offs through iterative design (Rosson and Carroll, 2001). Begin with analytic evaluations to determine if designs meet requirements, such as scalability to data quantity and appropriateness for producing desired insights. In later iterations, empirical evaluations involving users should be undertaken, such as the "wizard of Oz" technique, usability testing, or controlled experiments (Chen and Yu, 2000; Tory and Möller, 2004a). Desired insights identified in requirements analysis should be implemented as benchmark user tasks in the empirical evaluations. Alternatively, since benchmark tasks often overly constrain the testing to simplistic insights that discount the discovery aspect of visualization, the insight-based methodology (Saraiya et al., 2004) attempts to measure the insight generated by visualizations by using an

open-ended experimental protocol without benchmark tasks. In the following sections we highlight the major design decisions in the information visualization design process.

## 2   VISUALIZATION PIPELINE

The *visualization pipeline* is the computational process of converting information into a visual form with which users can interact (Card et al., 1999) (Figure 2). The first step is to transform raw information into a well-organized canonical data format. The resulting format typically consists of a data set containing a set of data entities each of which has associated data attribute values. Various data-processing steps can be used to manipulate the data as needed. Derived data, such as data mining or clustering results, can be very useful for assisting in insight generation (Fayyad et al., 2001). The second step, the heart of the visualization process, is to map the data set into visual form. The visual form contains visual glyphs that correspond to the data set entities. The third step embeds this visual form into views, which display the visual form on screen and provide various view transformations, such as navigation. The view is then presented to the user through the human visual system. Users interpret the view to (partially) mentally reconstruct the underlying information. Finally, users can interact with any of the steps in the pipeline to alter the resulting visualization and make further interpretations. This entire pipeline comprises an information visualization.

### 2.1   Visual Mapping

The visual mapping at the second step is the heart of visualization and must be designed carefully. The goal is to communicate information from computer to human. The medium of communication is a visual representation of the information. The data set is mapped computationally into visual form by some function $f$, which takes the data set as input and generates the visual representation as output. Then, when the visual representation is communicated to users, they must cognitively reverse the visual mapping by inverting function $f$ to decode the information from the visual representation. It is yet unclear how, when, and to what degree $f^{-1}$ is cognitively applied in the perceptual process, and a variety of models exist (Ware, 2004). Although some cognitive reasoning operates on the visual representation itself, eventually meaning must be decoded. Nonetheless, this visual communication process implies four important characteristics of the visual mapping function $f$:

1. *Computable*. $f$ is a mathematical function that can be computed by some algorithm. Although there is significant room for creativity in the design of these functions, execution of the functions must be algorithmic.

2. *Invertible*. It must be possible to use $f^{-1}$, the inverse of mapping function $f$, to reconstruct the data from the visual representation to a desired degree of accuracy. If this is not possible, the visualization will be ambiguous, misleading, or not interpretable.

3. *Communicable*. $f$ (or preferably $f^{-1}$) must be known by the user to decode the visual representation. It must be communicated with the visualization or already known by the user through prior experience. In usability terms, this is a learnability issue.

4. *Cognizable*. $f^{-1}$ should minimize cognitive load for decoding the visual representation. This is a human perception and performance issue.

The visual mapping step is accomplished by two sub-steps (Card et al., 1999) (Figure 3). First, each data entity is mapped into a visual *glyph*. The vocabulary of possible glyphs consists primarily of points (dots, simple shapes), lines (segments, curves, paths), regions (polygons, areas, volumes), and icons (symbols, pictures). Second, attribute values of each data entity are mapped onto *visual properties* of the entity's glyph. Common visual properties of glyphs include spatial position ($x$, $y$, $z$), size (length, area, volume), color (gray scale, hue, intensity), orientation (angle, slope, unit vector), and shape. Other visual properties include texture, motion, blink frequency, density, and transparency. For example, in Figure 1, U.S. counties are mapped to circular points. Income and education levels of each county are mapped to the horizontal and vertical position of the point, respectively, and population value is mapped to the size of the point.

### 2.2   Visual Properties

In general, data attributes should be prioritized according to the problem requirements and desired insights. The prioritization can then be applied to map the higher priority data attributes to the most effective visual properties. Spatial position properties are the most effective and should be reserved to lay out the data set in the visual representation according to the most important data attributes.

Shape
**Figure 3** Vocabulary of glyphs and some visual properties of glyphs. (Adapted from Card et al., 1999.)

The remaining visual properties, called *retinal properties* (Bertin, 1983), can be used next. The effectiveness of these properties are determined by many interdependent factors, including preattentive processing (Healey et al., 1996), perceptual independence and separability (Ware, 2004), data type (quantitative, ordinal, categorical) (Card et al., 1999), polarity (greater than, less than) (Ware, 2004), task (Carswell, 1992; Wickens and Hollands, 2000), and attention (Chewar et al., 2002). Commonly accepted orderings of the effectiveness of these attributes are based on empirical evidence (e.g., Cleveland and McGill, 1984; Nowell et al., 2002) as well as experience (Bertin, 1983; Mackinlay, 1986).

The order shown in Figure 3, most effective on top, is intended for quantitative data. To interpret quantitative data visually, effective visual properties should enable users to visually estimate order and ratios of multiple data values. Spatial properties are most effective because the human visual system can accurately judge spatial ratios. Color maps are less effective and must be carefully designed (Harrower and Brewer, 2003). Rainbow color maps are not effective, because they lack perceptual ordering and linear scale. For categorical data, color and shape become more effective. Categorical data only requires users to be able to distinguish groups. Unique hues assigned to each group are an effective approach. Some visualization design systems attempt to use such rules to generate effective mappings automatically [e.g., Apt (Mackinlay, 1986), Sage (Roth et al., 1994), and Tableau (Tableau Software, 2010)].

Finally, for any remaining data attributes, interaction techniques can be applied. In general, direct visual mapping of information is most effective for rapid insight, but only a limited number of data attributes can be simultaneously mapped, whereas interaction techniques require slower physical actions by the user to reveal insights but are essentially unlimited. When mapping additional data attributes would overly clutter the visual representation and reduce comprehension of more important attributes, interaction techniques can be used instead. Interaction techniques enable users to alter the visual mapping function or other stages of the visualization pipeline, based on additional data attributes. By viewing the resulting changes in the visual representation, users can infer additional information about those attributes over time. For example, the *dynamic queries*

technique provides interactive query widgets for unmapped data attributes and can be used to dynamically filter the entity glyphs (Ahlberg and Wistrand, 1995) (Figure 1).

## 3 INFORMATION STRUCTURE

The visual mapping process provides an initial starting point for visualization design, but more advanced methods are needed as data complexity increases. Identifying underlying structures within the target information helps to further guide the design process. These structures provide high-level organization to a data set and often provide guidance for the design of appropriate visualizations. Since these structures are likely to be very important to users' mental models of the information, they are typically mapped to the spatial position attributes and form the primary layout of the visualization. In general, there are four common classes of information structures [adapted from Shneiderman 1996, Card et al. (1999), and Spence 2001], as discussed in Sections 3.1–3.4. These are not strict or mutually exclusive classifications but useful guides.

### 3.1 Tabular Structure

Data tables consist of rows (*entities*) and columns (*attributes*). This is often referred to as *multidimensional data*, because each attribute defines a dimension of the data space within which each entity identifies a single point. Examples include databases and spreadsheet tables, such as the census data in Figure 1. Visualizations of tables that contain a small number of attributes can be designed relatively easily using the visual mapping process described in Section 2. However, such visualizations lack scalability to many attributes, due to the limited number of nonconflicting visual properties from which to choose. To address this problem, a variety of creative methods have been developed for tables of many attributes. Primarily, these involve the use of more complex glyphs and spatial layouts.

First, heatmaps (e.g., Saraiya et al., 2004) preserve the tabular spreadsheet visual representation but represent each cell of the table as a simple colored square by using a color scale to map the data values. This offers users a familiar visual structure in a highly compact visual form. TableLens (Rao and Card, 1994) (Figure 4*a*) uses a similar approach but converts cells to horizontal bar glyphs with cell values mapped to bar length. This exploits the length property, which is better than color for encoding quantitative data. Also, since the bars are very thin, many values can be packed onto the screen, providing an excellent overview of a long tabular data set. TableLens encodes each data entity (row) with multiple glyphs (bars), one glyph for each of the entity's attribute values (columns). Interactively selecting a set of rows will expand them to reveal the detailed data values in textual form. Users can vertically sort the table by any attribute. By spatially sorting the data according to one attribute, distributions and relationships to other attributes can be seen. However, it is perceptually difficult to relate two unsorted attributes. Hence, users must sort each attribute interactively to explore all potential relationships.

(a)

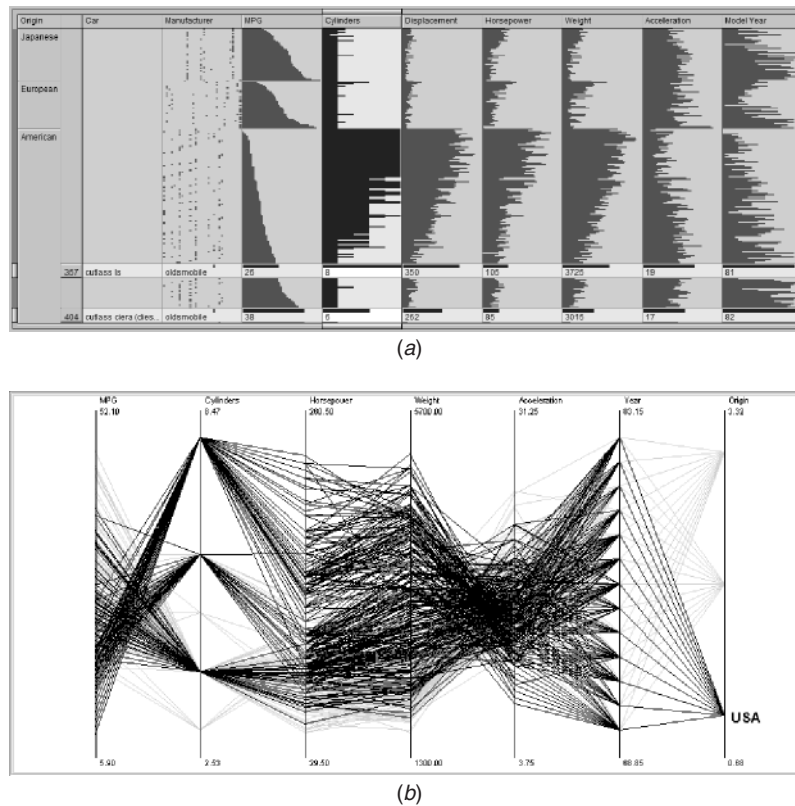
(b)


**Figure 4** (a) InXight TableLens; (b) XmdvTool's Parallel Coordinates. Both show the same data set about automobiles. Clearly, the United States dominates the market in large, powerful, gas-guzzling cars. Two outliers, cars with large engines yet high MPG, are highlighted in TableLens, revealing their detailed values. TableLens sorts the data by one attribute, whereas Parallel Coordinates sorts all the attributes simultaneously. [(a) From Rao and Card (1994). Courtesy of InXight). (b) From Ward (1994). Courtesy of Matthew Ward.]

The *proximity compatibility principle* (Wickens and Hollands, 2000) predicts that representations that use a single glyph per data entity, such as in scatterplots (Figure 1), would be better than TableLens for recognizing relationships between attributes. But as indicated previously, such representations are more limited in scalability. Herein is the trade-off: TableLens provides an overview of many attributes with reasonable capability for relationship insights, whereas scatterplots provide excellent insight on relationships but only for the two attributes mapped to *x* and *y* (and potentially a small number of other attributes using color, size, etc.).

To analyze the scalability of heatmaps, consider an approximate screen resolution of $1000 \times 1000$ pixels. If each colored cell requires a $10 \times 10$-pixel area (about the size of one typed character) to be recognizable, then a heatmap could display $100 \times 100 = 10,000$ cells. For TableLens, if each bar glyph is only 1 pixel thick, 1000 data entities (rows) can be shown. Columns will need to be approximately 50–100 pixels wide to enable reasonable visual discretion of quantitative data such as percentages, resulting in 10–20 attributes being visible. Hence, TableLens can display a tabular

data set containing 1000 data entities and 20 attributes. Much larger data sets can be explored in TableLens by using its aggregation and interactive navigation (e.g., scrolling) strategies, but only $1000 \times 20$ values are visible simultaneously. For data sets larger than the screen size, TableLens aggregates adjacent rows by showing averages or minimum and maximum values so as to reduce the data to fit the screen. Because of their scalability, heatmaps are a popular approach for data tables that have a large number of attributes (on the order of 100 columns).

A second approach is to use nonorthogonal axes. The Cartesian coordinate system uses orthogonal axes to visually map two or three attributes of a tabular data set to space (Figure 1). However, orthogonal axes fundamentally limit scalability of the number of attributes. As an alternative, Parallel Coordinates (Inselberg, 1997) (Figure 4b) displays attribute axes as parallel vertical lines. Each data entity is then mapped to a polyline that connects the entity's attribute values on each attribute axis. Hence, data attributes are mapped to the vertical position of the respective vertices of the polyline. Users can recognize clusters of similar

entities and relationships between adjacent attributes. Patterns of crossing lines between adjacent axes indicate an inverse relationship between those two attributes, and noncrossing lines indicate a proportional relationship. To combat occlusion and clutter, interactively selecting entities highlights their polylines across all axes. A scalability analysis of Parallel Coordinates would give a result similar to that of TableLens. However, it can potentially display many more rows because the lines overlap. Other possible arrangements of axes include radial (Kandogan, 2000) and circumferential (Miller, 2004). Parallel Coordinates is a popular approach for data tables that have many rows (over 1000), because it emphasizes viewing patterns between attributes and recognizing clusters of entities in the data rather than individual entities.

A third approach is to use more complex iconic glyphs. For example, star plots (Chambers et al., 1983) map data attributes to the length of the radial needles emanating from a star icon, and Chernoff faces (Chernoff, 1973) attempt to exploit the human ability to rapidly recognize facial features and expressions. Although these iconic methods do not scale up very well, they are frequently used when combining with other information structures (such as networks) because they leave the spatial position properties available for other uses (Ward, 2002).

A fourth approach is to simplify the glyphs and visual representations by splitting the attributes up into *multiple views*. For example, four attributes can be displayed using the *x* and *y* axes of two separate scatterplots. Scatterplot matrices take this approach to the extreme, displaying many plots for all possible combinations of attribute pairs (Cleveland, 1993) as a large matrix of small plots. An interactive technique called *brushing and linking* connects the plots (Becker and Cleveland, 1987). When users select glyphs in one plot (*brushing*), the corresponding glyphs for the same underlying data entities are highlighted in the other plot (*linking*). The multiple views with brushing-and-linking technique is frequently used to view a single data set in several different visual representations at the same time, such as plots and geographic maps, to relate the various contexts (Roth et al., 1996; North et al., 2002) (see Section 6.2).

## 3.2 Spatial and Temporal Structures

Spatial and temporal structures have a strong one-, two-, or three-dimensional component in which navigation is likely to be required. One-dimensional (1D) examples include time lines, music, video streams, lists, linear documents, and slide shows. Two-dimensional (2D) examples are road maps, satellite images, photographs, and blueprints. Three-dimensional (3D) examples are magnetic resonance imaging (MRI) and computed-tomography (CT) medical scans, computer-aided design/manufacturing (CAD/CAM) architectural plans, and virtual environments. Continuous functions, including those with domains greater than three dimensions, also fall in this category (Tory and Möller, 2004b). These spatial and temporal structures are the most natural for mapping onto spatial displays.

For example, the Music Animation Machine (Malinowski, 2004) (Figure 5a) provides a simple time line representation of music that scrolls as the music plays. Notes are represented as horizontal bars, with vertical position representing pitch, horizontal position representing timing, length indicating duration, and color indicating other attributes, such as instrument, timbre, or hand (in the case of piano). Similarly, LifeLines (Plaisant et al., 1996) represents events in a person's medical history, but in a more compact form, with zooming for navigation. For time lines that contain periodic cycles, such as calendars, visual spirals can be used to proximate the cycles while maintaining a continuous line (Carlis and Konstan, 1998). Streaming video can be viewed as a 3D video cube (2D frames + 1D time) (Elliott and Davenport, 1994).

In 3D data spaces, the main challenge is viewing the interior of the 3D structure beyond the exterior surface when occlusion is problematic. Architectural walk-through applications (polygonal data) typically use first-person perspective projection, with six-degree-of-freedom navigation for a lifelike experience (Stoakley et al., 1995). For medical imagery (volumetric data), strategies include slicing and transparency. For example, the Visible Human Explorer presents 2D slices that can be animated through the 3D body (North et al., 1996). In 3D volume rendering, transparency can give users X-ray vision into the space by adjusting the opacity of various contents within the space through interactive control of the visual transfer function (Kniss et al., 2001).

Hyperdimensional continuous spaces must somehow be reduced to three or fewer dimensions for display. Worlds within Worlds (Beshers and Feiner, 1993) (Figure 5b) displays subspaces of hyperdimensional functions by nesting a 3D coordinate frame within another 3D coordinate frame. The location of the origin (0,0,0) of the inner frame within the outer frame determines the values of the outer frame dimensions used to generate the subspace for the inner frame. By interactively sliding the inner frame around the inside of the outer frame, the full space can be explored. Repeated nesting can enable greater numbers of dimensions. Other methods include hierarchical axes (Mihalisin et al., 1991) and slicing (van Wijk and van Liere, 1993).

## 3.3 Tree and Network Structure

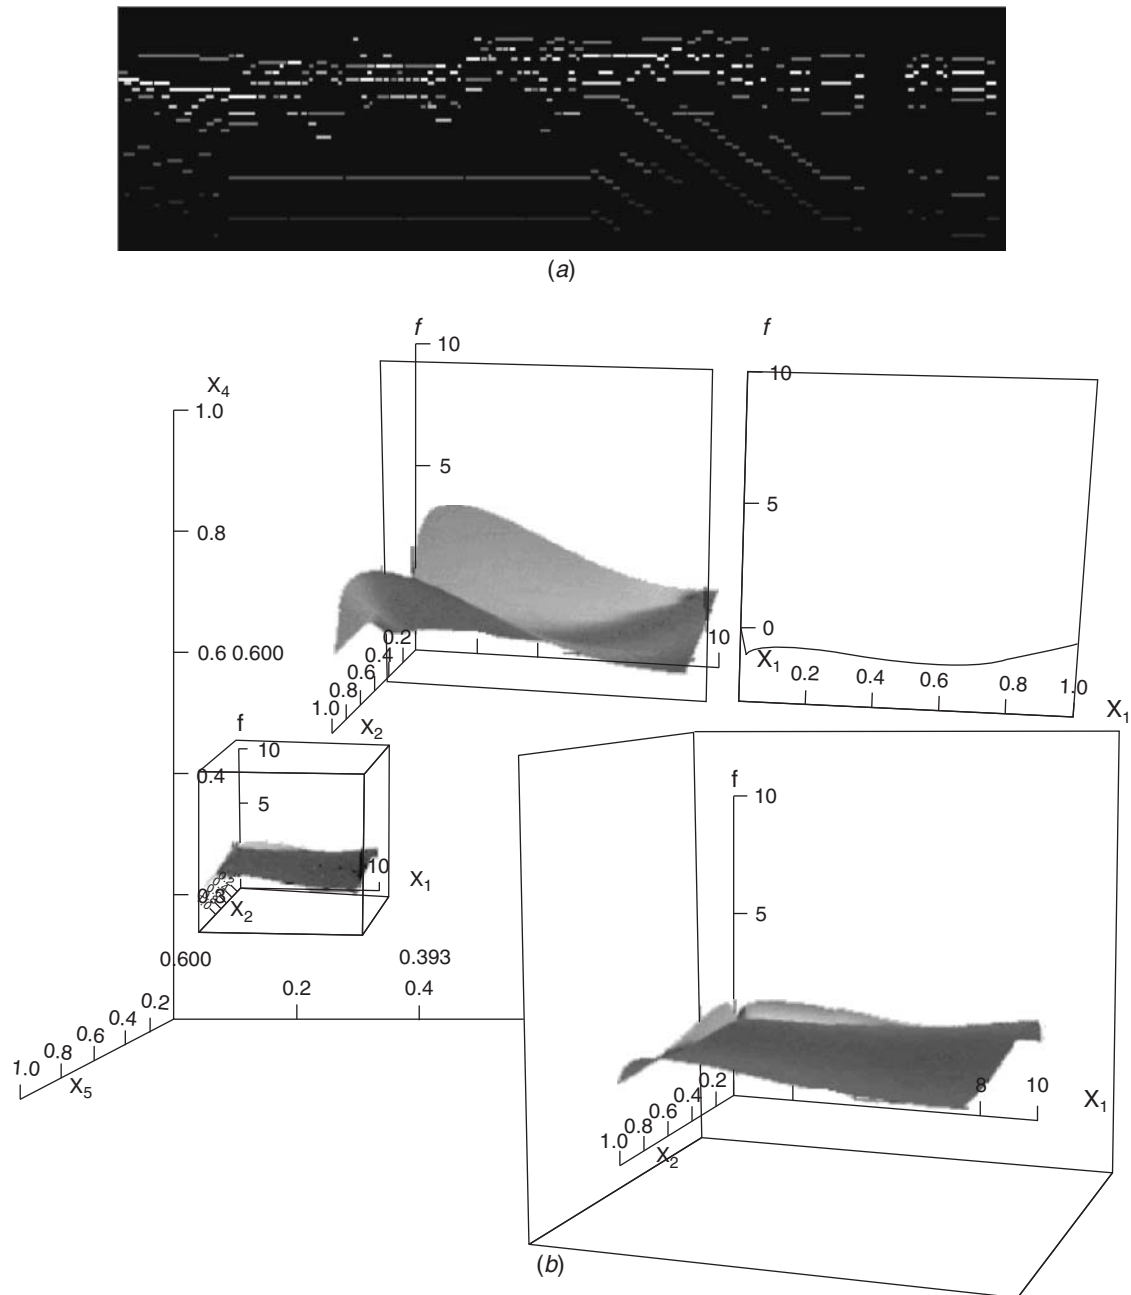
Tree and network structures contain specific *connections* between individual entities. In graph theory terms, a network consists of a set of vertices (entities) connected by a set of edges (connections), which can be either directed or undirected. Like data entities, connections can also contain attributes. Examples include social networks (Hansen et al., 2010), literature citations, or hyperlinks between Web pages. Tree structures are a special subset of networks that are distinct and common enough in digital information to warrant separate treatment. Trees have a hierarchical structure that connects data entities by parent−child connections. To be a tree, each child entity should have only one parent. Examples include computer file directories, menu systems, organization charts, and taxonomies such as the Dewey decimal system. Other useful variants of tree structures exist, such as


**Figure 5** (*a*) Music Animation Machine showing a portion of Bach's Brandenburg Concerto No. 4, third movement; (*b*) Worlds within Worlds nests inner coordinate frames within outer frames to decompose hyperdimensional spaces. [(*a*) From Malinowski (2004). Courtesy of Stephen Malinowski. (*b*) From Beshers and Feiner (1993). Copyright © 1993 IEEE.]

multitrees (Furnas and Zacks, 1994) and polyarchies (Robertson et al., 2002). New types of insights involve understanding the connection structure, such as the breadth or depth of the tree. The primary challenge for visualization is the spatial layout of the network or tree to reveal the structure of the connections. The

secondary challenge is to visualize data attributes of the entities and connections.

### 3.3.1  Trees

For tree structures, two primary approaches exist for representing parent–child connections visually: *link* and

*containment*. The *link* approach uses node−link diagrams. Entities are mapped to visual nodes, and connections are mapped to visual links between the nodes. Alternative spatial layouts of node−link diagrams include nested−indented, as in Windows Explorer or Mac Finder; top−down or left to right, as in SpaceTree (Grosjean et al., 2002); radial, as in Hyperbolic Tree (Lamping et al., 1995); balloon view (Jeong and Pang, 1998); or 3D ConeTrees, which combines balloon and left−right (Robertson et al., 1993) (Figure 6*a*). These systems emphasize the display of a single data attribute as a text label on the nodes.

Node−link diagrams tend to be space consuming, due to the amount of white space needed within each of these spatial layouts, making it difficult to get beyond 100 or 1000 nodes visible. Since large tree structures cannot be displayed completely on the screen, each layout requires interactive navigation. Navigation should be designed as fluid as possible to reduce tedious operations. The focus + context technique (Section 5.3) is a natural match for tree navigation, enabling users to drill down within an individual branch of focus in the tree while maintaining the context of the path to the root and siblings.

An important design goal is to reveal the size and depth of all tree branches, even when the entire tree cannot be displayed. SpaceTree accomplishes this by displaying collapsed subtrees as triangles, which are size encoded based on the number of nodes in the subtrees. This gives users clues about the overall tree structure. Hyperbolic Tree shrinks the size of nodes near the periphery to pack more nodes on the display. Three-dimensional approaches such as ConeTrees exploit the third dimension for additional space to lay out the tree, but due to occlusion, it is unclear whether that extra virtual space is helpful. The most important factor in three-dimensional designs is the interactive navigation (Wiss and Carr, 1999). Simple six-degree-of-freedom camera movement through a static three-dimensional scene is clearly not effective in these structures. ConeTrees employs a much more efficient interaction technique, cascading rotation of the three-dimensional cones to bring the desired child nodes to the front.

A particularly difficult user task with tree structures is comparing the structure of multiple trees, as in biological taxonomies. Tree Juxtaposer (Munzner et al., 2003) places two trees side by side for comparison using left−to−right layout, synchronized focus+context navigation, and color-coded highlighting of shared branches.

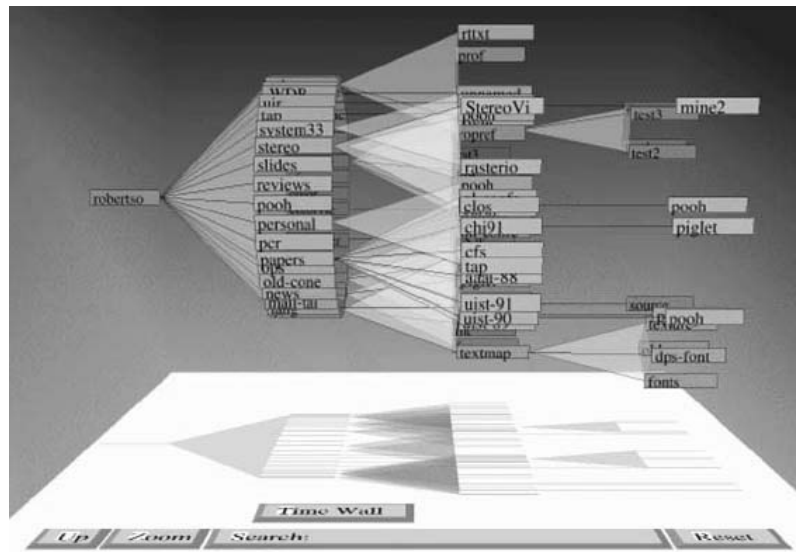
The *containment* approach for tree layout is exemplified by Treemaps (Johnson and Shneiderman, 1991) (Figure 6*b*). Child nodes, represented as rectangles, are contained visually within their parent nodes as in Venn diagrams. Treemaps are space filling, to maximize the use of every available pixel, and scales easily to 10,000 entities. Data attributes are mapped to retinal properties of the node rectangles, such as size and color. Hence, Treemaps emphasizes the visualization of nontextual attributes. In dense Treemaps, not enough space is left for textual node labels. Although clusters of nodes are visible, Treemaps can make it difficult to recognize the structure of the tree.

Nodes can be arranged within their parent node according to a variety of algorithms. The original Treemap used a slice-and-dice algorithm. It was simple but tended to generate rectangles with many different aspect ratios, some square and some long and narrow, which are difficult to visually compare. Newer algorithms generate more perceptually effective squarified Treemaps (Bederson et al., 2002), which attempt to keep node rectangles as close to square as possible (Figure 6*b*). SunBurst (Stasko et al., 2000) offers a radial version of the containment approach based on the stacked pie chart. In comparison to Treemaps, SunBurst can improve learnability for novices but reduces scalability because the number of leaf nodes is limited by one-dimensional circumferential space rather than the full two-dimensional area available to Treemaps.

In general, the link approach is better for gaining insight about the structure of the tree, while the containment approach is better for insights concerning node attributes within the structure and is more scalable to large trees.

### 3.3.2 Networks

For visualizing networks, the *node−link* approach is dominant. Many algorithms have been devised to lay out network diagrams spatially (Herman et al., 2000) and increasingly are tuned to specific types of networks (Figure 7*a*). Designs must consider network features such as number of nodes and links, directedness of links, node degree, any common patterns within the network structure, and attributes of nodes and links that should be visible. In general, the goal is to lay out the network to reveal hidden network patterns and avoid the "hair ball" problem. Graph layout algorithms can seek to optimize aesthetic constraints such as minimizing link crossings, minimizing link lengths, and maximizing symmetries (Purchase et al., 2002; Ware et al., 2002). Links can be drawn as straight lines, arcs, or orthogonal polylines or can be bundled together to reduce link clutter (Holten and van Wijk, 2009).

Some common graph layout algorithms include circular, layering, force directed, and predefined. *Circular* algorithms simply arrange the nodes in a circle and draw the links inside the circle and are useful for small graphs. *Layering* algorithms identify one or more root nodes and lay out all other nodes based on their shortest distance from the root(s) as a series of horizontal or vertical lines or concentric circles. Layering is useful for directed acyclic graphs, because it produces a treelike structure with distinct levels. *Force-directed* algorithms simulate links as physical stretchy springs connecting the nodes. When the simulation settles, it pulls connected nodes near each other, thus producing results similar to the way a person might draw a social network diagram. It also affords natural interaction in which users can directly manipulate node placement while the simulation runs. For this reason, force-directed algorithms are popular but are computationally expensive and lack scalability. *Predefined* layouts exploit node attributes to lay out the graph (Shneiderman and Aris, 2006). For example, SeeNet (Becker et al., 1995) arranges communications nodes according to geographical position and raises links


(a)

(b)

**Figure 6** (a) ConeTrees; (b) SequoiaView Treemap, showing directory structures on a computer system. ConeTrees emphasizes the tree structure and node labels, whereas Treemap emphasizes node attributes such as file size and type. [(a) With permission from Robertson et al. (1993). Copyright © 1993 ACM, Inc. (b) From van Wijk and van de Wetering (1999). Courtesy of Jarke van Wijk.]

off the surface as three-dimensional arcs. Arc properties such as color and line thickness are used to represent communications type and bandwidth.

To support larger graphs, *hierarchical clustering* algorithms group nodes into clusters based on connectivity. Clusters can then be collapsed into a single visual node to reduce the complexity of large graphs. This technique is often coupled with focus+context navigation to

enable users to explore the contents of the groups (van Ham and van Wijk, 2004). It is also possible to reduce networks to trees using minimum spanning trees or hierarchical aggregation (Feiner, 1988), thereby enabling the use of tree visualization methods. Alternatively, node navigation can be used in conjunction with layering to represent the network from the perspective of one node in focus (Yee et al., 2001).

Burch/Cheswick map of the Internet

[(a) From Cheswick (1998). Courtesy of William Cheswick. (b) From Henry et al. (2007). Courtesy of Nathalie Henry.]

A different approach is to visualize the network as an *adjacency matrix* (Henry et al., 2007) (Figure 7*b*). An adjacency matrix emphasizes the connections instead of the nodes, mapping each potential connection to a cell in the $N \times N$ matrix of all nodes. This approach easily supports very dense graphs that are too cluttered in the node–link approach. It enables insights into individual node connectivity and dense clusters but does not easily support path following and distance insights as the node–link approach does. The NodeTrix system attempts to combine the best of both methods (Henry et al., 2007).

### 3.4 Text and Document Collection Structure

This structure consists of arbitrary collections of documents, often text. Examples include digital libraries, news archives, digital image repositories, and software code. Of the four types of information structure, this type is the least structured and hence can be the most difficult to design visualizations for. Text is particularly challenging to map to visual form, because it is not obvious how text can be the input to a mapping function as described in Section 2.1. Mapping functions must take advantage of the minimal structure and other characteristics of text to generate useful data for computing visual representations. External structures of text or document collections such as tables of contents (tree structure), metadata (tabular structure), or citations (network structure) are categorized as other types of information structures and were discussed earlier. The emphasis of the structure described in this section is on the full text or the documents themselves. Solutions range from the macroscale (overview of large collections) to the microscale (a single document fragment).

A major class of text visualizations focuses on providing semantic maps of large document collections based on document topics. Generally, the goal is to cluster documents spatially in the visualization such that similar documents (documents containing similar content) are near each other and dissimilar documents are distant. This creates a map of the document space based on the metaphor of a physical library in which books are arranged carefully by topic. Similarity between documents can be measured in many ways and is generally the domain of *information retrieval* (Baeza-Yates and Ribiero-Neto, 1999). A common method is to compare the frequency of occurrence of dictionary words or phrases between the two documents. Densities of document clusters can then be analyzed to extract topic keywords for labeling the map. Document Galaxies (Wise et al., 1995) and Kohonen self-organizing maps (Lin, 1992) map individual documents to tiny dots that are clustered by text content. Selecting a dot from the map reveals a document summary or opens the full document. ThemeView (Wise et al., 1995) (Figure 8*a*) emphasizes the documents' topics, creating a three-dimensional terrain landscape representing the themes in the collection. Themes are mapped to terrain landscapes of mountains, with theme strength mapped to mountain height. Mountains that are adjacent or joined indicate the presence of documents that span both themes.

The keyword query approach provides a more focused map based on keywords specified by the user. VIBE (Olsen et al., 1993) visualizes how documents relate to the keywords. It spreads the user's keywords around the periphery of the display. Then, document dots are mapped into the space according to their strength of match to each keyword using a spring-based attraction model. TileBars (Hearst, 1995) inverts the map, showing how the keywords relate to each document. Document hits are listed as in a normal textual search engine, but each document has a tilebar that shows the density of the keywords in each section of the document.

Finally, documents can be arranged by the users themselves or by some default order. Miniature representations of the documents can be displayed to promote browsing by content. Web Book and Forager (Card et al., 1996) collects favorite Web pages in a virtual three-dimensional book that users can flip through quickly and scan visually. Books can be arranged on a virtual bookshelf. With DataMountain (Robertson et al., 1998), users arrange images of favorite Web pages or photos on an inclined plane (Figure 8*b*), taking advantage of spatial memory for recall. At the lowest level of text visualization, SeeSoft (Eick et al., 1992) visualizes the text of software code using a miniaturized representation. It displays each line of text as a tiny colored line segment (more on SeeSoft in Section 4.2).

### 3.5 Combining Multiple Structures

Frequently in real-world applications, information involves complex combinations of multiple information structures. Furthermore, information of one structure type could be computationally massaged into a different structure type to offer new ways to conceptualize the information. For example, an e-commerce website may consist of a text document collection of product pages which also contains a network structure of hyperlinks, is organized by a tree-structured site map, and has tabular metadata about product prices and page accesses. A visualization designer should consider each of these separate structures as a potential visual index into the underlying product information.

A frequent insight goal in these situations is to relate the various structures. However, designing a visual representation that effectively combines multiple structures is difficult. Since a structure typically consumes the primary spatial portion of the visual mapping, combining multiple structures in a single mapping can result in conflict. A primary decision is whether to attempt to combine them or to separate the structures into multiple views (Baldonado et al., 2000). Multiple views simplify the design, since each structure can use its most optimal mapping independently. The structures can then be related by interactive linking between the views (see Section 6.2). Linking is useful for querying one structure with respect to another. However, because interactive linking reveals only a small number of associations at a time, users must mentally integrate the relationships between the structures over time and can easily miss interesting associations. On the other hand, integrating two structures into a single view typically requires that one structure be used as the spatial basis, while the
(a)

(b)

**Figure 8** (*a*) ThemeView represents common themes in a large document collection as labeled mountains in a landscape. Probing reveals specific documents. (*b*) DataMountain lets users visually organize Web favorites, documents, or digital photos for later recall. [(*a*) From Wise et al. (1995). Courtesy of Pacific Northwest National Laboratory. (*b*) With permission from Robertson et al. (1998). Copyright © 1998 ACM, Inc.]

other is dismantled and embedded within that space. This enables a clear representation of how the second structure depends on the first, but clarity of the second structure can be lost. The order of nesting of the structures should be designed to match the users' task structure. Another potential solution is animating or morphing between the two structures (Robertson et al., 2002).

An example is PathSim (Polys et al., 2004) (Figure 9), an information-rich virtual environment for biology simulation which combines three-dimensional spatial structure of human anatomy with tabular structure of data collected on viral infection within anatomical components. In this design the tabular data are visually embedded directly within the three-dimensional anatomy as small manipulable visualizations adjacent to their corresponding anatomical components. The tabular

structure is dismantled to associate portions of the data set visually with components in the three-dimensional scene. Although this supports the task of understanding the effects in each anatomical component, it does not enable a single overview of all tabular results. To overcome this, a heads-up display is included according to the multiple-views approach. It shows aggregated tabular information as a summary of what is visible in the entire scene as users navigate in the three-dimensional anatomy.

## 4 OVERVIEW STRATEGIES

Designing methods for the visual representation of very large quantities of information is one of the fundamental problems in visualization research. As information quantity increases, it becomes more difficult to
**Figure 9** PathSim reveals simulated viral infection data within the human anatomy, combining tabular structure with three-dimensional spatial structure. Zooming in or out navigates to lower or higher levels of anatomical structure and shows correspondingly lesser or greater levels of aggregation of tabular data. Here, we see the effects of an Epstein–Barr virus infection of the tonsils. (From Polys et al., 2004.)

pack all the information visually on the available screen space. There simply are not enough pixels. Even if there were enough pixels, including all the details in a single display might make it appear visually cluttered. In general, a naive visualization design would be to consume the entire display with the full detail of only a few of the data entities and thereby limit the display to a relatively small portion of the full data set. This is analogous to peering into a vast room through a tiny keyhole and is called the *keyhole problem*. For example, the spreadsheet in Figure 1 shows the detailed numerical data, but the scrolling window reveals only about 40 rows at a time on a typical display.

To support visualization of very large information spaces, Shneiderman suggests the design mantra "*overview first, zoom and filter, then details on demand*" (Shneiderman and Plaisant, 2005). The solution to the keyhole problem is to start users with a broad overview of the full information space, sacrificing information details. Then provide interaction mechanisms that enable users to zoom in on desired information and filter out anything not of interest. Finally, quickly retrieve and display detailed information about individual data entities when selected by the user. There are several advantages to providing an initial visual overview of the information:

- An overview supports the formation of mental models of the information space.
- It reveals what information is present or not present.

- It reveals relationships between the parts of the information, providing broader insights.
- It enables direct access and navigation to parts of the information simply by selecting them from the overview.
- It encourages exploration.

Empirical evidence confirms that the use of visual overviews results in improved user performance in various information-seeking tasks [some studies are listed in Hornbæk et al. (2002)]. In general, visualization designers should seek to pack as much information into the overview as cleanly as possible. A major design decision is choosing which information to percolate up to the overview and which information to bury in the lower detail levels that can only be reached through user interaction. This is somewhat analogous to choosing which products to show in the store window. Ideally, an overview should provide some visual "scent" of all the detailed information hiding beneath it (Pirolli and Card, 1999).

To create overviews that attempt to pack a large data set onto a relatively small screen, there are two possible approaches in the visual mapping process: (1) reducing the quantity of data in the data set before the mapping is applied or (2) reducing the physical size of the visual glyphs created in the mapping.

## 4.1 Reducing Data Quantity

One method for reducing the data quantity while maintaining reasonable representation of the original data is

*aggregation*. Aggregation groups entities within the data set, creating a new data set with fewer total entities. Each aggregate becomes an entity itself, temporarily replacing the need for all entities contained within the aggregate. For example, a histogram applies aggregation to represent data distribution on one attribute (Spence, 2001).

When using aggregation, the first design decision is choosing which entities should be grouped together. Entities can be grouped by common attribute values (Stolte et al., 2002) or by more advanced methods such as clustering algorithms (Yang et al., 2003) or nearest neighbors. The next decision is determining the new attribute values of the aggregates. Ideally, aggregates' values should be representative of the member entities contained. Statistical summaries such as mean, minimum, maximum, and count are commonly used. Aggregation can be iteratively applied to generate tree structures of groups and subgroups (Conklin et al., 2002). The final decision is the visual representation of the aggregates, which, ideally, reveals some hint of their contents.

Aggregate Towers (Rayson, 1999) (Figure 10*a*) groups entities spatially if they overlap on a map. The aggregates are shown as towers whose height represents the number of entities in the aggregate. Zooming out of the map causes further aggregation as needed, and zooming in on the map segregates towers until no towers are needed. XmdvTool (Yang et al., 2003) (Figure 10*b*) clusters tabular data in a parallel coordinates plot. The extent of the contents of each aggregate is revealed by a glowing shadow that emanates from the aggregate's representative polyline.

Aggregation can also be used to group data attributes together. Dimensionality reduction methods reduce the number of data attributes in large multidimensional tabular data sets so that they can be visualized more easily (Rencher, 2002). The reduced set of attributes should approximately capture the main trends found

(*a*)

(*b*)

**Figure 10** (*a*) Aggregate Towers stacks military units that spatially overlap on a map. The black footprints show the spatial coverage of each tower. Zooming in segregates the units. (*b*) XmdvTool's Parallel Coordinates clusters the data from Figure 4*b* into six entities to reduce clutter. Translucent shading reveals the approximate spread of each cluster. [(*a*) From Rayson (1999). Copyright © 1999 IEEE. (*b*) From Yang et al., (2003). Courtesy of Matthew Ward.]

in the full set of attributes. For example, *principal-components analysis* projects the data entities onto a subspace of the original data space that best preserves the variance in the data. *Multidimensional scaling* uses measures of similarity between entities, based on their many attribute values, to compute a one-, two-, or three-dimensional map that groups similar entities spatially.

*Filtering* can also be used to reduce data quantity. VIDA (Woodruff et al., 1998) selects a representative subset of data entities based on data density and entity importance. Spotfire (Ahlberg and Wistrand, 1995) relegates less important data attributes to interactive methods such as dynamic queries, eliminating them from the input to the initial visual mapping function. Tree-structured information is easily reduced simply by filtering deeper levels of a tree to visualize the upper levels as an overview.

### 4.2 Miniaturizing Visual Glyphs

Alternatively, emphasis can be placed on miniaturization of the visual glyphs generated by the visual mapping process. Tufte argues for increased data density in visual displays by maximizing the data per unit area of screen space and maximizing the data–ink ratio (Tufte, 2001). A higher data–ink ratio is accomplished by minimizing the quantity of "ink" required for each visual glyph and eliminating chart junk that wastes ink on unimportant nondata elements.

SeeSoft (Eick et al., 1992) (Figure 11*a*) provides an overview of textual software code using miniaturization. Similar to TableLens (Figure 4*a*), each line of code is reduced to a single line segment of colored pixels whose length is proportional to the number of characters in the line of code. In this way, large software projects of up to 50,000 lines of code can be overviewed in a single screen. Color coding can be used to reveal other attributes of the lines of code, such as which programmer wrote it, whether it has been tested, or the amount of CPU time required to execute the line (code profiling). Pixel Bar Charts (Keim et al., 2002) reduces the size of visual glyphs for tabular data to a single pixel, colored by one attribute and ordered on the display by another attribute. The Information Mural (Jerding and Stasko, 1998) (Figure 11*b*) takes miniaturization to the

(*a*)

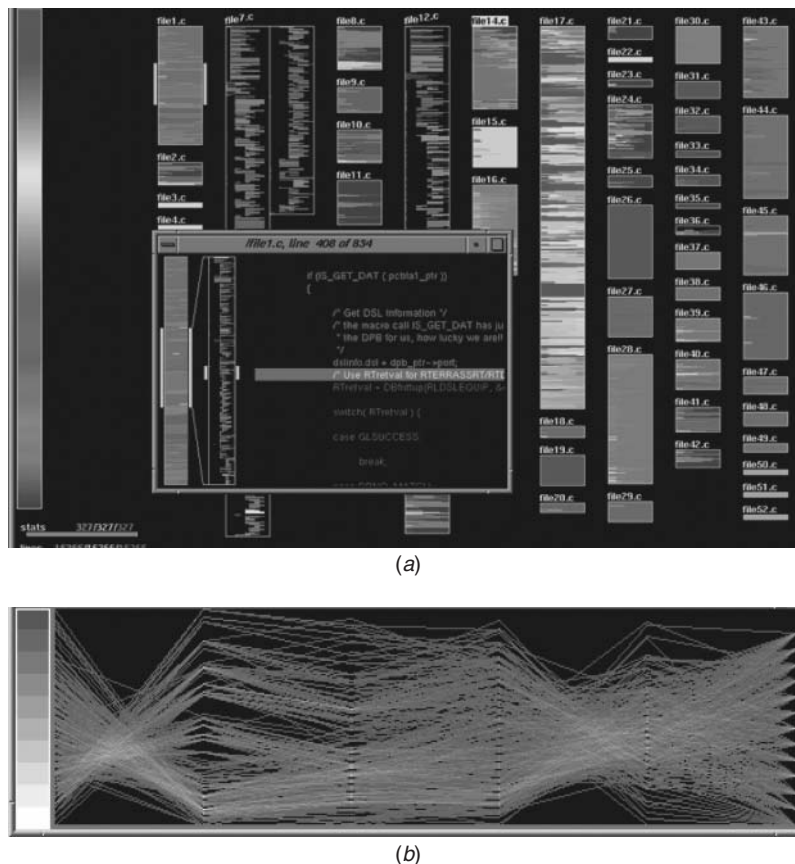
(*b*)


**Figure 11** (*a*) SeeSoft provides a miniaturized visual overview of software code, shading each line of code by an attribute such as date authored; (*b*) Information Mural shows the density of a parallel coordinates plot, enabling users to see hidden patterns that would otherwise be occluded within dense clutter as in Figure 4*b*. [(*a*) From Eick et al. (1992). Courtesy of Stephen Eick. (*b*) From Jerding and Stasko (1998). Courtesy of John Stasko.]

subpixel level. When many glyphs overlap and occlude each other, Mural visualizes the density of the glyphs like an X-ray image.

## 5 NAVIGATION STRATEGIES

After employing an overview strategy to provide a broad view of a large information space, the next design concern is that of navigation. Interactive methods are needed to support navigation between the broad overview and the details of the information. To support this need, three primary navigation design strategies have evolved: *zoom + pan*, *overview + detail*, and *focus + context*. These strategies reside at the third stage of the visualization pipeline, view transformation (see Figure 2).

These navigation strategies should be contrasted with the naive strategy called *detail only*. Detail only is the baseline strategy that does not employ an overview. It provides only the detail-level view of a portion of the information space (e.g., the spreadsheet in Figure 1*a*). Users can navigate by scrolling or panning to access the rest of the information space. In general, the detail-only strategy should be avoided. The principal disadvantage is disorientation due to lack of overview, leaving the user lost in the information space and wondering: Where am I? Where do I want to go? How do I get there?

### 5.1 Zoom + Pan

Zoomable visualizations begin with the overview and then enable users to zoom dynamically into the information space to reach details of interest. Users can zoom back out to return to the overview and zoom in again to another portion of detail. Users can also pan

across the space without zooming out. Zooming can be a smooth continuous navigation through the space as in Pad + + (Bederson et al., 1996) (Figure 12) or can be used to drill down through discrete levels of scale as in Treemaps (Johnson and Shneiderman, 1991). Although the zooming strategy provides an overview, disorientation remains when zooming in. It is easy for users to become lost in the space when zooming in and panning, since the overview is no longer present. This strategy is commonly found in online map browsing systems, since it well-suited to situations where there is not a clearly defined overview level in the information structure.

### 5.2 Overview + Detail

Overview + detail uses multiple views to display an overview and a detail view simultaneously. A field-of-view indicator in the overview indicates the location of the detail view within the information space. The views are bidirectionally linked such that manipulating the field of view in the overview causes the detail view to navigate accordingly. Similarly, when users navigate directly in the detail view, the field of view updates to provide location feedback. This strategy is commonly found in various digital imaging software (Plaisant et al., 1995) such as Photoshop. In SeeSoft (Eick et al., 1992), the miniaturized overview of text operates as a scrollbar for a detailed view of the actual text (Figure 11*a*, center). A zoom factor of 30:1 between overview and detailed view is the usability limit for navigating two-dimensional images, but intermediate views can be chained to reach higher total zoom factors (Plaisant et al., 1995). In navigating three-dimensional worlds, Worlds in Miniature (Stoakley et al., 1995) provides a small three-dimensional overview map attached to a

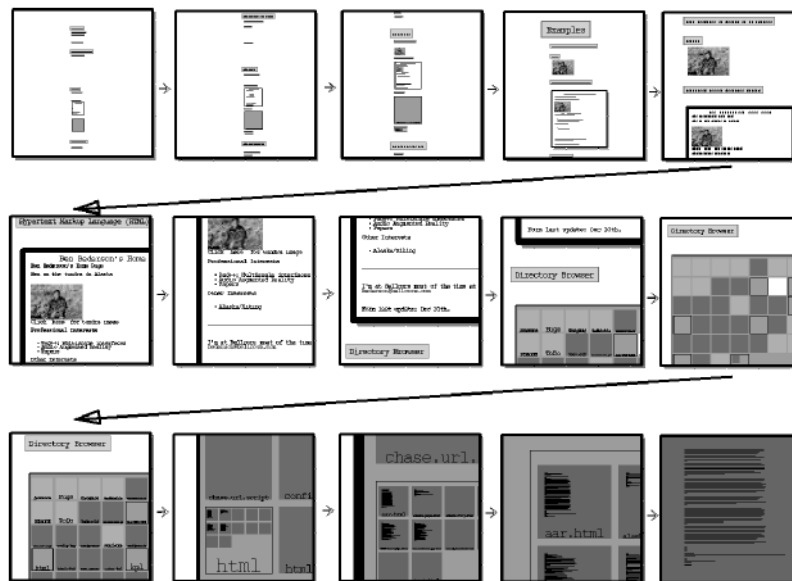

**Figure 12** Zooming sequence in Pad + + from a Web page to an embedded folder to an embedded text file. [From Bederson et al. (1996) Courtesy of Ben Bederson.]
**Figure 13** Worlds in Miniature uses overview + detail for navigating three-dimensional virtual environments. [With permission from Stoakley et al. (1995). Copyright © 1995 ACM.]

virtual glove (Figure 13, bottom center) to help orient users within the world.

Overview + detail preserves overview to avoid disorientation in the detailed view but suffers from a visual discontinuity between the overview and detailed views. Ideally, the detail view should not overlap or occlude the overview, but pop-ups such as tooltips and magnifying glasses are reasonable for small amounts of temporary detailed information. In some cases, it is useful to provide multiple detail views to allow users to compare different entities. For example, a document collection visualization (as in Figure 8) can allow users to open multiple documents simultaneously in different windows. Overview + detail is particularly applicable in scenarios that require maintaining awareness of dynamic events in the overview, as in wargaming.

## 5.3  Focus + Context

Focus + context expands a focus region directly within the overview context. The focus is enlarged and magnified to provide detailed information for that portion of the information space. Users can navigate simply by sliding the focus across the overview to reveal details for other portions of the space. To make room for the expanded focus region, the surrounding overview must be pushed back partially by distorting or warping the overview. For this reason, this strategy is sometimes referred to as fisheye (Furnas, 1986) or distortion-oriented (Leung and Apperley, 1994) techniques. Without distortion, the magnified region would occlude the adjacent context like a magnifying glass. Since the near context is the most important part of the context, the magnifying glass effect is undesirable, and distortion is required to preserve the overview. In general, the focal point is magnified the most, and the degree of magnification decreases with distance from the focal point. Careful design based on a variety of metaphors can help to minimize the negative effects of the distortion.

Several variants of the focus + context strategy have been developed for navigating one- and two-dimensional spaces, including:

- *Bifocal* (Spence, 2001): uses two distinct levels of magnification, such as TableLens (Rao and Card, 1994) (Figure 14*a*)
- *Perspective*: wraps information on three-dimensional angled surfaces, such as Perspective Wall (Robertson et al., 1993) (Figure 14*a*)
- *Wide angle*: creates a classic visual fisheye effect, such as Hyperbolic Tree (Lamping et al., 1995)
- *Nonlinear*: uses more complex magnification functions to create a magnified bubble effect (Keahey and Robertson, 1996) (Figure 14*b*)

As an alternative to spatial distortion, focus + context screens (Baudisch et al., 2002) offer *resolution distortion*, which may provide a better match to the human visual system. Fisheyes have also been developed for navigating three-dimensional spaces (Carpendale et al., 1997). The focus + context strategy offers continuity of detail within overview context but suffers from disorientation caused by dynamic distortion. It is best applied to nonspatial information structures where preservation of spatial distances is not critical.

Although studies have repeatedly shown advantages of these three navigation strategies over the detail-only strategy, comparisons among the three are inconclusive and depend greatly on the specifics of the individual designs, data domains, and user tasks (e.g., Hornbæk et al., 2002). An analytic summary follows:

Zoom + pan:

+ Screen space efficient
+ Infinite scalability
– Lose overview when zooming in
– Slower navigation

Overview + detail:

+ Stable overview
+ Scalable; chained views; multiple overviews or foci

(a)

(b)

**Figure 14** (a) Perspective Wall wraps a one-dimensional time line around a bent wall. The front portion provides detailed information, and perspective sidewalls provide overview context. (b) Nonlinear magnification can create this bubble effect, which magnifies the focus region, squeezes the near context, and maintains an otherwise stable far context. [(a) From Robertson et al. (1993). Courtesy of PARC. (b) From Keahey and Robertson (1996). Copyright © 1996 IEEE.]

– Visual disconnect between views; back-and-forth glancing

– Views compete for screen space; smaller overview

Focus + context:

+ Detail visually connected to surrounding context

– Limited scalability; typically under 10:1 zoom factor

– Distortion; unstable overview

## 6  INTERACTION STRATEGIES

Interaction strategies support further scalability and complexity of visualized information. Although it is preferable to map all data onto the display visually in a form that effectively reveals all desired insights without interaction, this is generally impossible for data of even modest complexity. Interaction strategies overcome this limitation by enabling users to explore additional mappings and insights interactively over time. Many interactive techniques exist (Yi et al., 2007). A few major categories of interaction strategies should be considered in every visualization design.

Interaction occurs at each step in the visualization pipeline (Figure 2). At the data transformation step, users need interactive control for data manipulation and editing. Many data analysts use Excel for its spreadsheet model of data manipulation, enabling them to easily format data and perform computations. For example, NodeXL (Hansen et al., 2010) is a network visualization system implemented within Excel. At the view transform step, navigation is the primary form of interaction as discussed in Section 5. The following interactions primarily occur at the visual mapping step.

### 6.1  Selecting, Grouping, and Extracting

The most fundamental need in visualization is interactive selection of individual data entities or subsets of data entities. Users select entities to identify data that is of interest to them. This is useful for many reasons, including viewing detailed information about the entities (details on demand), highlighting entities that are obscured or occluded in a crowded display, grouping a set of related entities, or extracting entities for future use.

In general, there are two possible criteria by which users can specify selections. First, users can select data entities directly. Direct manipulation visualizations enable users to select entities in a visualization directly using a variety of techniques (Wills, 1996), such as pointing at individual entities' glyphs (as in Figure 4a) or lassoing a group of glyphs. Second, users can select data entities indirectly through selection criteria on information structures (Section 3). For example, Xmd-vTool (Ward, 1994) enables users to make selections in tabular data in parallel coordinates by specifying range criteria on data attributes. In Figure 4b, all American-made cars are highlighted by selecting the U.S. range on the origin axis. Other structure-based selection techniques include selecting an entire branch in a tree structure, selecting a path in a network structure, or selecting a ThemeView mountain (Wise et al., 1995) in a

document collection structure. Another very useful form of indirect selection is search, which enables finding specific entities in a crowded display by their textual content. For example, in the co-authorship network in Figure 7b, users will want to search for specific authors or their own name.

Selection techniques should be designed to enable users to easily select entities, add entities into the current selection, remove entities from the current selection, and clear the selection. Selecting is sometimes called *brushing*, because it is like painting glyphs with a special type of paintbrush that behaves according to the selection technique.

While most selections are ephemeral, there is also the need to preserve some selections. This is useful when users want to define groups of important or interesting entities and possibly extract them from the visualization for future reference or reuse as a future selection. For example, computer network security analysts want to identify suspicious Internet Protocol (IP) addresses in visualizations of network traffic, and biologists want to identify interesting genes in gene expression data. They want to drag the interesting entities out of the visualization into a container where they will be preserved, so that they can continue exploration in the visualization without losing these interesting entities.

### 6.2  Linking

Linking is useful to relate information interactively among multiple views (Baldonado et al., 2000; North et al., 2002). Information can be mapped differently into separate views to reveal different perspectives or different portions of the information. The most common form of linking is called *brushing and linking* (Becker and Cleveland, 1987). Interactive selections of entities in one view are propagated to other views to automatically highlight corresponding entities, enabling users to recognize relationships. This strategy enables users to take advantage simultaneously of the different strengths of different visual representations. This is particularly useful for relating between different information structures (Figure 15), essentially using one structure to query another. Users can select entities according to criteria in one structure, which then shows the distribution of those entities within the other structure. Although linking is commonly used to relate two views of the same data set in a one-to-one fashion, it can also be used to relate entities across many-to-many database relationships for more complex scenarios. Linking also helps users coordinate multiple views during navigation or other interactive operations, such as synchronized scrolling. Tools such as Snap-Together Visualization (North et al., 2002) and Improvise (Weaver, 2004) enable users to mix and match a wide variety of views to produce customized combinations of linked views.

### 6.3  Filtering

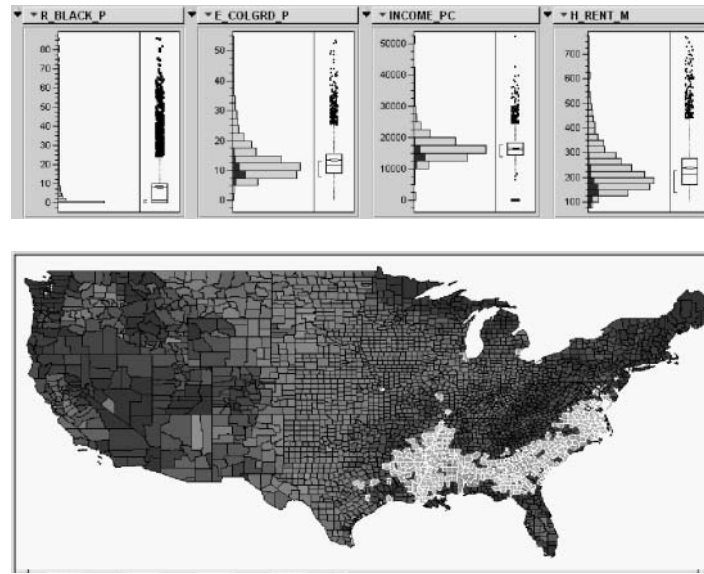
Interactive filtering enables users to dynamically reduce information quantity in the display and focus in on information of interest. *Dynamic queries* (Ahlberg and Wistrand, 1995) apply direct manipulation principles to


**Figure 15** Interactive brushing and linking between histogram plots (top) and a geographic map (bottom) of a census counties data set. Histograms (tabular information structure) show data distributions for four county attributes: percent population black, percent population with college degree, income per capita, and median rent. The map (two-dimensional spatial information structure) is colored by ''percent farmland.'' Selecting the counties that are more than 25% African American in the first histogram also highlights those counties in the other views. The highlighting in the map reveals that those counties are clustered in the southern and southeastern regions. Selecting counties in the map would similarly highlight them in the histograms. The histograms are generated by JMP (SAS, 2004) and the map by ArcView [Environmental Systems Research Institute (ESRI), 2004]. They are linked by Snap-Together Visualization (North et al., 2002).

querying attribute values. Visual widgets such as the range slider (Figure 1b, right) enable users to adjust query parameters rapidly and view filtered results in the visualization in real time. The widgets also provide a visual representation of the current query parameters. Because of the rapid feedback, dynamic query filters can be used not just to reduce information quantity but also to explore relationships between mapped attributes and query attributes. For example, in Figure 1, filtering with the query slider for "unemployment" to eliminate the low-unemployment counties from the display reveals that counties with high unemployment are all in the low-income and low-education area of the plot. The rapid query feedback also eliminates the difficulty of zero-hit or megahit query results, because users can quickly adjust the query parameters until a desirable number of hits is acquired. For example, by further filtering on "unemployment" in Figure 1, users find that there are 11 counties with an unemployment rate over 20%, most of which are located near the border with Mexico. Dynamic queries are the inverse of brushing; brushing highlights selected data, while dynamic queries elide unselected (filtered) data.

Magic Lenses (Fishkin and Stone, 1995) offers a spatially localized form of filter. For more advanced queries involving complex combinations of Boolean operations, metaphors such as Filter Flow (Young and Shneiderman, 1993) enable users to construct virtual pipelines of filters.

## 6.4 Rearranging and Remapping

Since a single mapping of information to visual form may not be adequate, it is straightforward to enable users to customize the mapping or choose among several mappings. Since the spatial layout is the most salient visual mapping, rearranging the spatial layout of the information is the most potent for generating different insights. For example, TableLens (Rao and Card, 1994) (Figure 4a) can spatially rearrange its view by choosing a different attribute to sort by, and Parallel Coordinates (Inselberg, 1997) (Figure 4b) can rearrange the left-to-right order of its axes. This enables users to explore relationships among attributes. In some visualizations, users may be able to directly manipulate data glyphs to create a custom arrangement manually. For example, some visualizations of network structures allow users to move nodes to new positions within the graph layout so that they can refine the results of the automatically generated layout.

In general, any part of the mapping process throughout the visualization pipeline can be under user control. For example, Spotfire (Ahlberg and Wistrand, 1995) users can customize the scatterplot view (Figure 1b) by choosing data attributes to map to various visual properties, such as $x$, $y$, color, and size. It also provides a variety of visual representations to choose from, including heat maps, parallel coordinates, histograms, and pie and bar charts. Visage (Roth et al., 1996) emphasizes a

technique called *data-centric interaction*, in which users can select data entities directly and drag them to different views to display them in new ways. At the extreme are systems such as Sage and SageBrush (Roth et al., 1994) that let users design new visual mappings for a data set using a set of basic primitives as described in Section 2. Sage can also automatically generate certain visual mappings for a given data set and task using a rule-based expert system.

## 6.5  History Keeping and Story Telling

During the course of extensive interactive exploration, users need to be able to undo interactions, backtrack, return to previous states, reuse common processes, keep bookmarks of important findings, annotate findings, and share results. Tracking a user's history of interaction is an important step to enabling these capabilities. History can be tracked at multiple levels, from low-level tracking of every interactive operation to high-level tracking of key findings. Tableau provides users with a visual history of snapshots of the visualization as they explore (Heer et al., 2008) (Figure 16). Clicking a history snapshot returns the visualization to that state. Snapshots can be taken automatically at every step or

only at major changes or manually whenever the user chooses. Snapshots can be presented as small thumbnail images of the visualization or as a textual script of interactive operations performed. Histories can be linear or branching.

Visualizations and histories can also be annotated by the user to track insights gained and tell stories. Storytelling spaces, such as Occulus's Sandbox (Wright et al., 2006), enable users to drag visualizations and entities into an editable storytelling space, where they can arrange snapshots and relevant information into a visual hypothesis for reporting purposes.

Annotated histories can be shared with others to support collaborative visualization activities. Data-sharing websites such as Swivel and Many Eyes (Viégas et al., 2007) enable users to upload data, choose appropriate visual mappings, and annotate visualizations, all in a public forum where others can participate in a distributed asynchronous social process. Many users can collaboratively build upon each others' exploration to develop much deeper stories.

Because there are many interaction strategies required in a flexible exploratory visualization system, it is critical that careful usability processes are applied in

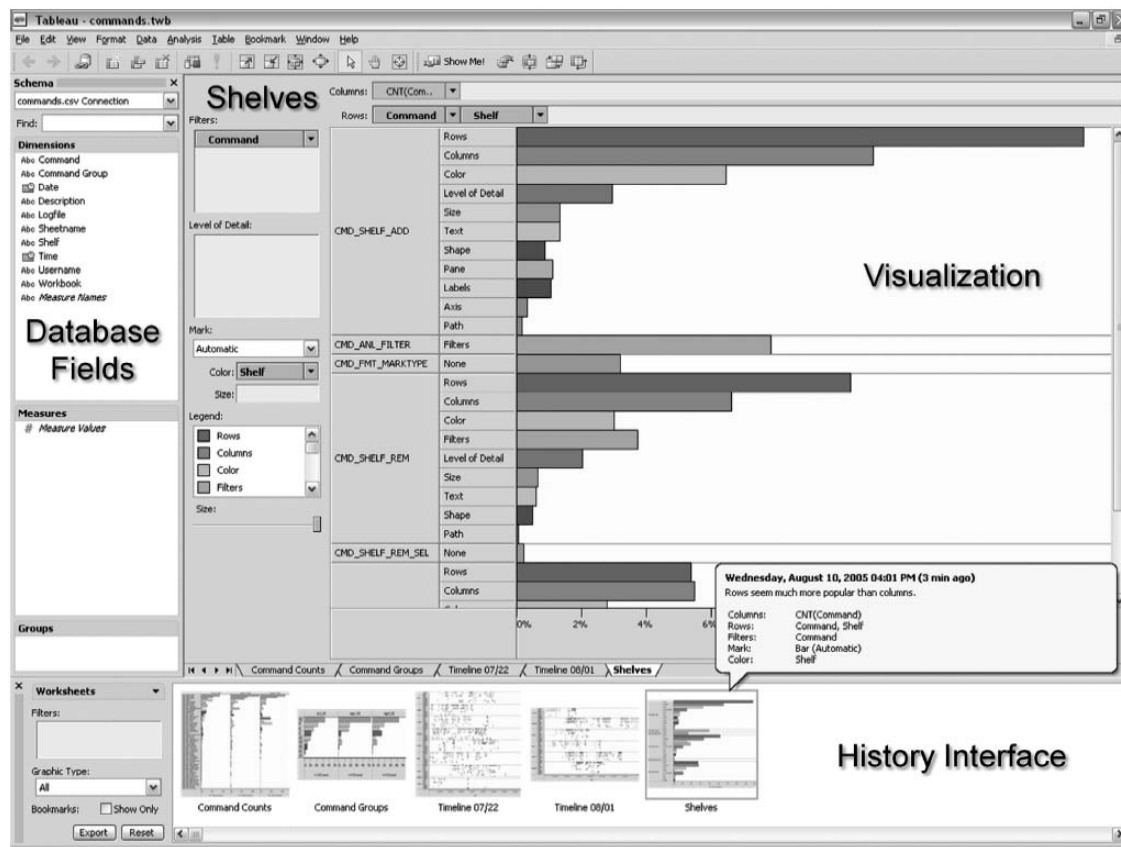

**Figure 16**  Tableau displays a history of snapshots below the main visualization, enabling users to quickly return to any previous state during their exploration. [From Heer et al., (2008). Courtesy of Jeff Heer.]

their design. The many interactions must be designed in an integrated, coherent, and consistent form along with the visual representation. Small usability problems with interaction techniques can significantly reduce the effectiveness of an otherwise well-designed visual representation (Saraiya et al., 2004).

## 7  VISUAL ANALYTICS

The recent rise of the new field of *visual analytics* (Thomas and Cook, 2005) brought forth new emphases in visualization. Visual analytics brings together several fields related to the analysis of data and thus considers the broader context within which visualization resides. Visual analytics seeks to unify the entire analytical process that data analysts encounter and places visualization as the user interface to the process. This has several important implications for the field of visualization.

First, visual analytics emphasizes the role of analysts' cognitive analytical reasoning and sensemaking processes. The sensemaking process model (Pirolli and Card, 2005) (Figure 17) identifies a broad range of analytic activities. Visualization has concentrated on the foraging loop portion of this process. Yet, the sensemaking process highlights the need for new tools to support the synthesis loop as well as the need for a *science of interaction* (Pike et al., 2009) that cleanly integrates all steps of this highly cyclical and fluid process. While past psychological research in visualization has focused primarily on perceptual issues, greater focus is now clearly needed on cognitive issues associated with visualization. Deeper theories are needed to understand how visualization supports analytical reasoning.

Second, visual analytics emphasizes the integration of visualization with computational analytical methods for large-scale data such as data processing, data transformation, data mining, and statistical analysis. Initial work in this area has applied visualization to enable users to control parameters of the computational methods and display the computed results. For example,

iPCA (Jeong et al., 2009) (Figure 18) provides an interactive form of principal-components analysis in which users can manipulate parameters such as the weighting of input dimensions to explore the high-dimensional space and produce insightful projections. New interaction models are needed to enable a deeper mixed-initiative style of interaction between the analyst and the computational methods and that make these complex algorithms usable by novices.

Third, visual analytics emphasizes the production and dissemination of analytical results. Visualization has previously focused on the exploration phase of data analysis, but new methods are needed to transition exploratory findings into presentations—the last step of the sensemaking process (Figure 17). New tools such as Active Reports (Chinchor and Pike, 2009) capture analytical process and provenance into the final report product so that readers can examine the process that led to the findings.

While many of these issues were previously recognized in visualization research, visual analytics has pushed them to the forefront of the research agenda.

## 8  THE FUTURE

Information visualization is a relatively young field (e.g., the IEEE Information Visualization Conference started in 1995). Significant further research is needed on new visual mappings, overview strategies, interaction and navigation strategies, evaluation methods, underlying theories, and guidelines. Among many grand challenges in visualization, a few critical areas of need that should be explored in the foreseeable future include:

1.  *Visualization of Massive Heterogeneous Data*. Applications in intelligence analysis and homeland security require new abilities to analyze terabytes of textual, voice, and video data in unstructured collections (Thomas and Cook, 2005). Bioinformatics is driving the need for

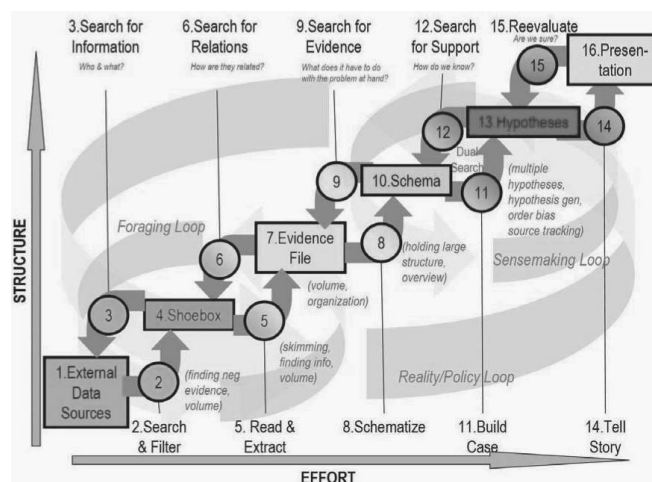

**Figure 17**  The sensemaking process for analysts. (Adapted from Pirolli and Card, 2005.)
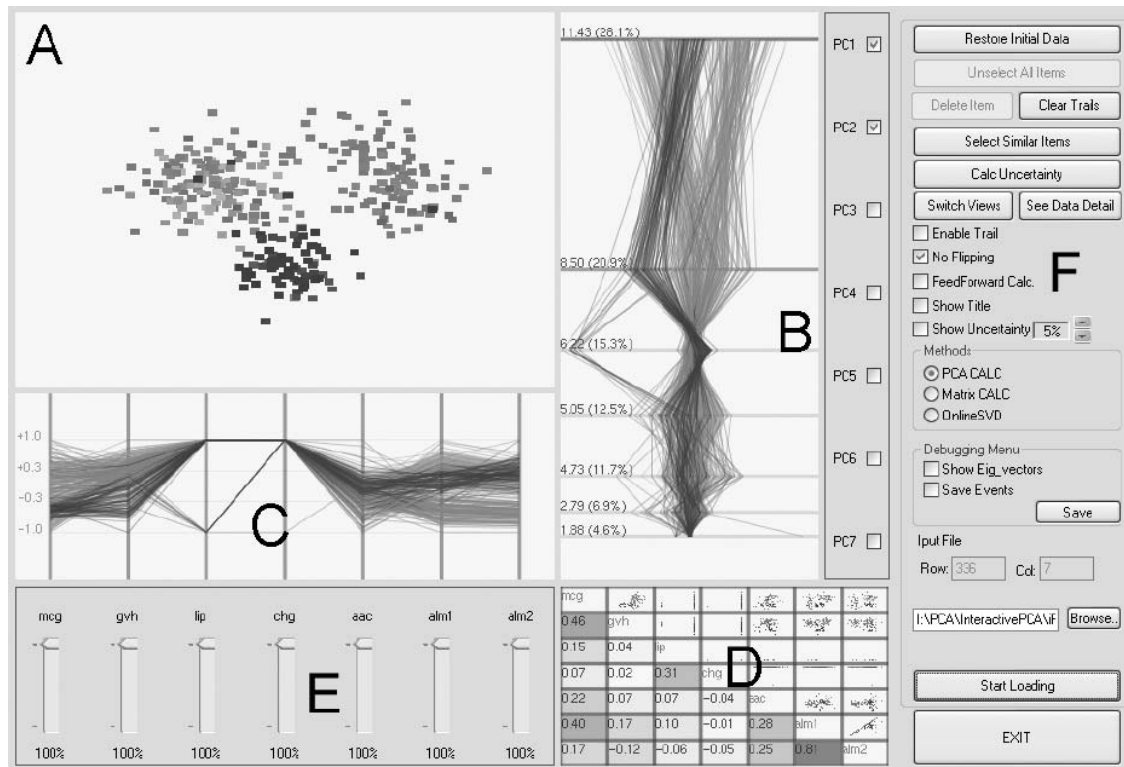

**Figure 18**    iPCA interactive principal-components analysis. [From Jeong et al. (2009). Courtesy of D. H. Jeong.]

new methods to visualize megadimensional tabular data sets, containing thousands or millions of data attributes and huge networks.

2. *Integrating Visualization with the Broader Analytic Context*. Visualization is not an independent task but must be integrated with data management, information retrieval, statistical analysis, data mining (Shneiderman, 2002), decision support, task management, and content authoring and publishing in support of visual analytics.

3. *Visualization with Novel Display and Interaction Devices*. Large high-resolution display technologies, multitouch tabletops, and mobile devices can fundamentally impact interactive visualization (Ni et al., 2006). New visualization strategies must be devised to expand the limits of visualization and exploit high-bandwidth interaction (Ball and North, 2007).

4. *Visualization Evaluation*. To support the iterative design of increasingly advanced visualizations, new evaluation methods are needed to identify and measure the long-term effect of visualizations on high-level insight generation and information analysis (North, 2006).

As researchers explore future visualization innovations and practitioners apply visualization design principles to new domains, the proliferation of effective information visualizations will lead to widespread improvements in the usability of information and to increased generation of valuable insight.

## 1 INTRODUCTION

The popularity of online communities is expanding. It was estimated that there were over 1.70 billion Internet users globally in 2009 (Pingdom, 2010) with one in four Internet users participating in chat rooms or online discussions (Madden and Rainie, 2003). Especially social networking sites have been exponentially increasing in population in the last few years. For example, just on the social network site Facebook, there are around 350 million users, and 50% of these users log in everyday (Pingdom, 2010).

In this chapter we try to provide a synopsis of the topic of human factors for online communities and social computing by first defining online communities and computer-mediated communication (CMC). This is followed by a review of the different types of CMC, with specific categories of online communities described in more depth. The chapter concludes with a brief summary and suggestions for new directions in the area of online communities.

## 2 DEFINITION OF ONLINE COMMUNITIES

Online communities emerge through the use of CMC applications. The term online community is multidisciplinary in nature, means different things to different people, and is slippery to define (Preece, 2000). There are a number of different definitions of online communities One provided by Rheingold (1993, p. 5) states that "[online] communities are social aggregations that emerge from the Net when enough people carry on those public discussions long enough, with sufficient human feeling, to form webs of personal relationships in cyberspace."

The cyberspace is the new frontier in social relationships, and people are using the Internet to make friends, colleagues, lovers, as well as enemies (Suler, 2004). As Korzeny pointed out, even as early as 1978, online communities are formed around interests and not physical proximity (Korzenny, 1978). People with common interests, such as hobbies, ethnicity, education, and beliefs are brought together through online communities

to discuss, debate, and share knowledge about these issues. As Wallace (1999) points out, meeting in online communities eliminates prejudging based on someone's appearance, and thus people with similar attitudes and ideas are attracted to each other.

Like any other technology, CMC has its benefits as well as its limitations. For instance, CMC discussions are often potentially richer than face-to-face discussions. However, users with poor writing skills may be at a disadvantage when using text-based CMC (SCOTCIT, 2003).

## 3 BRIEF HISTORY OF COMMUNITIES IN SOCIETY AND THEIR FUNCTION

The communities concept probably dates back several millennia to the days of ancient people who realized that working together and communicating help in their accomplishments.

There have been significant disagreements concerning the definition of an online community. Preece (2001) indicated that the online community concept means different things to different people. While some people may see an online community as a virtual place to exchange ideas and opinions, others may see it as a virtual environment to share the daily happenings in their lives, yet others may see it as an area where they can sell their goods and make a profit. At their beginnings, online communities have also been defined as virtual environments where it was easier to create networks of hatred and support deviant behavior (Preece, 2001).

While taking into consideration the disagreements concerning what exactly an online community entails, the idea of coming together on a networked environment can be traced back to the early days of the user network (usenet) systems in the early 1990s. It can be argued that with the exponential growth of the World Wide Web starting in 1994 a large number of these networks built around special-interest, demographic, or occupational groups moved to the Web-based environment. At the beginning most online communities were by invitation only or required a strict process to join, but as the demand grew, the sign-up processes became easier and online communities reached millions of online members.

Whereas the most common early Web-based online communities were made up of professional and special-interest groups, over the years the variety of services that online communities offered increased dramatically. Towards the end of the 1990s, communities that cater to individuals and their social activities and interactions increased at a rapid pace. The number of gaming communities has also grown rapidly in the last 15 years, with multiuser dungeons (MUDs) and multiuser object-oriented dungeons (MOOs) in the 1990s and early 2000s being largely replaced by massive multiplayer online role-playing games (MMORPGs). The online gaming concept easily qualifies as an online community as it allows interaction between the players in a number of ways, including live chat and video.

## 4 TODAY'S ONLINE COMMUNITIES AND THEIR FUNCTIONS

Today, the social structure of the World Wide Web largely relies on the online communities framework, where the social aspect of communities is easily part of the goal definitions in most sites. Any site with a bulletin board can be considered an online community site. Other types of communications for qualifying to be an online community site include having an online chat or e-mail option, a news group, list server, or other type of community marketing option. In the last decade, Wellman (1997) identified two types of relationships on online communities: strong-tie and weak-tie relationships. In today's communities, relationships among members vary to a great extent. On a social networking site such as MySpace® or Facebook®, interacting members know each other on a first-name basis, and most members know each other before becoming "friends" on the online community. This is an example of a strong-tie relationship with participants personally knowing each other. On a business-oriented online community, however, participants may only be interested in interacting on the basis of their job identities and to exchange information for hiring and other job-related purposes. This may be an example of a weak-tie relationship where participants do not know each other personally. An example potentially difficult to categorize would be a health care–related online community for cancer patients where community members may exchange information concerning their illness without knowing their personal identities for the purpose of protecting their identity. Communities for practice can exchange information with the ultimate goal of making a profit. In short, due to the sheer number of communities, the relationships between their members vastly vary, with some community members having a tight relationship while others have a professional-only relationship while many other communities have relationships between the members somewhere in between. Whereas initially online communities were sometimes categorized based on the technologies they used to communicate (such as bulletin boards, newsgroups, or "chat networks,"), now online communities are able to combine multiple, sometimes comprehensive communication technologies to provide their members with a wide variety of options to communicate with each other. Additionally, the advent of multimedia capabilities in online environments allows some online communities to turn into "multimedia hubs" where participants can post any image, sound bite or video they want. This allows for more interactive as well as information-rich interactions among members.

Online communities of today deliver a number of services to their customers, which include individuals as well as companies. There are a number of functionalities; the list below presents a sample of the most common ones. They are organized in three broad categories: communities for individuals, communities for professionals, and communities for organizations:

### Communities for Individuals
- Social communities to share their social lives and socialize

- Health care communities to share health-related advice, information, and experiences
- Cultural and special-interest group communities to share information (book reading, movie communities, etc.)
- Shopping communities to shop and share information and experiences (Amazon, E-Bay, etc.)
- Educational communities (e.g., online classes)
- Political communities

### Communities for Professionals

- To share information regarding their professional skills for collaboration and employment possibilities (LinkedIn®, Pipl®, etc.)
- For members of the same profession to exchange information (community for spinal surgery, community for real estate sales professionals)

### Communities for Organizations

- Health care organizations
- Retailers and other for-profit organizations
- Social work
- Government
- International organizations
- Customer- and company-specific portals

In the next chapter, the most significant types of communities are discussed with a human factors emphasis in more detail.

## 5 TYPES OF COMPUTER-MEDIATED COMMUNICATION AND ONLINE COMMUNITIES

### 5.1 Communities for Interest Groups

Different interest groups can build their own community, for example, those interested in business, sports, books, movies, and music. The types of online communities presented in this section cannot be considered comprehensive as the very high number of interest groups have resulted in thousands of online community types. In designing online communities for interest groups, designers need to keep in mind that the users of these communities may potentially have little in common except for the concept of the online community. Therefore, a broad group of user specifications need to be considered in designing these communities with several options that can be presented to the users for the purposes of customization. Interface designs in these communities can be kept simple with minimal use of multimedia. The usability and human computer interaction principles developed by Shneiderman (1992) and Nielsen (1993) can to some great extent be applied to these types of communities, taking into consideration the broad user range, resulting in a design that can be usable for different demographic and cultural groups such as users from different countries as well as from different age groups and education levels.

Different interest groups will have different expectations from the online communities design. For example,

users of an interest group on literature may deal with largely text-based interfaces while an interest group on movies would have an online community interface which would be heavy on video clips and images. A basic set of usability principles can be followed in design for online communities at a minimum. Today, just as in other types of online communities, special-interest group communities also offer customization features where users can choose interface elements such as colors, layout, and text size.

### 5.2 Communities for Health Care

In recent years, the number of communities specializing in health care has increased dramatically. Health care communities can target users with certain conditions, healthy users, or organizations. Health-focused communities can be for-profit or nonprofit organizations, while they are mostly free to individual members except for cases where some special premium services are offered (e.g., finding a doctor for a patient). Health care communities targeting users with certain conditions (such as cancer or epilepsy) are in most cases informational and private. Users can interact with each other without knowing each others' names. In these types of health care communities, most information exchanged deals with certain conditions and symptoms relating to ailments and their solutions. Additionally, the sites can provide some advice and recommendations for the users to improve their quality of life, either through automatically generated suggestions or by getting help from health care professionals. Similarly, health care community sites targeting healthy users usually focus on health care advice and recommendations to lead a healthy life. Recently, sites like Google Health® and Microsoft Health Vault® target the healthy population with the goal of allowing interactions for a healthy life style for different age groups, in some cases specifically the elderly population.

Usability and human factors issues in health care communities should be approached with caution as some health care communities will have target users with specific ailments that may require special design compensations for their user groups (e.g., online communities targeting users with visual ailments or blindness). The design issues in health care communities may need to be considered on a case-by-case basis depending on the nature of the community and the types of users it targets. Whereas most design issues may deal with visual elements and navigation, if the target audience consists of common individuals (sometimes referred to as "health consumers"), design issues for populations with disabilities need to be given special emphasis in the design if the target population generally has such a disability. For example, if the user group consists of people with low vision, the design of the online community Web pages should compensate for this by providing strong contrast and larger text and image sizes as well as ensuring that the sites are compatible for screen readers for the blind.

### 5.3 Online Virtual Game Communities

With the advent of ubiquitous broadband Internet connection and the increasing graphical processing power

of personal computers, a new paradigm of gaming has emerged. A paradigm of gaming that allows players to remotely play together the same computer game, theMMORPGs, has changed the game industry dramatically. MMORPGs provide a fictional setting where a large group of users voluntarily immerse themselves in a graphical virtual environment and interact with each other by forming a community of users.

Although the concept of multiplayer gaming is not new, the game world of most local network multiplayer games, as opposed to MMORPG, is simplistic and can accommodate only around 16 concurrent players in a limited space.

A MMORPG enables thousands of players to simultaneously play in an evolving virtual world over the Internet. The game world is usually modeled with highly detailed three-dimensional (3D) graphics, allowing individuals to interact not only with the gaming environment but also with other players. Usually this involves the players representing themselves through the use of avatars—the visual representation of the player's identity in the virtual world.

The MMORPG environment is a new paradigm in computer gaming in which players are part of a persistent world, a world that exists independent of the users (Yee, 2005). Unlike other games where the virtual world ceases to exist when players switch off the game, in an MMORPG, the world exists before the user logs on and continues to exist when the user logs off. More importantly, events and interactions occur in the world even when the user is not logged on as there are many other players who are constantly interacting, thus transforming the world. To accommodate the large number of users, the worlds in MMORPGs are vast and varied in terms of "geographical locations," characters, monsters, items, and so on. More often than not, new locations or items are added by the game developers from time to time according to the demands of the players.

An MMORPG, like any role-playing game (RPG), involves killing monsters, collecting items, developing characters, and so on. However, it also contains an extra aspect of internal sociability. Unlike single-player games which rely on other external modes of communication (such as mailing lists, discussion forums outside the game) to form the gaming culture, the culture is formed within the MMORPG environment itself.

In such a way, these MMORPG virtual worlds represent the persistent social and material world, which is structured around narrative themes (usually fantasy) where players are engaged in various activities: slaying monsters, attacking castles, scavenging for goods, trading merchandise, and so on. On one hand, the game's virtual world represents the escapist fantasy; on another, it supports social realism (Kolbert, 2001).

This means games are no longer meant to be a solitary activity played by a single individual. Instead, the player is expected to join a virtual community that is parallel with the physical world in which societal, cultural, and economical systems arise. It has gradually become a world that allows players to immerse themselves into experiences which closely match those of

the real world: seek virtual relationships, hold virtual marriages, set up virtual shops, and so on.

Such games are ripe for cultural analysis of the social practices around them. Although fundamentally MMORPGs are video games with virtual spaces where the players interact, they should be regarded not just as a game software but as a community, a society, and, if you wish, a culture. These games are becoming the most interesting interactive computer-mediated communication and networked activity environments (Taylor, 2002). Thus, understanding the pattern of participation in these game communities is crucial, as such virtual communities function as a major mechanism of socialization of the players to the norms of the game culture that emerges.

Such communities that formed around the game can be broadly divided into two categories: in-game and out-of-game communities. Most MMORPGs are created to encourage long-term relationships among the players through the features that support the formation of in-game communities. One of the most evident examples is the concept of guilds. Guilds are a fundamental component of the MMORPG culture for people who are natural organizers to run a virtual association which has formalized membership and rank assignments to encourage participation. Sometimes, a player might join a guild and get involved in a guild war in order to fight for the castle. Each guild usually has a leader and several guilds can team up in a war. This involves complicated leader–subordinate and leader–leader relationships.

Apart from relatively long-term relationships such as guild communities, MMORPGs also provide many opportunities for short-term relationship experiences. For example, a player could team up with another player to kill monsters in order to develop the abilities of their avatars (level up) or some more expert players could help newer players get through the game.

When trying to win the game, players often need to get information from other resources: guidebooks, discussion forums, other players, and so on. Therefore, game playing is generally more concerned with player–player interaction than with player–game interaction. What is at first confined to the game alone soon spills over into the virtual world beyond it (e.g., websites, chat rooms, email) and even life off-screen (e.g., telephone calls, face-to-face meetings).

Apart from these external communities around the game which are mediated through e-mails or online forums (which also exist in many other games), there is an interesting phenomenon that fuses the internal and external game communities. The participation in an external community starts to break the magic circle of the game—the game space is no longer separate from real life—as the out-of-game community trades in game items for real money.

For example, Norrath, the world of EverQuest, was estimated to have the seventy-seventh largest economy in the real world based on buying and selling in online auction houses (Castronova, 2001, p. 1):

About 12,000 people call it their permanent home, although some 60,000 are present there at any given time. The nominal hourly wage is about USD3.42

per hour, and the labors of the people produce a GNP per capita somewhere between that of Russia and Bulgaria. A unit of Norrath's currency is traded on exchange markets at USD0.0107, higher than the Yen and the Lira.

Having illustrated the social phenomenon around such a playful virtual community, it is believed that it is fruitful to research such communities as we might be able to derive some useful implications on how successful computer-supported collaborative work (CSCW) and computer-supported collaborative learning (CSCL) environments can be designed. For this reason, in Section 6 we will describe some of the methodologies that can be used in such studies, and in Section 7 we will present the application of some of these methods to two case studies.

### 5.4 Communities for Profit

A community for profit can be in three main forms, two of which employ the community aspects and processes directly to generate revenue, while the online community aspect may be a supporting factor in generating revenues for the profit-making entity.

By definition, online communities are made up of people with common interest or profession coming together electronically to exchange ideas and allow collaboration. Although online communities aimed at providing the electronic environment to support this communication mostly target individuals, companies can also play a role as customers for such online communities. Due to this focus on individual users, a large number of commonly known online communities generate revenue based on advertisements. Large communities such as Microsoft Network (MSN®), Google®, Facebook®, and Yahoo®, while varying in the types of services they deliver to individual customers, rely heavily on customized advertisements (Krammer, 2008). However, security and privacy concerns become critical issues when sites provide advertisements which are based on the content of the user-provided input, as these types of advertisements require that what the users type or do on the site is recorded without the user's knowledge in order to be used for advertisement purposes later (Hu et al., 2007). This issue should be considered in providing advertisements for individual users of online communities as part of the trade-off between revenue stream and violation of user rights concerning privacy.

The second method employed by the online communities for revenue generation includes charging users membership or one-time fees to use the online community site services. Because most social networking sites are free to end users and the aversion of common Internet users to pay for basic services such as e-mail services, bulletin boards, common information such as news, as well as other services offered by online communities, most community sites are free for basic membership. Those online communities that charge a fee for membership usually offer additional services on top of the common services or when the services provided are at a higher level and involve some additional costs to the online community provider. One example is a health community that provides advice to users from actual physicians on a case-by-case basis or experts in the area to answer user questions. Furthermore, sites can provide user-specific services such as recommending a doctor based on the patient-provided information. These "premium" services can be subject to a fee, although it can be argued that the majority of the major online communities are free to the end users and generate their revenue primarily from advertisers.

The third potential revenue generation method is arguably based on the notion that any electronic commerce company that employs a method such as user feedback on products can be considered an online community as it fits the definition of the provider of an electronic service that allows individuals with something in common (in this particular case, individuals that are interested in a product). Companies like Amazon® and eBay® largely rely on customers who provide feedback regarding their products for others to read, and this feedback plays a large role in other potential buyer's decisions to purchase the products. Electronic commerce companies see interaction among shoppers concerning products as a major component of customer relationship management (CRM), with the ultimate goal of positive product recommendations from other shoppers allowing shoppers to purchase the product, come back to shop for other products, and provide favorable feedback (Ozok et al., 2007). While the community issues may not be in the foreground for retail electronic commerce companies in general, this and some other studies suggest that treating the targeted consumers as a community and providing community-like services on their pages is becoming increasingly popular among online retailers.

One last relationship can be described between online communities and revenue generation in the form of portals. Consumer portals started as search engines for individual users to look up information relating to the keywords they entered, but since then, search engines have evolved to a rich information repository where users can look for the information they need. Portals like Google®, Yahoo!®, and Bing® can therefore also be seen as having some online community aspect where users can exchange information directly or indirectly. As the online community aspects of portals in this regard play an indirect role in revenue generation, it is difficult to categorize the design issues involving portals as they relate to these aspects. However, the online community aspects of portals may need to be taken into consideration in future portal design issues.

## 6 ANALYZING ONLINE COMMUNITIES: FRAMEWORKS AND METHODOLOGIES

Various aspects and attributes of CMCs can help us better understand online communities: for instance, analysis of the frequency of exchanged messages and the formation of social networks or analysis of the content of the exchanged messages and the formation of virtual communities. To achieve such an analysis a number of theoretical frameworks have been developed and proposed. For example, Henri (1992) provides an

analytical model for cognitive skills that can be used to analyze the process of learning within messages exchanged between students of various online e-learning communities. Mason's (1991) work provides descriptive methodologies using both quantitative and qualitative analysis. Furthermore, five phases of interaction analysis are identified in Gunawardena et al.'s (1997) model:

   I.   Sharing/comparing of information
   II.  Discovery and exploration of dissonance or inconsistency among ideas, concepts, or statements
  III.  Negotiation of meaning/coconstruction of knowledge
  IV.  Testing and modification of proposed synthesis or coconstruction
   V.  Agreement statement(s)/applications of newly constructed meaning

Some of the methods used are as follows:

*Interviews.* An interview can be defined as a type of conversation that is initiated by the interviewer in order to obtain relevant information. Interviews are usually carried out on a one-to-one basis where the interviewer collects information from the interviewee. Interviews can take place by telephone and face to face (Burge and Roberts, 1993). There are three types of interviews: (a) structured interviews: consist of predetermined questions asked in fixed order like a questionnaire; (b) semistructured interviews: questions are determined in advance but may be reordered, reworded, omitted, and elaborated upon; (c) unstructured interviews: are not based on predetermined questions but instead the interview has a general area of interest and the conversation may develop freely.

Interviews can be used to gain insights about general characteristics of the participants of an online community and their motivation for participating in the community under investigation. The data collected come straight from the participants of the online communities, whereby they are able to provide feedback based on their own personal experiences, activities, thoughts, and suggestions.

*Questionnaires.* A questionnaire is a self-reporting query-based technique. Questionnaires are typically produced on printed paper, but due to recent technologies and in particular the Internet, many researchers engage in the use of online questionnaires, thus saving time and money and eliminating the problem of a participant's geographical distance. There are three types of questions that can be used with questionnaires: open questions, where the participants are free to respond however they like; closed questions, which provide the participants with several choices for the answer; and scales where the respondents must answer on a predetermined scale.

*Log Analysis.* A log, also referred to as web-log, server log, or log-file, is in the form of a text file and is used to track the users' interactions with the computer system they are using. The types of interactions recorded include key presses, device movements, and other information about the user activities. The data are collected and analyzed using specialized software tools and the range of data collected depends on the log settings. Logs are also time stamped and can be used to calculate how long a user spends on a particular task or how long a user has lingered in a certain part of the website (Preece et al., 2002). In addition, an analysis of the server logs can help us find out: when people visited the site, the areas they navigated, the length of their visit, the frequency of their visits, their navigation patterns, from where they are connected, and details about the computer they are using.

*Content and Textual Analysis.* Content analysis is an approach to understanding the processes that participants engage in as they exchange messages (McLoughlin, 1996). There have been several frameworks created for studying the content of messages exchanged in online communities.

*Social Network Analysis* (*SNA*). According to Krebs (2004, p. 1), "Social Network Analysis (SNA) is the mapping and measuring of relationships and flows between people, groups, organizations, computers or other information/knowledge processing entities. The nodes in the network are the people and groups while the links show relationships or flows between the nodes. SNA provides both a visual and a mathematical analysis of human relationships." Preece (2000) adds that it provides a philosophy and a set of techniques for understanding how people and groups relate to each other and has been used extensively by sociologists (Wellman, 1982, 1992), communication researchers (Rice, 1994; Rice et al., 1990), and others. Analysts use SNA to determine if a network is tightly bounded, diversified, or constricted; to find its density and clustering; and to study how the behavior of network members is affected by their positions and connections (Garton et al., 1997; Henneman, 1998; Scott, 2000).

There are two approaches to SNA:

*Ego-Centered Analysis.* Focuses on the individual as opposed to the whole network, and only a random sample of the network population is normally involved (Zaphiris et al., 2003). The data collected can be analyzed using standard computer packages for statistical analysis (Garton et al., 1997).

*Whole-Network Analysis.* The whole population of the network is surveyed and this facilitates conceptualization of the complete network (Zaphiris et al., 2003). The data collected can be analyzed using microcomputer programs like UCINET and Krackplot (Garton et al., 1997).

The following are important units of analysis and concepts of SNA (Garton et al., 1997; Wellman, 1982, 1992; Hanneman, 2001; Zaphiris et al, 2003):

- Nodes: The actors or subjects of study.
- Relations: The strands between actors. They are characterized by content,
- Direction and strength.
- Ties: Connect a pair of actors by one or more relations.
- Multiplexity: The more relations in a tie, the more multiplex the tie is.
- Composition: This is derived from the social attributes of both participants.
- Range: The size and heterogeneity of the social networks.
- Centrality: Measures who is central (powerful) or isolated in networks.
- Roles: Network roles are suggested by similarities in the network members' behavior.
- Density: The number of actual ties in a network compared to the total amount of ties that the network can theoretically support.
- Reachability: In order to be reachable, connections that can be traced from the source to the required actor must exit.
- Distance: The number of actors that information has to pass through to.
- Connect one actor with another in the network.
- Cliques: Subsets of actors in a network who are more closely tied to each other than to other actors who are not part of the subset.

Usability issues involving online community sites can be concluded to not be radically different from those that involve design of commercial websites. General design guidelines involving usability design of Web pages can to a great extent be observed in online community design. Major design issues specific to online communities may include those involving the potential cognitive and physical limitations of the targeted user group to which the community caters. However, as indicated earlier, producing general usability guidelines for online communities is difficult due to the different user groups for which the many online communities provide services.

## 7  CASE STUDIES

In this section we present two case studies that demonstrate the use of theoretical and analytical techniques for studying online communities. In the first case study, we demonstrate how the results from an attitude towards thinking and learning questionnaire can be combined with SNA to describe the dynamics of a computer-aided language learning (CALL) online community. In the second case study, we present a theoretical activity model that can be used for describing interactions in online game communities.

## 7.1  Computer-Aided Language Learning Communities

In the first case study we demonstrate a synthetic use of quantitative (SNA) and qualitative (questionnaire) methods for analyzing the interactions that take place in a CALL course. Data were collected directly from the discussion board of the "Learn Greek Online" (LGO) course (Kypros-Net, 2005).

LGO is a student-centered e-learning course for learning Modern Greek and was built through the use of a participatory design and distributed constructionism methodology (Zaphiris and Zacharia, 2001). In an ego-centered SNA approach, we have carried out an analysis of the discussion postings of the first 50 actors (in this case the students of the course) of LGO.

To carry out the SNA, we used "NetMiner" (Cyram, 2004), a tool which enables us to obtain centrality measures for our actors. The "in- and out-degree centrality" was measured by counting the number of interaction partners per individual in the form of discussion threads (e.g., if an individual posts a message to three other actors, then his or her out-degree centrality is 3, whereas if an individual receives posts from five other actors, then his or her in-degree is 5).

Due to the complexity of the interactions in the LGO discussion, we had to make several assumptions in our analysis:

Posts that received no replies were excluded from the analysis. This was necessary in order to obtain meaningful visualizations of the interaction.

Open posts were assumed to be directed to everyone who replied.

Replies were directed to all the existing actors of the specific discussion thread unless the reply or post was specifically directed to a particular actor.

In addition to the analysis of the discussion board interactions we also collected subjective data through the form of a survey. More specifically, the students were asked to complete an Attitudes Towards Thinking and Learning Survey (ATTLS). The ATTLS measures, through the use of 20 Likert scale questions, the extent to which a person is a "connected knower" (CK) or a "separate knower" (SK). People with higher CK scores tend to find learning more enjoyable and are often more cooperative, more congenial, and more willing to build on the ideas of others, while those with higher SK scores tend to take a more critical and argumentative stance to learning (Galotti et al., 1999).

The out-degree results of the social network analysis are depicted in Figure 1 in the form of a sociogram, and the in-degree results are depicted in Figure 2. Each node represents one student (to protect the privacy and anonymity of our students their names have been replaced by a student number). The position of a node in the sociogram is representative of the centrality of that actor (the more central the actor, the more active). As can be seen from Figure 1, students S12, S7, S4, and S30 (with out-degree scores ranging from 0.571 to 0.265) are at the center of the sociogram and possess the
**Figure 1**  Out-degree analysis sociogram.

highest out-degree. The same students also possess the highest in-degree scores (Figure 2). This is an indication that these students are the most active members of this online learning community, posting and receiving the largest number of postings. In contrast, participants in the outer circle (e.g., S8, S9, S14) are the least active with the smallest out-degree and in-degree scores (all with 0.02 out-degree scores).

In addition, a clique analysis was carried out (Figure 3) and it showed that 15 different cliques (the majority of which are overlapping) of at least three actors each have been formed in this community.

As part of the ego-centered analysis for this case study we look in more detail at the results for two of our actors: S12, who is the most central actor in our SNA analysis, that is, with the highest out-degree score,

and S9, an actor with the smallest out-degree score. It is worth noting that both members joined the discussion board at around the same time.

First, through a close look at the clique data (Table 1), we can see that S12 is a member of 10 out of the 15 cliques, whereas S9 is not a member of any, an indication of the high interactivity of S12 versus the low interactivity of S9. In an attempt to correlate the actors' position in the SNA sociogram with their self-reported attitudes toward teaching and learning, we looked more closely at the answers these two actors (S12, S9) provided to the ATTLS. Actor S12 answered all 20 questions of the ATTLS with a score of at least 3 (on a 1–5 Likert scale) whereas S9 had answers ranging from 1 to 5. The overall ATTLS score of S12 is 86 whereas that of S9 is 60. A clear dichotomy of opinions
**Figure 2** In-degree analysis sociogram.

occurred on 5 of the 20 questions of the ATTLS. S12 answered all 5 of those questions with a score of 5 (strongly agree) whereas S9 answered them with a score of 1 (strongly disagree). More specifically, S12 strongly agreed that he or she:

1. Is more likely to try to understand someone else's opinion than to try to evaluate it.
2. Often finds herself or himself arguing with the authors of books read, trying to logically figure out why they're wrong.
3. Finds that he or she can strengthen his or her position through arguing with someone who disagrees with them.
4. Feels that the best way to achieve his or her own identity is to interact with a variety of other people.

5. Likes playing devil's advocate—arguing the opposite of what someone is saying.

S9 strongly disagreed with all of the above statements. These are all indications that S12 is a CK whereas S9 is a SK.

This case study showed that the combination of quantitative and qualitative techniques can facilitate a better and deeper understanding of online communities.

## 7.2 Game Communities and Activity Theoretical Analysis

The main motivation of the second case study arises from the more general area of computer game-based learning. Game-based learning has focused mainly on how the game itself can be used to facilitate learning activities, but we claim that the educational
**Figure 3**   Clique analysis sociogram.

opportunity in computer games stretches beyond the learning activities in the game per se. Indeed, if you observe most people playing games, you will likely see them downloading guidelines from the Internet and

**Table 1  Clique Analysis of LGO Discussions**

| Cliques | Actors |
| --- | --- |
| K1 | S12, S7, S30, S40, S43, S44, S45 |
| K2 | S12, S7, S30, S4 |
| K3 | S12, S7, S10, S11, S13 |
| K4 | S12, S7, S14 |
| K5 | S12, S7, S25 |
| K6 | S12, S7, S41 |
| K7 | S12, S20, S21, S22 |
| K8 | S12, S29, S4, S30, S31, S32, S33, S34 |
| K9 | S12, S38, S39, S40 |
| K10 | S12, S46, S49, S50 |
| K11 | S1, S2, S3, S4, S5, S6, S7 |
| K12 | S16, S26, S27, S28 |
| K13 | S23, S20, S24 |
| K14 | S47, S46, S49, S50 |
| K15 | S48, S46, S49, S50 |

participating in online forums to talk about the game and share strategies. In actuality, almost all game playing could be described as a social experience, and it is rare for a player to play a game alone in any meaningful sense (Kuo, 2004). This observation is even more evident in MMORPGs, which have been discussed earlier in this chapter. For example, the participation in a MMORPG is constituted through language practice within the in-game community (e.g., in-game chatting and joint task) and out-of-game community (e.g., the creation of written game-related narratives and fan-sites). The learning is thus not embedded in the game, but it is in the community practice of those who inhabit it.

We believe that the study of computer games should be expanded to include the entire game community. Computer game communities can be categorized into three classes which we have identified (Figure 4) (Ang et al., 2005) as:

*Single Game Play Community*. This refers to a game community formed around a single-player game. Although players of a single-player game like The Sims 2 and Final Fantasy VII play the game individually, they are associated with an out-of-game community which discusses the game either virtually or physically.

**Figure 4** Types of game communities: (*a*) single game play community; (*b*) social game play community; (*c*) distributed game play community.

*Social Game Play Community*. This refers to multiplayer games which are played together in the same physical location. It creates game communities at two levels: in-game and out-of-game. Occasionally, these two levels might overlap. The out-of-game interaction might be affected by issues beyond the specific game system; for example, the community starts exchanging information about another game.

*Distributed Game Play Community*. This is an extension of the social game play community, but it emphasizes the online multiplayer game in which multiple sessions of a game are established in different geographical locations.

The study of game communities, especially out-of-game communities, from the perspective of education is still very much unexplored. We believe the potential of games in education is not limited to what is going on in the game. Educators could benefit by studying games as a social community because games are now becoming a culture that permeates the life of everyone, especially the younger generation. Black (2004) has investigated the interactions among participants in a virtual community of Japanese comic fans which involve a lot of reading and writing throughout the site. She examines how the fans in the community help each other with English language writing skills and with cross-cultural understanding. In this section we have pointed out that game communities can emerge from both single-player and multiplayer games. We believe that, by further studying the social interaction in the game community, we will be able to utilize games in learning in a more fruitful way. In the next section, we apply and evaluate one of these models of game communities to a specific scenario in knowledge building using activity theory.

## 8 FUTURE ISSUES IN ONLINE COMMUNITY DESIGN

Online communities have evolved very rapidly in the last 15 years. The most popular online community in the world today (according to mostpopularwebsites.net), Facebook®, is only six years old. While it is difficult to foresee the future and next steps in online communities in terms of popularity as well as in terms of human factors and design issues, it would be safe to say that online communities will continue their rapid change for the foreseeable future. It is likely that more interactive features will become prevalent for online communities serving individuals. Users will be able to communicate more commonly via videoconferencing, and the reach of relatives, friends, and colleagues will become easier with the help of continuous connection to online communities. Microblogging provided by sites such as Twitter® is likely to improve its features, allowing video- and audio-blogging. Additionally, mobile devices are already extremely prevalent, and online communities are likely to allow users to be constantly connected to their communities via their cell phone or other mobile device interfaces. Online communities are also likely to increase in the role of connecting people and professionals with each other, with capabilities of communities improving in terms of speed and accuracy.

With the increase in popularity and capabilities of online communities, some challenges in online community design from human factors perspectives also need to be acknowledged. As users are likely to share private information on online communities which is intended for only those individuals that the users approve of, privacy and security are becoming major concerns in online communities. The concerns of users need to be addressed via community policies as well

as technologies that ensure that the information being shared in online communities is secure and intrusion does not happen. As online communities evolve, users with more limited technology may have a difficult time keeping pace with newly developing technologies or may move on to other communities. In the highly competitive environment of online communities, users have many options, and communities can lose popularity easily. Research in human factors and human computer interaction will allow community providers to keep track of user needs, preferences, and limitations and provide optimal communities for all types of users.

# CHAPTER 45

# HUMAN FACTORS AND INFORMATION SECURITY

**E. Eugene Schultz**
**Emagined Security**
**San Carlos, California**

## 1   OVERVIEW

In this chapter we delve into the relationship between information security (sometimes called *computer security*) and usability design. The goals of *information security* are to protect the confidentiality, integrity, and availability of systems, information, applications, and network devices as well as to prevent repudiation (untruthful denial) of electronically based transactions. Security-related breaches manifest themselves in a variety of forms, including intrusions into systems, worm and virus infections, misuse, denial of service, integrity compromises in systems and/or data, scams, hoaxes, and many others. A taxonomy of the major security-related tasks that people must perform includes the following tasks: identification and authentication; assurance of integrity, confidentiality, availability, and system integrity; and intrusion detection. *Usability* flaws in a number of corresponding areas—password selection, third-party authentication, file access control, Web server configuration, firewall configuration, encryption of sensitive information, electronic commerce transactions, auditing and logging, and intrusion detection—are analyzed. These flaws are almost certainly also linked to the most costly form of security-related incident—damage and disruption to and/or theft of systems and data due to insiders. Employees and contractors who are disgruntled may, for example, be less motivated than other users to overcome usability hurdles in computing systems, something that may escalate damage and/or disruption considerably. Better default parameters in operating system and application software and the availability of settings that produce pervasive changes in the security of systems and applications, thus obviating the need to interact with systems many times or with more difficulty to tighten these settings, would go a long way in addressing the usability problems discussed in this chapter.

## 2   INTRODUCTION

Using computers is a way of life almost everywhere around the world. Without computers, life in virtually every country would be radically different. Although appreciating how different life would be without computers is easy, many people fail to appreciate what happens if computers are unreliable for a variety of reasons. In some cases, such as when computers are used to regulate energy flow within buildings, computer unreliability might not radically disrupt computing activity because people could in these circumstances simply take manual control of functions normally performed by computers. But in other cases, such as in air traffic control systems, the ramifications of computers becoming unreliable can potentially be considerably more draconian.

Computers become unreliable for a variety of well-known reasons: electrical failure, damage due to water or fire, and hardware and software flaws ("bugs") that threaten the normal operation of computers, to name a few. Strangely, until relatively recently, people have been largely unaware of the many security-related reasons for unreliability in computing systems, such as remote access by unauthorized users or the execution of malicious programs, even though security threats may be more costly and disruptive than others, such as power outages.

Protecting computers, the information residing in them and sent over networks, applications, and network components such as routers and switches against security-related threats falls within the purview of the field of information security, also known as computer security (Garfinkle et al., 2003). Included in the goals of information security are ensuring confidentiality of information; protecting the integrity of systems, data, and applications; ensuring that systems, data, and applications are available when needed; and ensuring that anyone who initiates an electronic transaction cannot repudiate or deny having done so afterward. Although once an obscure area, information security has become increasingly important over the last two decades as the number, magnitude, and impact of security breaches have grown. Available statistics show that:

- According to a recent Ponemon Institute (2009) survey, the average cost of an incident in which personally identifiable information (PII) has been compromised was $6,655,758 in 2009. This amount has grown every year since the Ponemon Institute started collecting statistics on this subject four years ago.
- According to a recent Computer Security Institute (CSI, 2009) Annual Computer Crime Survey, the average cost of a security breach in 2009 was $234,000.
- According to the Internet Crime Complaint Center (IC3, 2009), in 2009, 336,655 crime complaints were filed, a 22.3% increase over 2008. The vast majority of referred cases were related to fraud, which amounted to $559.7 million (up from $264.6 million in total reported losses in 2008).

Federal and state/provincial laws as well as regulations in the private sector require the implementation of information security measures to protect certain types of information such as PII that could be used to perpetrate identity theft. These laws and compliance regulations, which typically prescribe penalties such as fines for computer-related actions such as gaining unauthorized access to systems, have also greatly contributed to the growth of information security in numerous countries.

## 3 SECURITY BREACHES

A security incident is one in which an actual or possible adverse outcome due to a breach or bypass in a security mechanism has occurred (Schultz and Shumway, 2001). The nature of security breaches varies considerably. The most common types of security breaches include:

1. *Intrusions into Systems and Network Devices*. These are commonly known as *hacker attacks*. In most of these attacks, perpetrators break into user or system administrator's accounts using passwords captured ("sniffed") as they are entered during local log-ins or as they traverse networks during remote log-ins. *Brute-force attacks*, in which attackers run programs that

enter one password after another until one finally succeeds, are another variation of this type of attack. Alternatively, many attackers run programs that attempt to exploit vulnerabilities in systems and applications to gain unauthorized access. Once intruders break into a system, they often engage in activities such as reading users' files and email and planting Trojan horse programs that allow them once again to gain access to the victim system later.

2. *Malicious Code Infections*. Malicious code (also called "malware") is a program intended to subvert or bypass security functions built into systems and applications. Viruses are self-replicating programs that spread because of user actions, whereas worms are self-replicating programs that spread independently of user actions (Schultz and Shumway, 2001). The fact that worms work independent of users makes them particularly troublesome; from late 2008 through the present, for example, the Conficker worm and its variants have infected approximately 15 million PCs connected to the Internet (Schultz, 2009). Trojan horses are programs that are intended to be covert so that they are unlikely to be noticed and then eradicated. Trojan horse programs have grown disproportionately compared to viruses and worms, because computer crime is increasingly being perpetrated by desire for financial gain. To make money in this manner requires stealth—Trojan horses are stealthy, whereas viruses and worms are not (Schultz, 2006).

3. *Misuse and Subversion by Trusted Individuals, Such As Employees and Contractors*. Misuse and subversion are a less common but in many cases the most costly category of security breaches. These types of malfeasance are often due to motives such as greed or revenge.

4. *Denial-of-Service (DoS) Attacks*. Among the most common of all security breaches, these are intended to shut down or disrupt computing activities. According to the most recent CSI Computer Crime Survey, from 2008 to 2009 DoS attacks grew more than other types of attack—a growth rate of over 29% (CSI, 2009). They also are among the most costly of all because of organizations' dependence upon computing services. A particularly severe type of DoS attack is a distributed denial-of-service (DDoS) attack. In this type of attack malicious clients called bots are installed in systems throughout a network. When the "botmaster" sends the command, all bots in the botnet respond by sending volumes of malicious traffic that severely disrupts or brings down the network.

5. *Integrity Compromises*. Integrity compromises occur when perpetrators place malicious programs in systems they have accessed or modify

files within these systems. Web page deface-
ments are the most widely known type of
integrity compromise, although unauthorized
modification of system files and critical data
such as financial data are generally much more
costly than is typical.

6. *Social Engineering*. Social engineering means
"conning" someone to reveal information [e.g.,
a password or bank account number and
personal identification number (PIN)] desired
by a perpetrator. Many social engineering
attacks are perpetrated via email; others are via
phone calls to intended victims.

7. *Scams*. Scams are schemes in which email,
electronic messaging, websites, or chat rooms
are used to con unsuspecting users out of some-
thing (usually, money). *Phishing* (in reality
a type of social engineering attack) is cur-
rently the most common type of scam. One
kind of phishing attack involves a perpetra-
tor sending email that threatens people such
as bank customers with disruption of services
if recipients do not enter personal and/or finan-
cial information in a form on a Web page that
appears to belong to a legitimate company.
Other scams offer recipients of messages that
appear to come from people such as deposed
African political figures a large commission in
return for helping transfer what is described as
millions of dollars to the United States. The
catch is that recipients must first send a sum of
money to a designated address as a "measure
of good faith" before they allegedly received
any money.

8. *Hoaxes*. In hoaxes, bogus information is dis-
seminated electronically. For example, certain
network postings falsely claim that Win-
dows operating systems contain routines that
covertly glean data stored in these systems for
the National Security Agency (NSA).

9. *SQL Injection Attacks*. Relational database
management systems (RDBMSs) typically have
built-in controls to limit the potential unau-
thorized access to the information they store.
However, if database applications are not pro-
grammed in accordance with principles of
secure code development, perpetrators can sub-
mit specially crafted Structured Query Lan-
guage (SQL) statements to a database that cause
commands that retrieve database information
to be executed—an "SQL injection attack."
Perpetrators might also exploit SQL injection
vulnerabilities to compromise the database host
machine itself and use it as a "pivot point" to
break into other systems in the same network.

10. *Session Hijacking*. In a "session hijacking"
attack, perpetrators monitor traffic sent over
networks to obtain information such as Internet
Protocol (IP) addresses of clients and servers,
the state of the interaction between a Web
browser and a Web server, and so on. Using

this information, perpetrators may be able
to gain control of an existing connection or
create a new connection with exactly the same
characteristics as another one. With control over
the connection, the perpetrator has the same
privileges and access rights that the legitimate
user has.

11. *Spamming*. Spam is unwanted email ("junk
mail") and pop-up messages. Although sending
email does not in and of itself constitute a
security breach, the fact that the overwhelming
majority of spam has a sender address that has
been falsified does. Spam is thus, in effect, often
a type of repudiation attack. Furthermore, spam
now constitutes such a large proportion of the
email that users receive that organizations often
lose large amounts of money each year from lost
productivity (because each user must read and
then delete each spam message).

Despite the growing importance of information
security, system administrators and users often resist
using measures that improve security. User resistance
toward systems with which users must interact is a
well-known phenomenon (Turnage, 1990), as is the
fact that systems with poor user interaction methods
lead to greater user resistance than do other systems
(e.g., Markus, 1983; Al-Ghatani and King, 1999). User
resistance manifests itself in many ways. For example,
requirements for passwords that are so long and/or
complex can lead to users writing down their passwords,
something that may easily lead to computer account
compromises, as explained shortly.

Although usability design in systems is generally less
than optimal, poor usability design abounds in comput-
ing systems and devices designed to improve informa-
tion security, as explained shortly. The weaknesses in
this design may be "the straw that broke the camel's
back," in that measures used to raise security too often
create usability barriers that cause people to neglect or
abandon them, leaving their systems, applications, data,
and network devices vulnerable to all types of attacks.

## 4 TAXONOMY OF INFORMATION SECURITY TASKS

Analyzing the tasks that system administrators and users
must perform in securing systems, applications, and data
is a good starting point for examining usability issues in
information security. Schultz et al.'s (2001) taxonomy of
security tasks provides an analysis of six major security-
related tasks:

1. *Identification and Authentication*. *Identification*
means proving one's identity. *Authentication*,
very similar in meaning to identification, means
proving one's identity for the purpose of access-
ing a system or network. The most common
type of identification and authentication task
is entering a password, although many other
identification and authentication methods (such
as inserting a smart card and then entering a

short PIN) exist. Effective identification and authentication help prevent perpetrators from masquerading as other users.

2. *Protecting Data Integrity*. Although numerous data integrity protection methods exist, the most commonly used method is setting file system permissions to prevent all but very few users from being able to change, replace, or delete files and directories. Software for detecting changes in files and directories (often called *tripwire software*) is also becoming used more frequently. Data integrity protection methods help to prevent unauthorized deletion of and/or changes in data.

3. *Protecting Data Confidentiality*. Setting file permissions appropriately is also the most commonly used method of protecting data confidentiality. Another is encrypting data at rest (i.e., data stored on a system) as well as data in motion (e.g., data sent over a network). Controlling against privilege escalation in systems by drastically limiting the number of "superusers" (privileged users) is another data confidentiality assurance method because superusers can read every file on their system, regardless of what permissions have been set. Data confidentiality methods help prevent unauthorized disclosure and/or possession of information.

4. *Ensuring Data Availability*. Assuring that data and the applications that use them are available is another critical information security task. Tasks that help achieve this goal include making system and data backups as well as using other measures, such as fault-tolerant storage systems.[*] These tasks help in guarding against unauthorized deletion of or denying access to information and the programs that use them.

5. *Ensuring System Integrity*. The methods discussed previously that are used to protect data integrity are used in ensuring system integrity. Additionally, installing patches for vulnerabilities in systems and applications helps prevent unauthorized modification of system files. Inspecting system files for unauthorized changes is still another often-used method. These measures help to prevent unauthorized deletion and/or changes in system files.

6. *Accountability*. Accountability means being able to link user actions on computer systems, networks, and applications to individual users. One of the major methods of achieving accountability is inspecting the output of intrusion detection systems (IDSs). Intrusion detection means identifying attacks that have occurred and their outcomes (in terms of their success or lack thereof). Although intrusion detection

is not really a security countermeasure per se in that it does not help directly in preventing attacks, it is nevertheless a much used measure in that it enables technical experts to quickly identity and thwart attacks that are under way, thereby minimizing their impact. The most basic form of intrusion detection is inspecting system audit logs, a labor-intensive task at best. Intrusion detection is often performed by special software and hardware; even so, user interaction tasks are necessary.

Now that the basic kinds of tasks that must be performed in information security have been introduced, we'll explore the types of usability hurdles in information security and the impact they have.

## 5  FLAWS IN USABILITY DESIGN

As mentioned earlier, the area of information security abounds with examples of poor usability design. We will look at the usability design of password-based authentication, third-party authentication, file access control methods, Web configuration, firewall configuration, encryption of sensitive information, electronic commerce transactions, auditing and logging, and intrusion detection.

### 5.1  Password Selection and Memorability

Previous work by Proctor et al. (2000) demonstrates that entering a user name–password combination to log in to a system or network is not at all difficult from a human factors perspective. The fact that users become highly practiced over time in entering passwords when they see the appropriate prompt helps overcome the few usability hurdles that this task poses. A task analysis of generic password-based log-ins shows that users must engage in only a few relatively simple actions:

1. Visually sight the dialog box and the prompts and input field within (see Figure 1).
2. Use the pointing device to align the cursor/pointer to the correct location.
3. Home both hands at the keyboard.
4. Recall the password.
5. Enter the password by pressing the appropriate keystroke sequence.
6. Click on <OK> or press the <ENTER> key.

Although entry of a log-in name–password sequence is relatively easy for users, there is a more difficult human factors problem of which few users are aware. Hackers and password-cracking tools have become so efficient that passwords that users normally choose can be compromised in a very short time (Skoudis, 2004). Users can choose stronger (more difficult-to-guess) password, but doing so makes them more difficult to remember (Proctor et al., 2002). For example, "password" would be an easy-to-remember password, but it would be trivial to guess or crack. "6f*2Sl&," which has just as many characters as "password," would

---

[*] RAID, the redundant array of independent drives, is the most frequently used fault tolerance solution. RAID distributes data across multiple drives; if any drive fails, the data will thus be available on another.
Figure 1    Log-on screen in Windows 7.

be much more difficult to guess or crack, but few users would be able to remember this password. Many users are not aware of what differentiates good passwords from ones that are easy to guess or crack; even if they know how to create good passwords, they nevertheless often choose weak ones (such as combinations of characters that include their user account names) because of the additional effort needed to create good passwords (Bishop and Klein, 1995). To compensate for the inability to remember more-difficult-to-remember passwords, users could write them down, but doing so would enable anyone who found the slips of paper or whatever else on which the passwords are written to use them to gain unauthorized access to the users' accounts.

Proctor et al. (2002) conducted studies testing the effects of proactive constraints, that is, limiting the types of passwords that users could create, and password length on the ability to crack passwords. As expected, longer passwords were more difficult to crack than were shorter ones. They found that proactive constraints produced different effects for shorter passwords than for longer passwords, however. When passwords were shorter (five characters in length), however, constraints elevated resistance to cracking more than when passwords were longer (eight characters in length). Constraints and password length together required the most effort on the part of users and produced only slightly better resistance to password cracking than did password length alone, suggesting that requiring longer passwords but not imposing additional constraints represents a good trade-off point between usability and security.

Yan et al. (2004) conducted a study designed to test the effectiveness of passphrase passwords versus randomly assigned passwords. Passphrases involve using the first characters of each word within well-known phrases, for example, the passphrase for "now is the time for all good men to come to the aid of their country" would be "nittfagmtcttaotc." Longer and more complex passwords are harder to crack, but they are also harder to remember. Passphrases are an attempt to solve the problem of users being unable to remember longer and more complex phrases. A control group was instructed to create a password of at least seven characters in length, of which one character could not be alphabetic. The number of passwords that were cracked using a combination of password cracking methods was significantly highest for the control group, but no significant difference between the randomly assigned and passphrase groups was found. However, users reported that passphrases were easier to remember than randomly

assigned passwords. User ratings indicated that users found passphrases significantly less difficult to deal with than random passwords but that passphrases and user-selected passwords were not significantly different in rated difficulty. This study provides evidence that security and usability may not necessarily be orthogonal to each other—passphrases represent a good balance between security and usability.

Vu et al. (2007) performed a set of experiments to determine how mnemonic methods could be used to enhance both the memorability and security of passwords. In one study, users were tasked with creating a sentence and combining the first letters of the words into a password. In one condition, participants were instructed to use only the first letters. In a second condition users were told to also include a digit and special character in the sentence to form a password. The additional constraint to include a digit and special character lowered password memorability but substantially decreased susceptibility to cracking. The lc5 password-cracking tool cracked 62% of passwords without a digit and special character but only 2% from the group that had additional constraints. In this and another, similar experiment, password recall was better with a one-week retention interval when recall was also tested after 5 min. However, having to immediately reenter a password after creating it, something that is commonly required, did not appear to improve long-term retention. Additionally, the results bring into question the effectiveness of passphrases. Only when a special character and digit were embedded in passphrases did passphrases produce better recall than in the condition in which participants created passwords without having to use passphrases.

The results of studies on password creation and memorability described so far repeatedly point to the fact that conventional passwords fall far short when the trade-off between password strength and usability/memorability is considered. Aware of the shortfalls of requiring users to create and recall strings of alphanumeric characters and symbols, researchers in recent years have also explored the possibility of users creating and using graphical-based passwords. Chiasson et al. (2007) conducted studies in which participants were required to create graphical "passwords" by sequentially clicking on points within graphical displays. After a delay, participants were then tested for their ability to authenticate by clicking on the same points within these displays that they had originally chosen. These researchers found that users were able to authenticate accurately and reasonably rapidly, although accuracy

and speed were somewhat faster in a laboratory setting as compared to a real-world setting. Additionally, participants who had to authenticate using multiple graphical "passwords" tended to experience interference that lowered their performance. Users also tended to rate graphical "passwords" favorably. These results correspond to those of an earlier study of the usability of graphical passwords by Wiedenbeck et al. (2005), in which participants interacted with systems under more limited conditions than in the Chiasson et al. study. Habibilashkari and Farmand (2009) conducted surveys on usability and security of graphical log-ons, the results of which demonstrate that these log-ons result in acceptable levels of usability *and* security.

These studies show the viability of graphical interaction tasks as an alternative to conventional passwords. Graphical "passwords" are stronger than conventional passwords in terms of resistance to cracking yet are considerably more usable. The long-established fact that recall (as is required for conventional passwords) is generally more difficult than recognition (as required for "graphical" passwords) (cf. Eagle and Leiter, 1964) goes far in explaining why graphical log-ons tend to be easier for users. Additionally, memory for images tends to be superior to memory for verbal materials (Shepard, 1967).

## 5.2  Third-Party Authentication Tasks

Many information security experts believe that passwords are now too dangerous to use and that other forms of authentication must supplant password-based authentication. Third-party authentication is any form of authentication that is not built into operating systems but that is, instead, provided through vendor products or methods. Password-based authentication is built into virtually every commercial off-the-shelf operating system, but smart card–based authentication, one of the most common types of third-party authentication, is not. Smart cards are actually miniature computers with chips that are built into an object such as a plastic card (Corcoran, 2000). To authenticate using smart cards, users must insert a smart card into a smart card reader, which is normally attached to a keyboard. Proctor et al. (2000) performed a task analysis on a typical smart card–based user interaction sequence. They found that to authenticate using smart cards users had to:

1. Visually sight a prompt on the display terminal that directs the user to proceed with the smart card authentication process.
2. Visually sight the smart card.
3. Use several fingers and the thumb to grasp the smart card.
4. Visually sight the smart card reader.
5. Use the hand and arm to move the smart card toward the smart card reader until it is in close proximity.
6. Rotate the hand until the smart card is at the proper angle to be inserted.
7. Insert the smart card until it fits inside the smart card reader.

8. Visually sight the display terminal (or listen for auditory feedback) for confirmation that the smart card was read successfully.
9. Grasp the smart card in several fingers and the thumb, moving the hand and finger away from the smart card reader.
10. Confirm that smart card data have been processed properly and are valid.
11. Use the hand to place the smart card on a surface, such as a table surface.
12. Let go of the smart card with the fingers and thumb.
13. Read a prompt that begins the "normal" log-in name–password entry sequence.
14. Home the hand on the keyboard.
15. Engage in the steps normally required for a password-based log-in but enter the PIN instead.

The task sequence for this generalized smart card–based authentication task sequence involves many steps that are not included in password-based log-ins, showing that the former type of authentication presents additional levels of difficulty for users. Although the exact tasks vary in different smart card implementations, one thing seems clear—users who are accustomed to password-based authentication are likely to resist smart card–based authentication because a greater amount of work and more opportunity for error are inherent in the latter. Given the far greater strength of smart card versus password-based authentication, this is unfortunate. This is just one of the many cases in information security in which security and usability are orthogonal to each other. Other forms of third-party authentication, such as biometric authentication, authentication based on fingerprints, retinal patterns, facial shape, and so on, are available, but do they require less work on the part of users? A task analysis on user interaction with a generic fingerprint-based biometric authentication device showed that this method involved substantially more steps than does password-based authentication but somewhat fewer steps than smart card–based authentication (Proctor et al., 2000). The usability limitations in third-party authentication thus are not limited to task sequences involving smart card–based authentication.

Cranor and Garfinkle (2005) conducted a study in which participants had to secure the contents of email using a smart card and two types of universal serial bus (USB) devices, one a "base token"(a simple kind of memory stick) and the other an "advanced token." The order of tasks was counterbalanced across participants. The researchers found that smart cards required approximately twice as long as the USB base or advanced tokens and that the error rate for smart cards was seven times higher than for any other condition. Participants also rated smart card interaction as the most unfavorable. The authors attributed the results to the fact that more than one hardware component was involved in smart card–based interaction, whereas a single piece of hardware was involved in the USB device–based interaction tasks.

Once again, research points to inadequate usability in user interaction in performing security-related tasks, in this case, third-party authentication. Third-party authentication methods are potentially advantageous in that they require little or no memory on the part of the user. Faulty design of interaction sequences, particularly the number of steps involved in third-party authentication tasks, is a yet-to-be corrected problem.

### 5.3   File Access Control

File access control mechanisms are used to protect information from not only unauthorized disclosure and possession but also unauthorized modification and deletion. Virtually every modern operating system includes a file system that offers permissions such read, write, and execute to control access to files and directories by users and/or groups. Write access is particularly potentially dangerous; it generally allows not only modification of content but also deletion of files and/or directories. Setting file and directory permissions is, however, far from optimal from a usability perspective. One of the problems is that an excessive number of user interaction task steps is often required. Consider, for example, the following interaction steps required for changing the permissions of a file or directory in Windows NT (Schultz et al., 2001). To change the permissions for a single user, the system administrator or owner of a file must:

1. Inspect the desktop visually to find the icon for Windows Explorer or visually sight the Windows and E keys on the keyboard.
2. Bring up Windows Explorer by double clicking on the desktop icon or pressing the Windows and E keys simultaneously.
3. Use a pointing device to scroll through groups of icons for files and directories until sighting the desired one.
4. Right click on the selected icon using the pointing device.
5. Click on Properties using the pointing device.
6. Visually scan the tabs at the top of the new screen that appears to find the Security tab.
7. Click on Security.
8. Of the options that appear, click on Permissions.
9. Click on Add.
10. Scroll through the list of groups and users.
11. Click on the Show Users box.
12. Scroll down to the desired user name.
13. Click on the user name to highlight.
14. Scroll through Type of Access.
15. Highlight the desired type of access (e.g., Full Control, Change, Read) and release the selection button on the pointing device.
16. Click on OK on three different screens.

Worse yet, the standard Windows NT file permissions are only the beginning when it comes to securing files and directories because they are in effect high-level permissions intended mainly for the convenience of system administrators and users. Many *individual* or *advanced permissions* are also available to allow for more granular file and directory access control. In Windows NT there are 7 such permissions: Read, Write, Execute, Delete, Change Permissions, Take Ownership, and Full Control. In Windows 2000 there are 14 such permissions: Traverse Folder/Execute File, List Folder/Read Data, Read Attributes, Read Extended Attributes, Create Files/Write Data, Create Folders/Append Data, Write Attributes, Write Extended Attributes, Delete Subfolders and Files, Delete, Read Permissions, Change Permissions, Take Ownership, and Synchronize. To add or delete any of these additional permissions, additional user interaction steps, almost none of which are intuitive to novice users, must be performed.

Various methods of changing file permissions without having to use a graphical user interface (GUI) also exist. These alternative methods may involve considerably fewer steps on the part of the user but require the entry of commands and flags in a syntax that is extremely unforgiving. For example, in Windows NT, 2000, XP, and Server 2003, someone must enter the following command to change file permissions on a file named Payroll in a folder named Finance for a user (named Brown in this example) from change (modify) to read only:

```
cacls  D:\Finance\Payroll  / E  / R  Brown:C  / G
   brown:R
```

In Linux and Unix systems users must enter the following command to remove Read and Write access from the group that owns the file "foo" in user Brown's home directory as well as from world (other):

```
chmod og-rw /home/Brown/foo
```

Experienced system administrators would have little trouble entering any of these commands to change file permissions, but only because of prolonged practice. Less experienced system administrators and users would experience extreme difficulty entering these commands correctly because of the nonintuitive nature of the command primitives and syntax.

### 5.4   Configuring Web Servers

The universal popularity of the World Wide Web (WWW) makes optimizing usability design in Web servers a necessity. Websites face enormous competition, to the point that user interaction with the majority of them must be satisfactory to users if users are going to be willing to visit (and, in particular, revisit) them. The main usability limitations in the Web arena thus instead involve webmasters' interactions with Web servers. Interaction sequences involved in setting up and administering Web servers tend to be extremely nonintuitive. For example, consider how to deny default access to directories in Apache Web servers (Schultz, 2002a). The webmaster must insert the following directives (commandlike objects) in the server's configuration:

<Directory />
Order Deny,Allow
Deny from all
</Directory>

The webmaster must next make exceptions by specially permitting access to the directories intended for Web access by users. For example, the following directives allow access to the/usr/users/*/public_html and/usr/local/httpd directories:

<Directory /usr/users/*/public_html>
Order Deny,Allow
Allow from all
</Directory>
<Directory /usr/local/httpd>
Order Deny,Allow
Allow from all
</Directory>

Although experienced webmasters can deal readily with Apache directories, novices are not so fortunate. Directives have a difficult syntax, one that once again illustrates the usability problems that plague information security. Ironically, Microsoft's Internet Information Server (IIS) Web server is considerably easier to use because of well-designed control panels that obviate the need for recalling complex syntactic conventions such as Apache directives. At the same time, however, IIS webmasters must often go through four to six levels of menus to get to a particular function even though menu depth produces a longer menu navigation time than does menu breadth (Schultz and Curran, 1986).

## 5.5 Configuring Firewalls

Firewalls are barriers between one network and another that are put in place to insulate one network from attacks from another (Cheswick et al., 2003). Implementing well-designed and well-maintained firewalls is one of the most important security measures that an organization can put in place. Firewalls vary considerably in their functionality; some do little more than block certain kinds of incoming packets bound for certain IP addresses and/or ports, whereas others analyze packets very thoroughly to determine whether or not they constitute desirable input to applications before sending them on via an entirely new connection that they create.

Regardless of the functionality, most commercially available firewalls have one thing in common: poor usability design. Consider, for example, the following access control entries in a Cisco PIX firewall:

#access-list acl_out permit tcp any any eq telnet

#access-list acl_out deny tcp any any

#access-list acl_out deny udp any any

#access-list acl_in permit tcp any host 128.13.23.9
eq ftp

#access-list acl_in permit tcp any host 128.13.23.9
eq
netbios-ssn

Each of these entries controls packet traffic in a unique manner. For example, the topmost entry says in effect that all telnet packets (i.e., packets sent in connection with the telnet service that allows one system to connect to another) are allowed to go outbound from the network in which PIX is placed, regardless of where they originated and where they are being sent. The second and third rules say that all other outbound traffic based on TCP (Transmission Control Protocol) and UDP (User Datagram Protocol) is blocked, again independently of the source or destination. The fourth rule says that all inbound FTP (File Transfer Protocol) packets bound for IP address 128.13.23.9 are allowed. The fifth and final rule says that all inbound NetBIOS packets, packets often used in connection with Windows network sessions, bound for the same system are also allowed.

In this case, one might expect that a very experienced firewall administrator would readily understand each of these rules, although this might not be true for a less experienced firewall administrator. Even if these assumptions are true, however, this might not make as much difference when it comes to making errors in firewall configurations as one might expect. Wool (2004) has conducted studies that have shown that firewall administrators often make errors in firewall rules that leave internal networks exposed to attacks that well-configured firewalls would block. Wool asserts that these errors are due to the fact that firewall interfaces deal with directionality of packets, that is, whether they are inbound or outbound, differently from how firewall administrators think about traffic flow through firewalls. Worse yet, some vendors fail to provide explanations of directionality in documentation provided with firewalls. This incongruity, according to Wool, results in poor usability that leaves firewall administrators confused and error prone when they configure firewalls.

The fact that the order of rules within an access control list (ACL) is extremely important in determining exactly how the rules work is another critical human factors consideration, as is the likelihood that the ACL will be extremely long, sometimes as much as 6000 (or even more) entries. Furthermore, several firewalls, many versions of PIX included, do not allow firewall administrators to edit the ACLs directly. Instead, they must add new rules that affect the existing ACL list. This makes the job of obtaining exactly the right rule set in the correct order even more difficult.

So far the usability analysis of firewalls has been limited to network firewalls, firewalls that filter traffic between one network and another. Another type of firewall is a "personal firewall," one designed to filter out individual systems from potentially malicious traffic that may be sent to them. Herzog and Shahmehri (2007) evaluated the usability and security of 13 different personal firewalls. Once again significant usability limitations were identified. The investigators concluded that providing better user guidance and making the design of the application behind personal firewalls more transparent to users would substantially improve usability.

## 5.6   Encrypting Messages Sent over the Network

Anyone who expects the content of any message sent across a network or any information sent during a network session to be safe from unauthorized reading is badly deluded. Attackers often use hardware or software to capture the content of all packets going over the network, thereby enabling them to glean not only cleartext passwords but also potentially valuable information such as credit card numbers. *Encryption*, which means systematically scrambling the content of a cleartext message using a key and then applying a key to unscramble it (Schneier, 1998), provides a potentially very strong type of protection against unauthorized reading or possession of messages and network session content.

Despite the many advantages of encryption, the use of encryption by everyday users is rare, once again because of associated usability problems. Whitten and Tygar (1999) showed how deficient the usability design of a well-known encryption program, PGP (Pretty Good Privacy), is. PGP can be used to encrypt the content of messages and files sent across the network. The fact that free versions of this software exist and that PGP can run on a variety of operating systems makes it a good candidate for widespread use. To use this tool to send an encrypted message to another user, users of Windows systems must double click on an icon (a gray PGP padlock) on the desktop and choose a menu selection called Encrypt to encrypt the contents of a message (or possibly the contents of the clipboard). Once the user decides which to encrypt, the screen shown in Figure 2 appears.

If the user wants to encrypt a message sent to someone such as someone in Figure 2, the user must first scroll to that user's name and then confirm that the person has the same type of encryption,such as Diffie-Hellman/Digital Signature Standard (DH/DSS) public key encryption, that the originator of the message has. Very few users understand enough about encryption to make this decision. The user must next double click on the other user's name, making the name and key information appear in a window below the list of names.

If the user clicks only once, the error dialog box shown in Figure 3 appears.

The error message provides no meaningful feedback to users. Once the user double clicks on the name of another user, an additional set of nonintuitive choices appears related to whether the user wants a secure viewer and/or conventional encryption. If the user checks both of the radio buttons representing these choices, another error message that provides no meaningful feedback appears. If the user manages to click on the correct radio buttons, the message content looks like the one shown in Figure 4. The user can (finally) send the message. The fact that even experienced PGP users often have trouble using PGP and that adding, deleting, and generating keys needed for encryption and decryption involve additional long and conceptually different interaction sequences attests further to the usability problems inherent in the use of PGP.

Not all encryption is as difficult to use as is PGP. Users of Windows 2000 and XP systems can, for example, encrypt the contents of any file of which they are the owner by performing the following interaction steps:

1.   Bring up Windows Explorer.
2.   Sight the icon for the to-be-encrypted file.
3.   Right click on the icon to Properties.
4.   Click on Advanced.
5.   Click on Encrypt Contents to Secure Data.
6.   Click on Apply.
7.   Click on Encrypt the File Only.
8.   Click on OK twice.

**Figure 3**   PGP error dialog box.

**Figure 4**   PGP-encrypted message.

At this point all might seem well as far as the user goes, but there is a serious problem of which most users are unlikely to be aware. Although the file will be encrypted transparently whenever the user closes it and it will also be decrypted transparently whenever the user opens it, if something happens to the user's key—if it should be deleted or corrupted—the contents of the file will be unrecoverable because they cannot be decrypted. As a precaution, the user (or the system administrator acting on behalf of the user) needs to engage in additional tasks related to making an "escrow" key for file recovery purposes. Doing so is not a trivial task from a human–computer interaction standpoint, another case in point for the conclusion that information security and usability requirements are often opposed to each other.

### 5.7   Electronic Commerce Transactions

Electronic commerce transactions require secrecy, integrity, and nonrepudibility more than anything else. Many ways of achieving secrecy exist, but secrecy alone is not enough in many such transactions. Several corporations created a special protocol, the Secure Electronic Transaction (SET) protocol, to address all three needs at once by encrypting all traffic generated in connection with transactions, using strong user authentication, confirming credit card numbers, and approving each transaction. SET does not merely encrypt network traffic, however; it also keeps personal information obtained from merchants as well as the specific types of purchases made from financial institutions that process the transactions.

Despite the inherent goodness of SET from an information security perspective, SET's usability design weaknesses have made it an extremely unpopular protocol with those who use it. As Schultz (2011) has pointed out, to start a SET transaction, each customer must request and then fill in entries in an electronic wallet or digital certificate, a kind of electronic credit card that contains information about a customer and

that customer's credentials. The issuing institution (normally, a bank or credit card company) provides copies of certificates issued to third-party merchants. These certificates contain the public keys[*] of both the merchant and the issuing institution. The customer initiates a transaction, causing the customer's Web browser to receive and validate the merchant's certificate. The browser uses the merchant's public key to encrypt a message related to the transaction and the issuing institution's public key to encrypt the payment information. This information, as well as information that uniquely links payment to this particular transaction, is sent to the issuing institution and the merchant. The merchant confirms the identity of the customer by verifying the customer's digital signature[*] contained within the customer's certificate. Next, the merchant transmits the order message to the issuing institution. The order message contains the issuing institution's public key, customer payment information, and merchant's certificate. The issuing institution confirms the identity of the merchant and verifies the message itself. The issuing institution verifies the payment portion of the message and then digitally signs and sends authorization back to the merchant, who can then supply the goods or services specified in the customer's order.

If you are confused at this point, you can readily understand how those who use SET often feel. Many of the major steps in a SET transaction can be broken down into multiple individual user interaction tasks. Many of the steps involving the merchant and issuing institution are automated, however, so it is the customer

---

[*] A public key is one half of a public–private key pair in which encryption of data is performed using one key and decryption is performed using the other. This type of encryption is often called "public key encryption." A digital signature is a public key–based cryptographic method used to uniquely identify each person using public key encryption as well as other cryptographic methods. Digital signatures help protect against repudiation.

who is faced with the majority of the human–computer interaction tasks, many of which are not very intuitive. SET shows once again that information security and usability design are very often orthogonal to each other.

SSL (secure sockets layer) encryption is the most frequently used kind of encryption in electronic commerce (as well as in Web-based transactions in general). Using SSL should not in theory be difficult, because the number of user interaction steps involved is small. Analysis and research show otherwise, however. For example, Mannan and van Oorschot (2007) observed computer-savvy users perform electronic banking-related tasks, many of which involved the use of SSL. The researchers found that many users did not understand the purpose of SSL and the certificates that it requires for mutual authentication between the Web browser and Web server. They also found that users often did not notice the padlock icon that appears in the lower right corner in most browsers whenever SSL encryption is in place, most likely because this icon is typically very small and thus easy to overlook. Hol (2008) also points out that when this icon is displayed, it provides no information about the identity of the Web server to which the browser is connected. Furthermore, perpetrators may create fake Web pages with fake padlocks completely unbeknownst to users. Finally, the warning that is displayed to users when an unknown or untrusted SSL certificate is being evaluated (see Figure 5 below) or another potentially unsafe condition could occur is difficult for users to understand. Consequently, they are likely to simply click on "Allow" rather than halting their electronic commerce transaction to determine what

might be wrong at that point. And, according to Hol, even if they take the time to examine the content of a certificate, they are unlikely to understand what it means.

Worse yet, users typically do not know what "dangerous" and "safe" Web content is, what a malicious cookie is, or what aspects of a particular Extensible Markup Language (XML) or Active X object are "unsecure" or "secure" (Schultz, 2011). They thus might go so far as to turn off all Web-related warnings. If they do not do so, they are at least likely to have an implicit trust for events that happen in connection with Web servers and thus keep clicking "Yes," "Allow," and similar options when warnings are displayed.

## 5.8 Auditing and Logging

Auditing and logging in operating systems enable system administrators to examine what users and applications have done, something that can lead to corrective action such as disabling accounts of malicious users as well as modifying information security policy. Accessing audit logs is not generally very difficult in most operating systems. In Unix and Linux, for example, the root user (the superuser) needs only to enter the who and last commands to discover who is currently logged in and the log-in and log-out times of each user, respectively. A major exception is in Novell NetWare. To view Netware audit reports for volume auditing, the system administrator must enter AUDITCON and then select the Change current server to choose the appropriate service. From the AUDITCON main menu, the system administrator must select Change current volume to designate the volume of interest and then

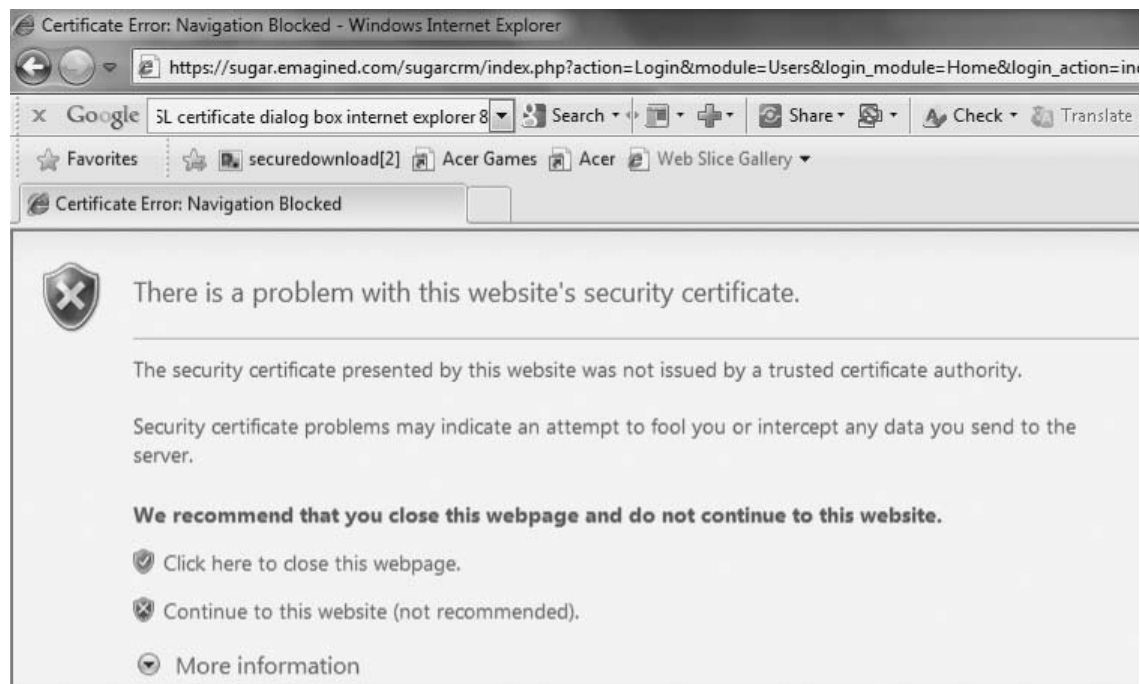

**Figure 5**  An Internet Explorer warning.

select Auditor volume log-in from the AUDITCON main menu. The Enter volume password input box will appear. The system administrator must enter the auditing password for the chosen volume and then press <ENTER> and then select "Auditing reports," a selection within the Available audit options menu that will be displayed. The difficulty of performing these tasks is self-explanatory.

The generally more difficult part from a human–computer interaction standpoint is configuring logging. Unix and Linux system logging (syslog) is controlled by configuring a file, /etc/syslog.conf. There are eight priorities of logging: emerg (highest), alert, crit, err, warning, notice, info, debug (lowest). There are also seven types of logable messages, each concerning a different part of or function within the system: kernel, user, mail, daemon, auth, lpr, and local. The syslog messages can be sent to one or more of the following: the system console, a central log server, and/or to a file within the system in which syslog has been enabled.

The entries in an /etc/syslog.conf file in a Unix system are as follows:

```
*.crit;kern.debug;auth.info      /dev/console
*.alert;user.notice              root
auth.debug                       /var/adm/authlog
mail.notice                      /var/adm/maillog
```

The first line specifies that any type of event that has a priority of critical or higher[*] will be sent to the terminal (console) on which the event occurred. Any kernel-related event with a priority of debug or higher as well as any authentication-related event with a priority of information or higher will also be sent to the terminal. The second line entries cause any event with a priority of alert or higher to be sent to the root (superuser) account in the system in which this event has occurred; additionally, any user-related event with a priority of notice or higher will also be sent to root. The third line specifies that any authentication-related event will be sent to a local file, /var/adm/authlog. The fourth line causes all mail-related events with a priority of notice or higher to be sent to the mail log, /var/adm/maillog. Regardless of any specific entry, there is nothing in the format of the /etc/syslog.conf file that makes configuring system logging straightforward.

The built-in graphical user interface in Windows 2000, XP, Vista, Windows 7, and Windows Server 2003 and 2008 makes configuring security logging (auditing) in these systems somewhat more intuitive. Nevertheless, the number of user interaction steps involved is still excessive. On a Windows XP Professional workstation, for example, one must:

1. Go from Start to Control Panel.
2. Double click on Administrative Tools.
3. Double click on Local Security Policy.

4. Enumerate the Security Settings container.
5. Enumerate the Local Policies container.
6. Click on Audit Policy.
7. For each setting or change desired, double click on the name of the audit category (Audit account log-on events, Audit policy changes, Audit privilege use, and so on).
8. Click on Success and/or Failure.
9. Click on Apply.
10. Click on OK.
11. Repeat steps 7–10 for each additional audit category.

Figure 6 shows the Audit Policy configuration screen. Even though configuring Security Logging in Windows systems is more intuitive than in Unix and Linux, the number of interaction steps, especially when multiple audit categories must be selected, is fairly large.

## 5.9 Intrusion Detection Monitoring

Intrusion detection means identifying security breaches that occur. Intrusion detection has become an important component of most organizations' information security program. Intrusion detection enables technical staff to identify and respond readily to incidents, thereby minimizing the amount of financial and other types of loss (Endorf et al., 2004).

IDSs automate the process of detecting intrusions, thereby increasing proficiency and reducing the number of personnel needed.

Although most IDSs are not all that difficult to configure, reading the output of these systems can be quite a challenge. Consider, for example, the following output from Snort, the most widely used IDS today (Caswell and Foster, 2003):

```
[**] SCAN-SYN FIN [**]
11/02-16:01:36.792199 109.10.0.1:21 ->
    16.16.90.1:21
TCP TTL:24 TOS: 0x0 ID:39426
**SF**** Seq: 0x27896E4 Ack: 0xB35C4BD Win:
    0x404
```

Even a proficient technical person would have difficulty understanding what this output means without careful study of Snort documentation. Following is another example of Snort output:

```
[**] [1:1959:1] RPC portmap request NFS UDP [**]
[Classification: Decode of an RPC Query] [Pri-
    ority: 2]
08/14-04:12:43.991442 109.10.0.1:46637 ->
16.16.90.1:111
UDP  TTL:250  TOS:0x0  ID:38580  IpLen:20
    DgmLen:84 DF
Len: 56
```

Snort is only one of many IDSs. Bro (see ftp://ftp.ee.lbl.gov/.vp-bro-pub-0.7a90.tar.gz), another IDS,

---

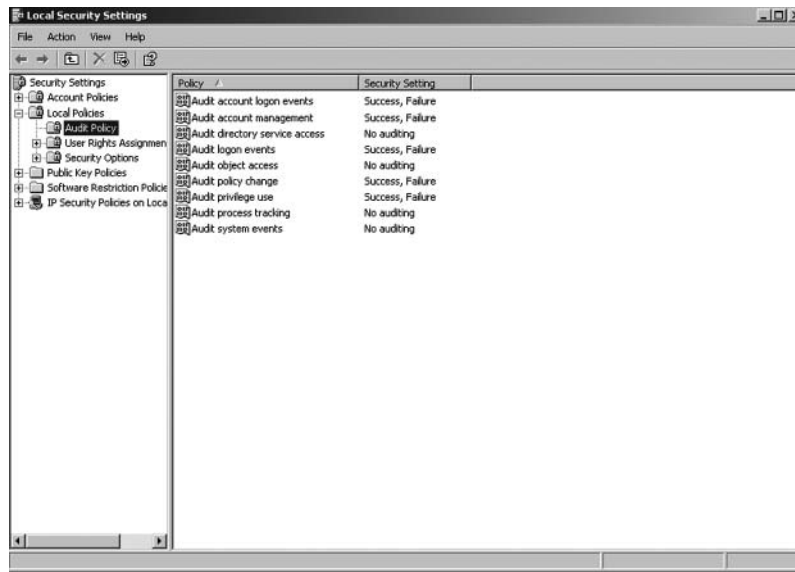
[*] This is not necessarily true, however. In some flavors of Unix, choosing a priority of debug results in only debug-related events being logged.


**Figure 6** Audit Policy screen in Windows XP.

also illustrates the problem of poor usability design in information security with output such as the following:

The output of Bro almost seems to be designed to be confusing to everyone but people who thoroughly understand how the system works. Bro's user interface is not at all atypical of today's IDSs.

Werlinger et al. (2008) conducted interviews with technical staff who used IDSs and also observed them as they actually used IDSs. The authors asserted that the sheer complexity of IDSs makes them difficult for even technically proficient users to use. Some of the areas Werlinger et al. singled out as in need of improvement from a usability perspective were:

- Installation—too complex
- Initial configuration—too complex and nonintuitive
- Lack of automated discovery of computers and devices on networks, something that necessitates considerable work on IDS analysts' part
- Reporting—not sufficiently flexible in providing information IDS analysts need
- Error messages—too terse and uninformative
- Lack of tools for adjusting alarm thresholds

As mentioned earlier, intrusion detection is in and of itself a difficult task, even for technically accomplished individuals. The usability problems in this area thus provide disproportionally difficult hurdles for IDS users.

## 6  IMPLICATIONS

Failure to pay sufficient attention to effective usability design in the information security arena has caused a plethora of dire consequences, the most apparent of which is failure to implement measures needed to defend systems and networks against attack. If too much effort, confusion, error, and/or frustration results from attempting to engage in security-related tasks, users will simply refrain from engaging in these tasks or will perform them inadequately. Consequently, stronger forms of authentication than password-based authentication will not be implemented, firewalls will not be inadequately configured, file system permissions will allow too much access by too many users, sensitive data and passwords will traverse networks in cleartext, operating system patches will never get installed, auditing will not be enabled or will be configured inadequately, intrusion detection data will be ignored, and so on.

Why does the world of information security repeatedly turn its proverbial back on the principles of effective human–computer interaction? The "Sherman M51 Tank" analogy may help in understanding what may be happening. Over a half century ago the Sherman M51 tank represented a major advance in warfare from the standpoint of the firepower it delivered, but poor human factors design greatly hampered tank crews' ability to operate it. The weaponry-related advantages apparently outweighed the human factors–related disadvantages, as judged by the many M51 tanks that were built and deployed. In information security the same kinds of trade-offs apply. When one considers the advantages of third-party authentication, such as smart card–based authentication compared to normal password-based authentication, information security professionals will readily endorse third-party authentication. At the same time, however, users and system administrators (and, in particular, managers) may not understand just how advantageous smart card–based authentication is compared to the usability disadvantages, leading them to favor conventional (password-based) authentication.

Additional negative consequences of failing to consider usability design also need to be considered. Vendors of products designed to improve security are in general not exactly reaping record profits. Vendors could considerably boost their sales by redesigning the user interfaces to their products.

Perhaps most important in the information security arena, however, is the potential relevance of the usability problems documented in this chapter to the insider threat. Security breaches instigated by insiders—employees, contractors, and consultants—account for far more financial and other forms of loss than any other source (Schultz, 2002b). User resistance to interaction tasks with poor usability design is well documented. This resistance

surfaces in a variety of ways, including passive behavior, verbal behavior, hesitance to continue in interacting with computers, loss of attention to tasks, and many others (Martinko et al., 1996). A study by the Information Security Forum (http://www.securityforum.org) in 2000 shows that inadequate security behavior of staff members rather than poor security measures per se account for as much as 80% of all security-related loss. Furthermore, even when staff members realize that security controls have been put in place with sound justification, they quickly reject controls that are ineffective, inefficient, and ambiguous (Leach, 2003). Poor usability design thus appears to be closely linked to insider attacks, internal misuse, and insider error that result in massive losses. Although the link between usability design and insider-related loss is currently indirect, empirical studies on these issues will in time provide more definitive results.

## 7  SOLUTIONS

Applying well-accepted principles of usability design in the information security arena is the most obvious solution to the problems presented in this chapter. Table 1 lists the problems presented in this chapter and possible usability solutions for each. A good high-level approach to an effective solution is to assume that most people who have security needs are not very aware of exactly what these needs are and what must be done to meet them. First and foremost, operating systems and applications need to have more secure settings right out of the box. Vendors typically use default settings that cause the least disruption to users rather than providing settings that raise security to at least an acceptable minimum. The unfortunate result is higher susceptibility to attacks. Allowing options in user interfaces that set security to a desired level without requiring that users know all the individual settings and what they mean is an excellent solution. A good example of how this can be done is the security options for Microsoft Internet Explorer (IE), a widely used Web browser, as shown in Figure 7.

A slide bar allows users to choose privacy levels varying from high to medium to low, thereby precluding the need to navigate to and choose settings from an excessive number of screens. In Figure 7 the user has chosen a level of security that is slightly below medium. The result is that third-party cookies (objects used to keep information about users in Web transactions) from websites that do not have a defined privacy policy will be blocked. The IE user interface in this example also is conducive to explorability—users can choose privacy levels without being locked in to a particular choice. Users may not fully understand the choices they explore and/or choose, but they will be better off than the way things are with the current user interfaces in the information security arena.

Table 1 summarizes the areas investigated in this chapter, usability problems associated with each area, and possible solutions. Information security has come a long way over the years. Unfortunately, the same cannot be said for usability design in systems used in protecting

**Table 1  Usability Problems in Information Security and Possible Solutions**

| Task | Usability Problems | Possible Solutions |
| --- | --- | --- |
| Password entry | Stronger passwords require more effort to create, are more difficult to remember. | Use an alternative form of authentication (e.g., graphical log-in) that does not require users to create and remember difficult-to-remember authentication credentials. |
| Third-party authentication | Task involves excessive number of user interaction steps. | Design more efficient interaction sequences. |
| Setting file access controls | The number and difficulty of user interaction steps are often overwhelming to users. | Design more efficient and simpler interaction sequences. |
| Configuring Web server security parameters | Syntax for changing parameters is often nonintuitive; interaction with menus may involve an excessive number of levels. | Syntax should be made more intuitive; menus should have greater breadth, not depth. |
| Configuring firewall security parameters | Syntax for changing parameters is often nonintuitive. | Syntax should be made more intuitive. |
| Encryption | User interaction may involve nonintuitive steps; may involve an excessive number of steps. | Design more efficient and simpler user interaction steps. |
| Electronic commerce transactions | User interaction may involve nonintuitive steps; number of steps may be excessive; error and warning messages may be confusing. | Design more efficient and simpler user interaction steps; error messages should be made clearer and more informative. |
| Configuring auditing and logging | Syntax for setting auditing and logging parameters is often nonintuitive; number of steps may be excessive. | Syntax should be made more intuitive; design more efficient user interaction steps. |
| Intrusion detection | Output may be cryptic and poorly formatted, installation and configuration of IDSs is complex, defining systems and devices user intensive, reporting is inflexible, error messages are terse. | Output should be easier to interpret and should be formatted in a manner that facilitates recognition of important data; fewer installation steps, more intuitive configuration settings, autodiscovery of network entities, flexible reporting, more detailed and understandable error messages. |

**Figure 7**   Dialog box for setting privacy level in Windows Internet Explorer.

systems and detecting when systems become attacked. The good news is that more research on usability and security is being conducted and published every year. How to improve usability while at the same time having sufficient levels of security is becoming increasingly clear. But both usability and security need to be integrated *early* in the systems development life cycle if both are to be optimal. Having to retrofit either generally results in expenditure of more resources as well as less efficient mechanisms and functions. The time to start integrating both usability and security into systems is during the *requirements* phase, not later.

# CHAPTER 46

# USABILITY TESTING

**James R. Lewis**
**Software Group**
**International Business Machines Corporation**
**Boca Raton, Florida**

## 1 INTRODUCTION

Usability testing is an essential skill for usability practitioners—professionals whose primary goal is to provide guidance to product developers for the purpose of improving the ease of use of their products. It is by no means the *only* skill with which usability practitioners must have proficiency (Uldall-Espersen et al., 2008), but it is an important one. Surveys of experienced usability practitioners consistently reveal the importance of usability testing (Mao et al., 2005; Vredenburg et al., 2002).

One goal of this chapter is to provide an introduction to the practice of usability testing. This includes some discussion of the concept of usability and the history of usability testing, various goals of usability testing, and running usability tests. A second goal is to cover important statistical topics for usability testing, such as sample size estimation for usability tests, computation of confidence intervals, and the use of standardized usability questionnaires.

## 2 THE BASICS

### 2.1 What Is Usability?

The term *usability* came into general use in the early 1980s. Related terms from that time were *user friendliness* and *ease of use*, which *usability* (sometimes spelled *useability*) has since displaced in professional and technical writing on the topic (Bevan et al., 1991). Well before the 1980s, a refrigerator advertisement from March 8, 1936 cited usability as a feature (S. Isensee,

personal communication, January 17, 2010, see http://tinyurl.com/yjn3caa). The earliest scientific publication (of which I am aware) to include the word *usability* in its title was Bennett (1979).

It is the nature of language that words come into use with fluid definitions. Ten years after the first scientific use of the term *usability*, Shackel (1990, p. 31) wrote, "one of the most important issues is that there is, as yet, no generally agreed definition of usability and its measurement." Eight years later, Gray and Salzman (1998, p. 242) stated: "Attempts to derive a clear and crisp definition of usability can be aptly compared to attempts to nail a blob of Jell-O to the wall." Twenty years after Shackel, according to Alonso-Ríos et al. (2010, p. 53), "A major obstacle to the implantation of User-Centered Design in the real world is the fact that no precise definition of the concept of usability exists that is widely accepted and applied in practice."

There are several reasons why it has been so difficult to define usability. Usability is not a property of a person or thing. There is no thermometer-like instrument that can provide an absolute measurement of the usability of a product (Dumas, 2003; Hertzum, 2010; Hornbæk, 2006). Usability is an emergent property that depends on the interactions among users, products, tasks, and environments.

Introducing a theme that will reappear in several parts of this chapter, there are two major conceptions of usability. These dual conceptions have contributed to the difficulty of achieving a single agreed-upon definition. One conception is that the primary focus of usability should be on measurements related to the

accomplishment of global task goals (summative, or measurement-based, evaluation). The other conception is that practitioners should focus on the detection and elimination of usability problems (formative, or diagnostic, evaluation).

The first (summative) conception has led to a variety of similar definitions of usability, some embodied in current standards (which, to date, have emphasized summative evaluation). For example (Bevan et al., 1991, p. 652):

> The current MUSiC definition of usability is: the ease of use and acceptability of a system or product for a particular class of users carrying out specific tasks in a specific environment; where "ease of use" affects user performance and satisfaction, and "acceptability" affects whether or not the product is used.

Usability is the "extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use" [International Organization for Standardization (ISO), 1998, p. 2; American National Standards Institute (ANSI), 2001, p. 3]. As defined in ISO 9126-1, usability is one of several software characteristics that contribute to quality in use (in addition to functionality, reliability, efficiency, maintainability, and portability), and Bevan (2009) has recommended including flexibility and safety along with traditional summative conceptions of usability in a more complete quality-of-use model. The quality in use integrated measurement (QUIM) scheme of Seffah et al. (2006) includes 10 factors, 26 subfactors, and 127 specific metrics. Winter et al. (2008) proposed a two-dimensional model of usability that associates a large number of system properties with user activities. Alonso-Rios et al. (2010) published a preliminary taxonomy for the concept of usability that includes traditional and nontraditional elements, organized under the primary factors of Knowability, Operability, Efficiency, Robustness, Safety, and Subjective Satisfaction.

These attempts to provide a more comprehensive definition of usability have yet to undergo statistical testing to confirm their defined structures. An initial meta-analysis of correlations among prototypical summative prototypical usability metrics (effectiveness, efficiency, and satisfaction) that used published scientific studies from the human–computer interaction (HCI) literature found generally weak correlations among the different metrics (Hornbæk and Law, 2007). A replication using data from a large set of industrial usability studies, however, found strong correlations among prototypical usability metrics measured at the task level, with principal-components and factor analyses that provided statistical evidence for the underlying construct of usability with clear underlying objective (effectiveness, efficiency) and subjective (task-level satisfaction, test-level satisfaction) factors (Sauro and Lewis, 2009).

One of the earliest formative definitions of usability (ease of use) is from Chapanis (1981, p. 3):

> Although it is not easy to measure "ease of use," it is easy to measure difficulties that people have in using something. Difficulties and errors can be identified, classified, counted, and measured. So my premise is that ease of use is inversely proportional to the number and severity of difficulties people have in using software. There are, of course, other measures that have been used to assess ease of use, but I think the weight of the evidence will support the conclusion that these other dependent measures are correlated with the number and severity of difficulties.

Practitioners in industrial settings generally use both conceptualizations of usability during iterative design. Any iterative method must include a stopping rule to prevent infinite iterations. In the real world, resource constraints and deadlines can dictate the stopping rule (although this rule is valid only if there is a reasonable expectation that undiscovered problems will not lead to drastic consequences). In an ideal setting, the first conception of usability can act as a stopping rule for the second. Setting aside, for now, the question of where quantitative goals come from, the goals associated with the first conception of usability can define when to stop the iterative process of the discovery and resolution of usability problems. This combination is not a new concept. In one of the earliest published descriptions of iterative design, Al-Awar et al. (1981, p. 31) wrote: "Our methodology is strictly empirical. You write a program, test it on the target population, find out what's wrong with it, and revise it. The cycle of test–rewrite is repeated over and over until a satisfactory level of performance is reached. Revisions are based on the performance, that is, the difficulties typical users have in going through the program."

## 2.2 What Is Usability Testing?

Imagine the two following scenarios.

***Scenario 1*** Mr. Smith is sitting next to Mr. Jones, watching him work with a high-fidelity prototype of a Web browser for personal digital assistants (PDAs). Mr. Jones is the third person that Mr. Smith has watched performing these tasks with this version of the prototype. Mr. Smith is not constantly reminding Mr. Jones to talk while he works but is counting on his proximity to Mr. Jones to encourage verbal expressions when Mr. Jones encounters any difficulty in accomplishing his current task. Mr. Smith takes written notes whenever this happens and also takes notes whenever he observes Mr. Jones faltering in his use of the application (e.g., exploring menus in search of a desired function). Later that day he will use his notes to develop problem reports and, in consultation with the development team, will work on recommendations for product changes that should eliminate or reduce the impact of the reported problems. When a new version of the prototype is ready, he will resume testing.

***Scenario 2*** Dr. White is watching Mr. Adams work with a new version of a word-processing application. Mr. Adams is working alone in a test cell that looks almost exactly like an office, except for the large mirror

on one wall and the two video cameras overhead. He has access to a telephone and a number to call if he encounters a difficulty that he cannot overcome. If he places such a call, Dr. White will answer and provide help modeled on the types of help provided at the company's call centers. Dr. White can see Mr. Adams through the one-way glass as she coordinates the test. She has one assistant working the video cameras for maximum effectiveness and another who is taking time-stamped notes on a computer (coordinated with the video time stamps) as different members of the team notice and describe different aspects of Mr. Adams's task performance. Software monitors Mr. Adams's computer, recording all keystrokes and mouse movements. Later that day, Dr. White and her associates will put together a summary of the task performance measurements for the tested version of the application, noting where the performance measurements do not meet the test criteria. They will also create a prioritized list of problems and recommendations, along with video clips that illustrate key problems, for presentation to the development team at their weekly status meeting.

Both of these scenarios provide examples of usability testing. In scenario 1 the emphasis is completely on usability problem discovery and resolution (formative, or diagnostic, evaluation). In scenario 2 the primary emphasis is on task performance measurement (summative, or measurement-focused, evaluation), but there is also an effort to record and present usability problems to the product developers. Dr. White's team knows that they cannot determine if they've met the usability performance goals by examining a list of problems, but they also know that they cannot provide appropriate guidance to product development if they present only a list of global task measurements. The problems observed in the use of an application provide important clues for redesigning the product (Chapanis, 1981; Norman, 1983). Furthermore, as J. Karat (1997, p. 693) observed: "The identification of usability problems in a prototype user interface (UI) is not the end goal of any evaluation. The end goal is a redesigned system that meets the usability objectives set for the system such that users are able to achieve their goals and are satisfied with the product."

These scenarios also illustrate the defining properties of a usability test. During a usability test, one or more observers watch one or more participants perform specified tasks with the product in a specified test environment (compare this with the ISO/ANSI definition of usability presented earlier in this chapter). This is what makes usability testing different from other user-centered design (UCD) methods or marketing research (Dumas and Salzman, 2006). In interviews (including the group interview known as a focus group), participants do not perform worklike tasks. Usability inspection methods (such as expert evaluations and heuristic evaluations) also do not include the observation of users or potential users performing worklike tasks. The same is true of techniques such as surveys and card sorting. Field studies (including contextual inquiry) can involve the observation of users performing work-related tasks in target environments but restrict the control that

practitioners have over the target tasks and environments. Note that this is not necessarily a bad thing, but it is a defining difference between usability testing and field (ethnographic) studies.

This definition of usability testing permits a wide range of variation in technique (Wildman, 1995). Usability tests can be very informal (as in scenario 1) or very formal (as in scenario 2). The observer might sit next to the participant, watch through a one-way glass, or watch the on-screen behavior of a participant who is performing specified tasks at a location halfway around the world. Usability tests can be think-aloud (TA) tests, in which observers train participants to talk about what they're doing at each step of task completion and prompt participants to continue talking if they stop. Observers might watch one participant at a time or might watch participants work in pairs. Practitioners can apply usability testing to the evaluation of low-fidelity prototypes (MacKenzie and Read, 2007), high-fidelity prototypes, mixed-fidelity prototypes (McCurdy et al., 2006), Wizard of Oz (WOZ) prototypes (Dow et al., 2005; Kelley, 1985), products under development, predecessor products, or competitive products.

## 2.2.1 Where Did Usability Testing Come From?

The roots of usability testing lie firmly in the experimental methods of psychology (in particular, cognitive and applied psychology) and human factors engineering (Dumas and Salzman, 2006) with strong ties to the concept of iterative design. In a traditional experiment, the experimenter draws up a careful plan of study that includes the exact number of participants that the experimenter will expose to the different experimental treatments. The participants are members of the population to which the experimenter wants to generalize the results. The experimenter provides instructions and debriefs the participant, but at no time during a traditional experimental session does the experimenter interact with the participant (unless this interaction is part of the experimental treatment). The more formative (diagnostic, focused on problem discovery) the focus of a usability test, the less it is like a traditional experiment (although the requirements for sampling from a legitimate population of users, tasks, and environments still apply). Conversely, the more summative (focused on measurement) a usability test is, the more it should resemble the mechanics of a traditional experiment. Many of the principles of psychological experimentation that exist to protect experimenters from threats to reliability and validity (e.g., the control of demand characteristics, the Hawthorne effect) carry over into usability testing (Holleran, 1991; Macefield, 2007; Wenger and Spyridakis, 1989).

As far as I can tell, the earliest accounts of iterative usability testing applied to product design came from Alphonse Chapanis and his students (Al-Awar et al., 1981; Chapanis, 1981; Kelley, 1984) and had an almost immediate influence on product development practices at IBM (Kennedy, 1982; Lewis, 1982) and other companies, notably Xerox (Smith et al., 1982) and Apple (Williams, 1983). Shortly thereafter, John Gould and his associates at the IBM T. J. Watson Research Center

began publishing influential papers on usability testing and iterative design (Gould and Boies, 1983; Gould and Lewis, 1984; Gould et al., 1987; Gould, 1988), as did Whiteside et al. (1988) at DEC (Baecker, 2008; Dumas, 2007).

The driving force that separated iterative usability testing from the standard protocols of experimental psychology was the need to modify early product designs as rapidly as possible (as opposed to the scientific goal of developing and testing competing theoretical hypotheses). As Al-Awar et al. (1981, p. 33) reported: "Although this procedure [iterative usability test, redesign, and retest] may seem unsystematic and unstructured, our experience has been that there is a surprising amount of consistency in what subjects report. Difficulties are not random or whimsical. They do form patterns."

When difficulties of use become apparent during the early stages of iterative design, it is hard to justify continuing to ask test participants to perform the test tasks. There are ethical concerns with intentionally frustrating participants who are using a product with known flaws that the design team can and will correct. There are economic concerns with the time wasted by watching participants who are encountering and recovering from known error-producing situations. Furthermore, any delay in updating the product delays the potential discovery of problems associated with the update or problems whose discovery was blocked by the presence of the known flaws. For these reasons, the earlier you are in the design cycle, the more rapidly you should iterate the cycles of test and design.

### 2.2.2   Is Usability Testing Effective?

The widespread use of usability testing is evidence that practitioners believe that usability testing is effective. Unfortunately, there are fields in which practitioners' belief in the effectiveness of their methods does not appear to be warranted by those outside the field (e.g., the use of projective techniques such as the Rorschach test in psychotherapy) (Lilienfeld et al., 2000). In our own field, papers published since 1998 have questioned the reliability of usability problem discovery (Kessner et al., 2001; Molich et al., 1998, 2004; Molich and Dumas, 2008).

The common finding in these studies has been that observers (either individually or in teams across usability laboratories) who evaluated the same product produced markedly different sets of discovered problems. Molich et al. (1998) had four independent usability laboratories carry out inexpensive usability tests of a software application for new users. The four teams reported 141 different problems, with only one problem common among all four teams. Molich et al. (1998) attributed this inconsistency to variability in the approaches taken by the teams (task scenarios, level of problem reporting). Kessner et al. (2001) had six professional usability teams independently test an early prototype of a dialog box. None of the problems were detected by every team, and 18 problems were described by one team only. Molich et al. (2004) assessed the consistency of usability testing across nine independent organizations that evaluated the

same website. They documented considerable variability in methodologies, resources applied, and problems reported. The total number of reported problems was 310, with only 2 problems reported by six or more organizations, and 232 problems (61%) uniquely reported. The fourth comparative usability evaluation (CUE-4; Molich and Dumas, 2008) had a similar method and similar outcomes. "Our main conclusion is that our simple assumption that we are all doing the same and getting the same results in a usability test is plainly wrong" (Molich et al., 2004, p. 65).

This is important and disturbing research, but there is a clear need for more research in this area. A particularly important goal of future research should be to reconcile these studies with the documented reality of usability improvement achieved through iterative application of usability testing. For example, a limitation of research that stops with the comparison of problem lists is that it is not possible to assess the magnitude of the usability improvement (if any) that would result from product redesigns based on design recommendations derived from the problem lists (Hornbæk, 2010; Wixon, 2003). When comparing problem lists from many labs, one aberrant set of results can have an extreme effect on measurements of consistency across labs, and the more labs that are involved, the more likely this is to happen.

In the case of CUE-4 (Molich and Dumas, 2008), 17 professional usability teams evaluated the same website, with 9 teams conducting usability tests (5–15 participants per test) and 8 teams using expert review (1–2 reviewers per team). With one exception, the usability test teams used different sets of tasks for their evaluations. Across the 17 teams, there were 76 usability test participants and 10 expert reviewers, for a total of 86 individual experiences with the website. Using the binomial probability formula (see Section 3.1.2), it is possible to estimate the percentage of problems discovered with this sample size for problems of different likelihoods of discovery. For individual problems that would affect 10% of participants, the likelihood of having the problem turn up at least once in this study is about 99.99%, making their discovery virtually certain. For problems with a 1% probability of occurrence, the likelihood of discovery (at least once) with a sample size of 86 is about 58%, better than even odds. Even problems with probabilities of occurrence as low as 0.1% had about an 8% likelihood of discovery. It is not possible to know how many specific problems were available for discovery as a function of their probabilities of occurrence, but it seems reasonable that a mature website would have eliminated most high-probability problems, leaving a mass of less probable (hard-to-discover) problems, leading to little overlap in problem discovery across the teams. As Molich and Dumas (2008, p. 270) concluded, "The limited overlap could be interpreted as a sign that some of the teams . . . had conducted a poor evaluation. Our interpretation, however, is that the usability problem space is so huge that it inevitably leads to some instances of limited overlap." Furthermore, difficulties in matching problem descriptions can lead to an appearance of greater underlap than

occurs when observers have an opportunity to discuss problem matching (Hornbæk, 2010; Hornbæk and Frøkjær, 2008a, 2008b).

The interpretation of the results of these studies (Kessner et al., 2001; Molich et al., 1998, 2004; Molich and Dumas, 2008) as indicative of a lack of reliability (e.g., Law et al., 2005) stands in stark contrast to the published studies in which iterative usability tests (sometimes in combination with other UCD methods) have led to significantly improved products (Al-Awar et al., 1981; Kennedy, 1982; Lewis, 1982, 1996b; Kelley, 1984; Gould et al., 1987; Bailey et al., 1992; Bailey, 1993; Ruthford and Ramey, 2000). For example, in a paper describing their experiences in product development, Marshall et al. (1990, p. 243) stated: "Human factors work can be reliable—different human factors engineers, using different human factors techniques at different stages of a product's development, identified many of the same potential usability defects." Published cost–benefit analyses (Bias and Mayhew, 1994) have demonstrated the value of usability engineering processes that include usability testing, with cost–benefit ratios ranging from 1 : 2 for smaller projects to 1 : 100 for larger projects (C. Karat, 1997).

Most of the papers that describe the success of iterative usability testing are case studies (such as Høegh and Jensen, 2008; Marshall et al., 1990—for adaptation of usability testing to an Agile framework see Sy, 2007; Illmensee and Muff, 2009), but a few have described designed experiments. Bailey et al. (1992) compared two user interfaces derived from the same base interface: one modified via heuristic evaluation and the other modified via iterative usability testing (three iterations, five participants per iteration). They conducted this experiment with two interfaces, one character based and the other a graphical user interface (GUI), with the same basic outcomes. The number of changes indicated by usability testing was much smaller than the number indicated by heuristic evaluation, but user performance was the same with both final versions of the interface. All designs after the first iteration produced faster performance and, for the character-based interface, were preferred to the original design. The time to complete the performance testing was about the same as that required for the completion of multireviewer heuristic evaluations.

Bailey (1993) provided additional experimental evidence that iterative design based on usability tests leads to measurable improvements in the usability of an application. In the experiment, he studied the designs of eight designers, four with at least four years of professional experience in interface design and four with at least five years of professional experience in computer programming. All designers used a prototyping tool to create a recipes application (eight applications in all). In the first wave of testing, Bailey videotaped participants performing tasks with the prototypes, three different participants per prototype. Each designer reviewed the videotapes of the people using his or her prototype and used the observations to redesign his or her application. This process continued until each designer indicated that it was not possible to improve his or her application. All designers

stopped after three to five iterations. Comparison of the first and last iterations indicated significant improvement in measurements such as number of tasks completed, task completion times, and repeated serious errors.

In conclusion, the results of the studies of Molich et al. (1998, 2004; Molich and Dumas, 2008) and similar studies show that usability practitioners must conduct their usability tests as carefully as possible, document their methods completely, and show proper caution when interpreting their results. The limitations of usability testing make it insufficient for certain testing goals, such as quality assurance of safety-critical systems (Thimbleby, 2007). It can be difficult to assess complex systems with complex goals and tasks (Howard, 2008; Howard and Howard, 2009; Redish, 2007). On the other hand, as Landauer stated (1997, p. 204): "There is ample evidence that expanded task analysis and formative evaluation can, and almost always do, bring substantial improvements in the effectiveness and desirability of systems." This is echoed by Desurvire et al. (1992, p. 98): "It is generally agreed that usability testing in both field and laboratory is far and above the best method for acquiring data on usability."

## 2.3 Goals of Usability Testing

The fundamental goal of usability testing is to help developers produce more usable products. The two conceptions of usability testing (formative and summative) lead to differences in the specification of goals in much the same way that they contribute to differences in fundamental definitions of usability (diagnostic problem discovery and measurement). Rubin (1994, p. 26) expressed the formative goal as follows: "The overall goal of usability testing is to identify and rectify usability deficiencies existing in computer-based and electronic equipment and their accompanying support materials prior to release." Dumas and Redish (1999, p. 11) provided a more summative goal: "A key component of usability engineering is setting specific, quantitative, usability goals for the product early in the process and then designing to meet those goals."

These goals are not in direct conflict, but they do suggest different focuses that can lead to differences in practice. For example, a focus on measurement typically leads to more formal testing (less interaction between observers and participants), whereas a focus on problem discovery typically leads to less formal testing (more interaction between observers and participants). In addition to the distinction between diagnostic problem discovery and measurement tests, there are two common types of measurement tests: comparison against objectives and comparison of products.

### 2.3.1 Problem Discovery Test

The primary activity in diagnostic problem discovery tests is the discovery, prioritization, and resolution of usability problems. The number of participants in each iteration of testing should be fairly small, but the overall test plan should be for multiple iterations, each with some variation in participants and tasks. When the focus is on problem discovery and resolution, the assumption is that more global measures of user performance

and satisfaction will take care of themselves (Chapanis, 1981). The measurements associated with problem discovery tests are focused on prioritizing problems and include frequency of occurrence in the test, likelihood of occurrence during normal usage (taking into account the anticipated usage of the part of the product in which the problem occurred), and magnitude of impact on the participants who experienced the problem. Because the focus is not on precise measurement of the performance or attitudes of participants, problem discovery studies tend to be informal, with a considerable amount of interaction between observers and participants. Some typical stopping rules for iterations are a preplanned number of iterations or a specific problem discovery goal, such as "Identify 90% of the problems available for discovery for these types of participants, this set of tasks, and these conditions of use." As Lindgaard (2006, p. 1069) pointed out, "It is impossible to know whether all usability problems have been identified in a particular test or type of evaluation unless testing is repeated until it reaches an asymptote, a point at which no new problems emerge in a test. Asymptotic testing is not, and should not be, done in practice; it is as unfeasible as it is irrelevant in a work context." See the section below on sample size estimation and adequacy for more detailed information on setting and using these types of problem discovery objectives.

### 2.3.2 Measurement Test Type I: Comparison against Quantitative Objectives

Studies that have a primary focus of comparison against quantitative objectives include two fundamental activities (Jokela et al., 2006). The first is the development of the usability objectives. The second is iterative testing to determine if the product has met the objectives. A third activity (which can take place during iterative testing) is the enumeration and description of usability problems, but this activity is secondary to the collection of precise measurements.

The first step in developing quantitative usability objectives is to determine the appropriate variables to measure. As part of the work done for the European MUSiC (Measuring the Usability of Systems in Context) project, Rengger (1991) produced a list of potential usability measurements based on 87 papers out of a survey of 500 papers. He excluded purely diagnostic studies and also excluded papers if they did not provide measurements for the combined performance of a user and a system. He categorized the measurements into four classes:

- *Class* 1: goal achievement indicators (such as success rate and accuracy)
- *Class* 2: work rate indicators (such as speed and efficiency)
- *Class* 3: operability indicators (such as error rate and function usage)
- *Class* 4: knowledge acquisition indicators (such as learnability and learning rate)

In a later discussion of the MUSiC measures, Macleod et al. (1997) described measures of effectiveness (the level of correctness and completeness of goal achievement in context) and efficiency (effectiveness related to cost of performance, typically the effectiveness measure divided by task completion time). Optional measures were of productive time and unproductive time, with unproductive time consisting of help actions, search actions, and snag (negation, canceled, or rejected) actions.

Macleod et al.'s (1997) description of the measures of effectiveness and efficiency seem to have influenced the objectives expressed in ISO 9241-11 (ISO, 1998, p. iv): "The objective of designing and evaluating visual display terminals for usability is to enable users to achieve goals and meet needs in a particular context of use. ISO 9241-11 explains the benefits of measuring usability in terms of user performance and satisfaction. These are measured by the extent to which the intended goals of use are achieved, the resources that have to be expended to achieve the intended goals, and the extent to which the user finds the use of the product acceptable."

In practice [and as recommended by ANSI (2001)], the fundamental global measurements for usability tasks are successful task completion rates (for a measure of effectiveness), mean task completion times [for a measure of efficiency—either the arithmetic mean or, as recently suggested by Sauro and Lewis (2010), the geometric mean], and mean participant satisfaction ratings (collected either on a task-by-task basis or at the end of a test session; see Section 3.3 for more information on measuring participant satisfaction). There are many other measurements that practitioners could consider (Nielsen, 1997; Dumas and Redish, 1999), including but not limited to (1) the number of tasks completed within a specified time limit, (2) the number of wrong menu choices, (3) the number of user errors, and (4) the number of repeated errors (same user committing the same error more than once).

After determining the appropriate measurements, the next step is to set the goals. Ideally, the goals should have an objective basis and shared acceptance across the various stakeholders, such as marketing, development, and test groups (Lewis, 1982). The best objective basis for measurement goals is data from previous usability studies of predecessor or competitive products. For maximum generalizability, the historical data should come from studies of similar types of participants completing the same tasks under the same conditions (Chapanis, 1988). If this information is not available, an alternative is for the test designer to recommend objective goals and to negotiate with the other stakeholders to arrive at a set of shared goals.

According to Rosenbaum (1989, p. 211): "Defining usability objectives (and standards) isn't easy, especially when you're beginning a usability program. However, you're not restricted to the first objective you set. The important thing is to establish some specific objectives immediately, so that you can measure improvement. If the objectives turn out to be unrealistic or inappropriate, you can revise them." Such revisions, however, should take place only in the early stages of gaining experience and taking initial measurements with a product. It is important not to change reasonable goals to accommodate an unusable product.

When setting usability goals, it is usually better to set goals that make reference to an average (mean) of a measurement than to a percentile. For example, set an objective such as "The mean time to complete task 1 will be less than 5 minutes" rather than "95% of participants will complete task 1 in less than 10 minutes." The statistical reason for this is that sample means drawn from a continuous distribution are less variable than sample medians (the 50th percentile of a sample), and measurements made away from the center of a distribution (e.g., measurements made to attempt to characterize the value of the 95th percentile) are even more variable (Blalock, 1972). Cordes (1993) conducted a Monte Carlo study comparing means and medians as measurements of central tendency for time-on-task scores and determined that the mean should be the preferred metric for usability studies (unless there is missing data due to participants failing to complete tasks, in which case the mean from the study will underestimate the population mean).

A practical reason to avoid percentile goals is that the goal can imply a sample size requirement that is unnecessarily large. For example, you cannot measure accurately at the 95th percentile unless there are at least 20 measurements (in fact, there must be many more than 20 measurements for accurate measurement). For more details, see Section 3.1.

An exception to this is the specification of successful task completions (or any other measurement that is based on counting events), which necessarily requires a percentile goal, usually set at or near 100% (unless there are historical data that indicate an acceptable lower level for a specific test). If 10 out of 10 participants complete a task successfully, the observed completion rate is 100%, but a 90% exact binomial confidence interval for this result ranges from 74 to 100%. In other words, even perfect performance for 10 participants with this type of measure leaves open the possibility (with 90% confidence) that the true completion rate could be as low as 75%. See Section 3.2.2 for more information on computing and using this information in usability tests.

After the usability goals have been established, the next step is to collect data to determine if the product has met its goals. Representative participants perform the target tasks in the specified environment as test observers record the target measurements and identify, to the extent possible within the constraints of a more formal testing protocol, details about any usability problems that occur. The usability team conducting the test provides information about goal achievement and prioritized problems to the development team, and a decision is made regarding whether or not there is sufficient evidence that the product has met its objectives. The ideal stopping rule for measurement-based iterations is to continue testing until the product has met its goals.

When there are only a few goals, it is reasonable to expect to achieve all of them. When there are many goals (e.g., 5 objectives per task multiplied by 10 tasks, for a total of 50 objectives), it is more difficult to determine when to declare success and to stop testing. Thus, it is sometimes necessary to specify a metaobjective of the percentage of goals to achieve.

Despite the reluctance of some usability practitioners to conduct statistical tests to quantitatively assess the strength of the available evidence regarding whether or not a product has achieved a particular goal, the best practice is to conduct such tests. The best approach is to conduct multiple $t$-tests or nonparametric analogs of $t$-tests (Lewis, 1993) because this gives practitioners the level of detail that they require. There is a well-known prohibition against doing this because it can lead investigators to mistakenly accept as real some differences that are due to chance [technically, alpha ($\alpha$) inflation]. On the other hand, if this is the required level of information, it is an appropriate method (Abelson, 1995). Furthermore, the practice of avoiding alpha inflation is a concern more related to scientific hypothesis testing than to usability testing (Wickens, 1998), although usability practitioners should be aware of its existence and take it into account when interpreting their statistical results. For example, if you compare two products by conducting 50 $t$-tests with alpha set to 0.10, and only 5 (10%) of the $t$-tests are significant (have a $p$-value below 0.10), you should question whether or not to use those results as evidence of the superiority of one product over the other. On the other hand, if substantially more than 5 of the $t$-tests are significant, you can be more confident that the differences indicated are real.

In addition to (or as an alternative to) conducting multiple $t$-tests, practitioners should compute confidence intervals for their measurements. This applies to the measurements made for the purpose of establishing test criteria (such as measurements made on predecessor versions of the target product or competitive products) and to the measurements made when testing the product under development. See Section 3.2 for more details.

### 2.3.3 Measurement Test Type II: Comparison of Products

The second type of measurement test is to conduct usability tests for the purpose of direct comparison of one product with another. As long as there is only one measurement that decision makers plan to consider, a standard $t$-test (ideally, in combination with the computation of confidence intervals) will suffice for the purpose of determining which product is superior.

If decision makers care about multiple dependent measures, standard multivariate statistical procedures [such as multivariate analysis of variance (MANOVA) or discriminant analysis] are not often helpful in guiding a decision about which of two products has superior usability. The statistical reason for this is that multivariate statistical procedures depend on the computation of centroids (a weighted average of multiple dependent measures) using a least-squares linear model that maximizes the difference between the centroids of the two products (Cliff, 1987). If the directions of the measurements are inconsistent (e.g., a high task completion rate is desirable, but a high mean task completion time is not), the resulting centroids are uninterpretable for the purpose of usability comparison. In some cases it is possible to recompute variables so they have consistent directions (e.g., recomputing task completion rates as task failure rates). If this is not possible,

another approach is to convert measurements to ranks (Lewis, 1991a) or standardized (*Z*) scores (Sauro and Kindlund, 2005) for the purpose of principled combination of different types of measurements.

To help consumers compare the usability of different products, ANSI (2001) has published the Common Industry Format (CIF) for usability test reports. Originally developed at the National Institute of Standards and Technology (NIST), this test format requires measurement of effectiveness (accuracy and completeness —completion rates, errors, assists), efficiency (resources expended in relation to accuracy and completeness—task completion time), and satisfaction (freedom from discomfort, positive attitude toward use of the product—using any of a number of standardized satisfaction questionnaires). It also requires a complete description of participants and tasks.

Morse (2000) reviewed a NIST project conducted to pilot test the CIF. The purpose of the CIF is to make it easier for purchasers to compare the usability of different products. The pilot study ran into problems, such as inability to find a suitable software product for both supplier and consumer, reluctance to share information, and uncertainty about how to design a good usability study. To date, there has been little if any use (at least, no published use) of the CIF for its intended purpose.

## 2.4 Variations on a Theme: Other Types of Usability Tests

### 2.4.1 Think Aloud

In a standard, formal usability test, test participants perform tasks without necessarily speaking as they work. The defining characteristic of a TA study is the instruction to participants to talk about what they are doing as they do it (in other words, to produce verbal reports). If participants stop talking (as commonly happens when they become very engaged in a task), they are prompted to resume talking.

The most common theoretical justification for the use of TA is from the work in cognitive psychology (specifically, human problem solving) of Ericsson and Simon (1980). Responding to a review by Nisbett and Wilson (1977) that described various ways in which verbal reports were unreliable, Ericsson and Simon provided evidence that certain kinds of verbal reports could produce reliable data. They stated that reliable verbalizations are those that participants produce during task performance that do not require additional cognitive processing beyond the processing required for task performance and verbalization.

TA is not feasible when testing systems that include speech recognition (Lewis, 2008, 2011). For usability testing of other systems, the use of TA is fairly common. Dumas (2003) encouraged the use of TA because (1) TA tests are more productive for finding usability problems (van den Haak and de Jong, 2003; Virzi et al., 1993) and (2) thinking aloud does not affect user ratings or performance (Bowers and Snyder, 1990; Ohnemus and Biers, 1993; Olmsted-Hawala et al., 2010). There is some evidence in support of these statements, but the evidence is mixed.

Earlier prohibitions against the use of TA in measurement-based tests assumed that thinking aloud would cause slower task performance. Bowers and Snyder (1990), however, found no measurable task performance or preference differences between a test group that thought aloud and one that did not. Surprisingly, there are some experiments in which the investigators reported better task performance when participants were thinking aloud. Berry and Broadbent (1990) provided evidence that the process of thinking aloud invoked cognitive processes that improved rather than degraded performance, but only if people were given (1) verbal instructions on how to perform the task and (2) the requirement to justify each action aloud. Wright and Converse (1992) compared silent with TA usability testing protocols. The results indicated that the TA group committed fewer errors and completed tasks faster than the silent group, and the difference between the groups increased as a function of task difficulty.

Regarding the theoretical justification for and typical practice of TA, Boren and Ramey (2000) noted that TA practice in usability testing often does not conform to the theoretical basis most often cited for it (Ericsson and Simon, 1980). "If practitioners do not uniformly apply the same techniques in conducting thinking-aloud protocols, it becomes difficult to compare results between studies" (Boren and Ramey, 2000, p. 261). In a review of publications of TA tests and field observations of practitioners running TA tests, they reported inconsistency in explanations to participants about how to TA, practice periods, styles of reminding participants to TA, prompting intervals, and styles of intervention. They suggest that, rather than basing current practice on Ericsson and Simon, a better basis would be speech communication theory, with clearly defined communicative roles for the participant (in the role of domain expert or valued customer, making the participant the primary speaker) and the usability practitioner (the learner or listener, thus a secondary speaker).

Based on this alternative perspective for the justification of TA, Boren and Ramey (2000) provided guidance for many situations that are not relevant in a cognitive psychology experiment but are in usability tests. For example, they recommend that usability practitioners running a TA test should continually use acknowledgment tokens that do not take speakership away from the participant, such as "mm hm?" and "uh-huh?" (with the interrogative intonation) to encourage the participant to keep talking. In normal communication, silence (as recommended by the Ericsson and Simon protocols) is not a nonresponse—the speaker interprets it in a primarily negative way as indicating aloofness or condescension. They avoided providing precise statements about how frequently to provide acknowledgments or somewhat more explicit reminders (such as "And now . . . ?") because the best cues come from the participants. Practitioners need to be sensitive to these cues as they run the test.

Krahmer and Ummelen (2004) conducted an exploratory comparison of the Ericsson and Simon (E&S) versus the Boren and Ramey (B&R) TA procedures (10 participants per condition). They found that the

outcomes were similar for both procedures, with participants in both conditions saying about the same number of words, uncovering essentially the same navigation problems, and providing about equal evaluations of the quality of the website they used. The main difference was that moderators in the B&R condition made, as expected, more interventions and, perhaps as a consequence, the participants seemed less lost and completed more tasks.

Hertzum et al. (2009) compared silent task completion with strict E&S and more relaxed TA, supplemented with eye tracking and assessment of mental workload. Strict E&S TA, other than requiring more time for task completion, led to similar results as the silent condition. Relaxed TA affected participant behavior in multiple ways. Relative to silence, the TA method did not affect successful task completion rates, which tended to be high in the study. In the relaxed TA condition, participants spent more time in general distributed visual behavior, issued more navigation commands, and experienced higher mental workload.

Olmsted-Hawala et al. (2010) used a double-blind procedure to investigate the effect of different TA procedures on successful task completion, task completion times, and satisfaction. Their experimental conditions were the traditional E&S, speech-communication-based B&R, a less restrictive coaching protocol in which moderators could freely probe participants, and silence (no TA at all), with 20 participants per condition. The outcomes were similar for silence, E&S, and B&R procedures. Participants in the coaching condition successfully completed significantly more tasks and had higher satisfaction ratings. Their results for B&R differed from those reported by Krahmer and Umullen (2004): "since the test administrator in the Krahmer & Umullen study offered assistance and encouragement to the test subject during the session, we think their speech-communication protocol is more akin to the coaching condition in our study" (Olmsted-Hawala et al., 2010, p. 2387).The evidence indicates that relative to silent participation, TA can affect task performance and reported satisfaction, depending on the exact TA protocol in use. If the primary purpose of the test is problem discovery, TA appears to have advantages over completely silent task completion. If the primary purpose of the test is task performance measurement, the use of TA is somewhat more complicated. As long as all the tasks in the planned comparisons were completed under the same conditions, performance comparisons should be legitimate. It is critical, however, that practitioners using TA provide a complete description of their method, including the kind and frequency of probing.

The use of TA almost certainly prevents generalization of task performance outside the TA task, but there are many other factors that make it difficult to generalize specific task performance data collected in usability studies. For example, Cordes (2001) demonstrated that participants assume that the tasks they are asked to perform in usability tests are possible (the "I know it can be done or you wouldn't have asked me to do it" bias). Manipulations that bring this assumption into doubt can have a strong effect on quantitative usability

performance measures, such as increasing the percentage of participants who give up on a task. If uncontrolled, this bias makes performance measures from usability studies unlikely to be representative of real-world performance when users are uncertain as to whether the product they are using can support the desired tasks.

The discussion above focuses on concurrent TA, with participants talking aloud as they perform tasks. An alternative approach is to use stimulated retrospective TA, in which participants perform tasks silently, and then talk as they review the video of their task performance—an approach that avoids any influence of TA on task performance but requires twice as much time to complete data collection in a usability study. Bowers and Snyder (1990) reported similar task performance and subjective measures for concurrent and retrospective TA, but participants provided different types of information as a function of TA style, with participants in the concurrent condition tending to provide procedural information, and participants in the retrospective condition tending to give explanations and design statements. Similar findings were reported by van den Haak and de Jong (2003), along with fewer successful task completions for TA relative to silent work. Using eye tracking as a way to assess a participant's focus of attention, Guan et al. (2006) found the retrospective method to be valid and reliable, with a low risk of introducing fabrication, and with no significant effect of task complexity. Karahasanovic et al. (2009), comparing concurrent and retrospective TA with a feedback collection method (FCM) in which participants respond to probes during task performance, found that all methods were intrusive with regard to completion rates and times, but the FCM was less time consuming to analyze.

Clemmensen et al. (2009) discussed the impact of cultural differences on TA. There are several ways in which cultural differences could affect testing, such as the instructions and tasks, the participant's verbalization, how the observer "reads" the participant, and the overall relationship between participant and observer. In particular, with regard to studies that have Western observers and Eastern participants, they recommended that observers should allow sufficient time for participants to pause while thinking aloud, rely less on expressions of surprise, and be sensitive to the tendency for indirect criticism.

### 2.4.2 Multiple Simultaneous Participants

Downey (2007) described group usability testing in which multiple observers watch a number of participants individually but simultaneously perform tasks. A key benefit of the method was obtaining data from more people over a shorter period of time. She reported that the method appeared to be most effective when tasks were relatively simple and a focused discussion followed the group's completion of the tasks.

Another way to encourage participants to talk during task completion is to have them work together (Wildman, 1995), a method sometimes called constructive interaction (Nielsen, 1993). This strategy is similar to TA in its strengths and limitations, but with potentially

greater ecological validity, including less participant awareness of the observer (van den Haak and de Jong, 2005; van den Haak et al., 2006).

Hackman and Biers (1992) compared three TA methods: thinking aloud alone (Single), thinking aloud in the presence of an observer (Observer), and verbalizations occurring in a two-person team (Team). They found no significant differences in performance or subjective measures. The Team condition produced more statements of value to designers than the other two conditions, but this was probably due to the differing number of participants producing statements in the different conditions. There were three groups, with 10 participants per group for Single and Observer and 20 participants (10 two-person teams) for the Team condition. "The major result was that the team gave significantly more verbalizations of high value to designers and spent more time making high value comments. Although this can be reduced to the fact that the team spoke more overall and that there are two people talking rather than one, this finding is not trivial" (Hackman and Biers, 1992, p. 1208).

### 2.4.3  Remote Evaluation

Recent advances in the technology of collaborative software have made it easier to conduct remote software tests—tests in which the usability practitioner and the test participant are in different locations (Albert et al., 2010; Ramli and Jaafar, 2009). This can be an economical alternative to bringing one or more users into a laboratory for face-to-face user testing. A participant in a remote location can view the contents of the practitioner's screen, and in a typical system the practitioner can decide whether the participant can control the desktop. System performance is typically slower than that of a local test session.

Some of the advantages of remote testing are (1) access to participants who would otherwise be unable to participate (international, special needs, etc.), (2) the capability for participants to work in familiar surroundings, and (3) no need for either party to install or download additional software. Some of the disadvantages are (1) potential uncontrolled disruptions in the participant's workplace, (2) lack of visual feedback from the participant, and (3) the possibility of compromised security if the participant takes screen captures of confidential material. Despite these disadvantages, McFadden et al. (2002) reported data that indicated that remote testing was effective at improving product designs and that the test results were comparable to the results obtained with more traditional testing.

As described above, synchronous remote usability testing has similar time constraints as laboratory-based tests (Dumas and Salzman, 2006). More fully automated asynchronous usability testing has become available which permits more rapid testing, typically with the participant receiving information about the task and responding to questions in one window while working with the product in a different window (West and Lehman, 2006). A clear disadvantage of this type of unmoderated testing is the lack of interaction between observers and participants, but Tullis et al. (2002) reported no substantial differences between unmoderated

and laboratory testing for quantitative measurements or problem discovery. West and Lehman (2006) also reported consistency between task success and satisfaction metrics between standard and automated summative usability testing but noted that having a usability engineer observe the sessions led to the discovery of a more comprehensive set of issues. In a study focused on problem discovery, Andreasen et al. (2007) reported similar outcomes between laboratory-based and synchronous remote usability testing but found fewer problems discovered with asynchronous testing. In contrast, Bosenick et al. (2007) reported the discovery of more usability issues with remote asynchronous testing. Hopefully, further research will reveal the reasons for these discrepant outcomes when comparing asynchronous usability testing to more standard laboratory-based testing.

### 2.5  Usability Laboratories

A typical usability laboratory test suite is a set of sound-proofed rooms with a participant area and observer area separated by a one-way glass and with video cameras and microphones to capture the user experience (Marshall et al., 1990; Nielsen, 1997), possibly with an executive viewing area behind the primary observers' area. The advantages of this type of usability facility are quick setup, a place where designers can see people interacting with their products, videos to provide a historical record and backup for observers, and a professional appearance that raises awareness of usability and reassures customers about commitment to usability. In a survey of usability laboratories, Nielsen (1994) reported a median floor space of 63 m$^2$ (678 ft$^2$) for the observer room and 13 m$^2$ (144 ft$^2$) for test rooms. This type of laboratory is especially important if practitioners plan to conduct formal, summative usability tests.

If the practitioner focus is on formative, diagnostic problem discovery, this type of laboratory is not essential (although it is still convenient). "It is possible to convert a regular office temporarily into a usability laboratory, and it is possible to perform usability testing with no more equipment than a notepad" (Nielsen, 1997, p. 1561). Making an even stronger statement against the perceived requirement for formal laboratories, Landauer (1997, p. 204) stated: "Many usability practitioners have demanded greater resources and more elaborate procedures than are strictly needed for effective guidance—such as expensive usability labs rather than natural settings for test and observations, time consuming videotaping and analysis where observation and note-taking would serve as well, and large groups of participants to achieve statistical significance when qualitative naturalistic observation of task goals and situations, or of disastrous interface or functionality flaws, would be more to the point."

In addition to remote usability testing (discussed above), another alternative to a formal, fixed-location usability laboratory is a mobile laboratory (Seffah and Habieb-Mammar, 2009). Advantages of mobile usability laboratories include portability to a participant's workplace and reduced cost relative to fixed laboratories. Because the mobile usability laboratory moves to the participant, disadvantages include the need to reduce the

size of the usability testing team and complications in allowing nonteam observers to view the test.

## 2.6 Test Roles

There are several ways to categorize the roles that testers need to play in the preparation and execution of a usability test (Rubin, 1994; Dumas and Redish, 1999). Most test teams will not have a person assigned to each role, and most tests (especially informal problem discovery tests) do not require every role. The actual distribution of skills across a team might vary from these roles, but the standard roles help to organize the skills needed for effective usability testing.

### 2.6.1 Test Administrator

The test administrator is the usability test team leader. He or she designs the usability study, including the specification of the initial conditions for a test session and the codes to use for data logging. The test administrator's duties include conducting reviews with the rest of the test team, leading in the analysis of data, and putting together the final presentation or report. People in this role should have a solid understanding of the basics of usability engineering, ability to tolerate ambiguity, flexibility (knowing when to deviate from the plan), and good communication skills.

### 2.6.2 Briefer

The briefer is the person who interacts with the participants (briefing them at the start of the test, communicating with them as required during the test, and debriefing them at the end of the test sessions). On many teams, the same person takes the roles of administrator and briefer. In a TA study, the briefer has the responsibility to keep the participant talking. The briefer needs to have sufficient familiarity with the product to be able to decide what to tell participants when they ask questions. People in this role need to be comfortable interacting with people and need to be able to restrict their interactions to those that are consistent with the purposes of the test without any negative treatment of the participants.

### 2.6.3 Camera Operator

The camera operator is responsible for running the audiovisual equipment during the test. He or she must be skilled in the setup and operation of the equipment and must be able to take directions quickly when it is necessary to change the focus of the camera (e.g., from the keyboard to the user manual).

### 2.6.4 Data Recorder

The video record is useful as a data backup when things start happening quickly during the test and as a source for video examples when documenting usability problems. The primary data source for a usability study, however, is the notes that the data recorder takes during a test session. There just is not time to take notes from a more leisurely examination of the video record. Also, the camera does not necessarily catch the important action at every moment of a usability study.

For informal studies, the equipment used to record data might be nothing more than a notepad and pencil. Alternatively, the data recorder might use data-logging software to take coded notes (often time stamped, possibly synchronized with the video). Before the test begins, the data recorder needs to prepare the data-logging software with the category codes defined by the test administrator. Taking notes with data-logging software is a very demanding skill, so the test administrator does not usually assign additional tasks to the person taking this role.

### 2.6.5 Help Desk Operator

The help desk operator takes calls from the participant if the user experiences enough difficulty to place the call. The operator should have some familiarity with the call-center procedures followed by the company that has designed the product under test and must also have skills similar to those of the briefer.

### 2.6.6 Product Expert

The product expert maintains the product and offers technical guidance during the test. The product expert must have sufficient knowledge of the product to recover quickly from product failures and to help the other team members understand the system's actions during the test.

### 2.6.7 Statistician

A statistician has expertise in measurement and the statistical analysis of data. Practitioners with an educational background in experimental psychology typically have sufficient expertise to take the role of statistician for a usability test team. Informal tests rarely require the services of a statistician, but the team needs a statistician to extract the maximum amount of information from the data gathered during a formal test (especially if the purpose of the formal test was to compare two products using a battery of measurements).

## 2.7 Planning the Test

One of the first activities that a test administrator must undertake is to develop a test plan. To do this, the administrator must understand the purpose of the product, the parts of the product that are ready for test, the types of people who will use the product, what they are likely to use the product for, and in what settings.

### 2.7.1 Purpose of the Test

At the highest level, is the primary purpose of the test to identify usability problems or to gather usability measurements? The answer to this question provides guidance as to whether the most appropriate test is formal or informal, TA or silent, problem discovery or quantitative measurement. After addressing this question, the next task is to define any more specific test objectives. For example, an objective for an interactive voice response (IVR) system might be to assess whether participants can accomplish key tasks without encountering significant problems. If data are available from a previous study of a similar IVR, an alternative objective might be to determine whether participants can complete

key tasks reliably faster with the new IVR than they did with the previous IVR. Most usability tests will include several objectives.

If a key objective of the test is to compare two products, an important decision is whether the test will be within subjects or between subjects. In a within-subjects test, every participant works with both products, with half of the participants using one product first and the other half using the other product first (a technique known as *counterbalancing*). In a between-subjects study, the test groups are completely independent. In general, a within-subjects test leads to more precise measurement of product differences (requiring a smaller number of participants for equal precision, due primarily to the reduction in variability that occurs when each participant acts as his or her own control) and the opportunity to get direct subjective product comparisons from participants. Tohidi et al. (2006) reported that participants exposed to alternative design solutions (within subjects) were more likely to provide informative criticism of the designs than participants who worked with only one of the designs (between subjects). For a within-subjects test to be feasible, both products must be available and set up for use in the lab at the same time, and the amount of time needed to complete tasks with both products must not be excessive. If a within-subjects test is not possible, a between-subjects test is a perfectly valid alternative. Note that the statistical analyses appropriate for these two types of tests are different.

### 2.7.2 Participants

To determine who will participate in the test, the administrator needs to obtain or develop a user profile. A user profile is sometimes available from the marketing group, the product's functional specification, or other product planning documentation. It is important to keep in mind that the focus of a usability test is the end user of a product, not the expected product purchaser (unless the product will be purchased by end users). The most important participant characteristic is that the participant is representative of the population of end users to whom the administrator wants to generalize the results of the test. Practitioners can obtain participants from employment agencies, internal sources if the participants meet the requirements of the user profile (but avoiding internal test groups), market research firms, existing customers, colleges, newspaper ads, and user groups.

To define representativeness, it is important to specify the characteristics that members of the target population share but are not characteristic of nonmembers. The administrator must do this for the target population at large and any defined subgroups. Within group definition constraints, administrators should seek heterogeneity in the final sample to maximize the generalizability of the results (Chapanis, 1988; Landauer, 1997) and to maximize the likelihood of problem discovery. It is true that performance measurements made with a homogeneous sample will almost always have greater precision than measurements made with a heterogeneous sample, but the cost of that increased precision is limited generalizability. This raises the issue of how to define homogeneity and heterogeneity of participants. After all,

at the highest level of categorization, we are all humans, with similar general capabilities and limitations (physical and cognitive). At the other end of the spectrum, we are all individuals—no two alike.

One of the most important defining characteristics for a group in a usability test is specific relevant experience, both with the product and in the domain of interest (work experience, general product experience, specific product experience, experience with the product under test, and experience with similar products). One common categorization scheme is to consider people with less than three months' experience as novices, with more than a year of experience as expert, and those in between as intermediate (Dumas and Redish, 1999). Other individual differences that practitioners routinely track and attempt to vary are education level, age, and gender.

When acquiring participants, how can practitioners define the similarity between the participants they can acquire and the target population? An initial step is to develop a taxonomy of the variables that affect human performance (where performance should include the behaviors of indicating preference and other choice behaviors). Gawron et al. (1989) produced a human performance taxonomy during the development of a human performance expert system. They reviewed existing taxonomies and filled in some missing pieces. They structured the taxonomy as having three top levels: environment, subject (person), and task. The resulting taxonomy took up 12 pages in their paper and covered many areas that would normally not concern a usability practitioner working in the field of computer system usability (e.g., ambient vapor pressure, gravity, acceleration). Some of the key human variables in the Gawron et al. (1989) taxonomy that could affect human performance with computer systems are:

- *Physical characteristics*
  - Age
  - Agility
  - Handedness
  - Voice
  - Fatigue
  - Gender
  - Body and body part size
- *Mental state*
  - Attention span
  - Use of drugs (both prescription and illicit)
  - Long-term memory (includes previous experience)
  - Short-term memory
  - Personality traits
  - Work schedule
- *Senses*
  - Auditory acuity
  - Tone perception
  - Tactual
  - Visual accommodation

- Visual acuity
- Color perception

These variables can guide practitioners as they attempt to describe how participants and target populations are similar or different. The Gawron et al. (1989) taxonomy, however, does not provide much detail with regard to some individual differences that other researchers have hypothesized to affect human performance or preference with respect to the use of computer systems: personality traits and computer-specific experience.

Aykin and Aykin (1991) performed a comprehensive review of the published studies to that date that involved individual differences in human–computer interaction (HCI). Table 1 lists the individual differences that they found in published HCI studies, the method used to measure the individual difference, and whether there was any indication from the literature that manipulation of that individual difference led to a crossed interaction.

In statistical terminology, an interaction occurs whenever an experimental treatment has a different magnitude of effect depending on the level of a different, independent experimental treatment. A crossed interaction occurs when the magnitudes have different signs, indicating reversed directions of effects. As an example of an uncrossed interaction, consider the effect of turning off the lights on the typing throughput of blind and sighted typists. The performance of the sighted typists would probably be worse, but the presence or absence of light should not affect the performance of the blind typists. As an extreme example of a crossed interaction, consider the effect of language on task completion for people fluent only in French or English. When reading French text, French speakers would outperform English speakers, and vice versa.

For any of these individual differences, the lack of evidence for crossed interactions could be due to a paucity of research involving the individual difference or could reflect the probability that individual differences will not typically cause crossed interactions in HCI. In general, a change made to support a problem experienced by a person with a particular individual difference will either help other users or simply not affect their performance.

For example, John Black (personal communication, 1988) cited the difficulty that field-dependent users had working with one-line editors at the time (decades ago) when that was the typical user interface to a mainframe computer. Switching to full-screen editing resulted in a performance improvement for both field-dependent and field-independent users—an uncrossed interaction because both types of users improved, with the performance of field-dependent users becoming equal to (thus improving more than) that of field-independent users. Landauer (1997) cites another example of this, in which Greene et al. (1986) found that young people with high scores on logical reasoning tests could master database query languages such as SQL with little training, but older or less able people could hardly ever master these languages. They also determined that an alternative way of forming queries, selecting rows from a truth table, allowed almost everyone to make correct specification of queries, independent of their abilities. Because this redesign improved the performance of less able users without diminishing the performance of the more able, it was an uncrossed interaction. In a more recent study, Palmquist and Kim (2000) found that field dependence affected the search performance of novices using a Web browser (with field-independent users searching more efficiently) but did not affect the performance of more experienced users.

If there is a reason to suspect that an individual difference will lead to a crossed interaction as a function of interface design, it could make sense to invest the time (which can be considerable) to categorize users

**Table 1  Results of Aykin and Aykin (1991) Review of Individual Differences in HCI**

| Individual Difference | Measurement Method | Crossed Interactions |
|---|---|---|
| Level of experience | Various methods | No |
| Jungian personality types | Myers–Briggs type of indicator | No |
| Field dependence/ independence | Embedded figures test | Yes; field-dependent participants preferred organized sequential item number search mode, but field-independent subjects preferred the less organized keyword search mode (Fowler et al., 1985) |
| Locus of control | Levenson test | No |
| Imagery | Individual differences questionnaire | No |
| Spatial ability | VZ-2 | No |
| Type A/type B personality | Jenkins activity survey | No |
| Ambiguity tolerance | Ambiguity tolerance scale | No |
| Gender | Unspecified | No |
| Age | Unspecified | No |
| Other (reading speed and comprehension, intelligence, mathematical ability) | Unspecified | No |

according to these dimensions. Another situation in which it could make sense to invest the time in categorization by individual difference would be if there were reasons to believe that a change in interface would greatly help one or more groups without adversely affecting other groups. (This is a strategy that one can employ when developing hypotheses about ways to improve user interfaces.) It always makes sense to keep track of user characteristics when categorization is easy (e.g., age or gender). Another potential use of these types of variables is as covariates (used to reduce estimates of variability) in advanced statistical analyses (Cliff, 1987).

Aykin and Aykin (1991) reported effects of users' levels of experience but did not report any crossed interactions related to this individual difference. They did report that interface differences tended to affect the performance of novices but had little effect on the performance of experts. It appears that behavioral differences related to user interfaces (Aykin and Aykin, 1991) and cognitive style (Palmquist and Kim, 2000) tend to fade with practice. Nonetheless, user experience has been one of the few individual differences to receive considerable attention in HCI research (Fisher, 1991; Mayer, 1997; Miller et al., 1997; Smith et al., 1999). According to Mayer (1997), relative to novices, experts have (1) better knowledge of syntax, (2) an integrated conceptual model of the system, (3) more categories for more types of routines, and (4) higher level plans.

Fisher (1991) emphasized the importance of discriminating between computer experience (which he placed on a novice–experienced dimension) and domain expertise (which he placed on a naive–expert dimension). LaLomia and Sidowski (1990) reviewed the scales and questionnaires developed to assess computer satisfaction, literacy, and aptitudes. None of the instruments they surveyed specifically addressed measurement of computer experience. Miller et al. (1997) published the Windows Computer Experience Questionnaire (WCEQ), an instrument specifically designed to measure a person's experience with Windows 3.1. The questionnaire took about 5 min to complete and was reliable (coefficient $\alpha = 0.74$; test–retest correlation = 0.97). They found that their questionnaire was sensitive to three experiential factors: general Windows experience, advanced Windows experience, and instruction. Arning and Ziefle (2008) published an 18-item computer expertise questionnaire for older adults (the CE) which assesses both theoretical computer knowledge and practical computer knowledge and takes about 20 min to complete.

Smith et al. (1999) distinguished between subjective and objective computer experience. The paper was relatively theoretical and "challenges researchers to devise a reliable and valid measure" (p. 239) for subjective computer experience, but did not offer one. One user characteristic not addressed in any of the literature cited is one that becomes very important when designing products for international use: cultural characteristics. For example, in adapting an interface for use by members of another country, it is extremely important that all text be translated accurately. It is also important to be sensitive to the possibility that these types of individual differences might be more likely than others to result in crossed interactions.

For comparison studies, having multiple groups (e.g., males and females or experts and novices) allows the assessment of potential interactions that might otherwise go unnoticed. Ultimately, the decision for one or multiple groups must be based on expert judgment and a few guidelines. For example, practitioners should consider sampling from different groups if they have reason to believe:

- There are potential and important differences among groups on key measures (Dickens, 1987).
- There are potential interactions as a function of group (Aykin and Aykin, 1991).
- The variability of key measures differs as a function of the group.
- The cost of sampling differs significantly from group to group.

Gordon and Langmaid (1988) recommended the following approach to defining groups:

1. Write down all the important variables.
2. If necessary, prioritize the list.
3. Design an ideal sample.
4. Apply common sense to collapse cells.

For example, suppose that a practitioner starts with 24 cells, based on the factorial combination of six demographic locations, two levels of experience, and the two levels of gender. The practitioner should ask himself or herself whether there is a high likelihood of learning anything new and important after completing the first few cells or whether additional testing would be wasteful. Can one learn just as much from having one or a few cells that are homogeneous within cells and heterogeneous between cells with respect to an important variable but are heterogeneous within cells with regard to other, less important variables? For example, a practitioner might plan to (1) include equal numbers of males and females over and under 40 years of age in each cell, (2) have separate cells for novice and experienced users, and (3) drop intermediate users from the test. The resulting design requires testing only two cells (groups), but a design that did not combine genders and age groups in the cells would have required eight cells.

The final issue is the number of participants to include in the test. According to Dumas and Redish (1999), typical usability tests have 6–12 participants divided among two to three subgroups. For any given test, the required sample size depends on the number of subgroups, available resources (time/money), and purpose of the test (e.g., precise measurement or problem discovery). It also depends on whether a study is single shot (needing a larger sample size) or iterative (needing a smaller sample size per iteration, building up the total sample size over iterations). For more detailed treatment of this topic, see Section 3.1.

### 2.7.3 Test Task Scenarios

As with participants, the most important consideration for test tasks is that they are representative of the types of tasks that real users will perform with the product. For any product, there will be a core set of tasks that anyone using the product will perform. People who use barbecue grills use them to cook. People who use desktop speech dictation products use them to produce text. For usability tests, these are the most important tasks to test.

After defining these core tasks, the next step is to list any more peripheral tasks that the test should cover. If a barbecue grill has an external burner for heating pans, it might make sense to include a task that requires participants to work with that burner. If in addition to the basic vocabulary in a speech dictation system the program allows users to enable additional special topic vocabularies such as cooking or sports, it might make sense to devise a task that requires participants to activate and use one of these topics. Practitioners should avoid frivolous or humorous tasks because what is humorous to one person might be offensive or annoying to another.

From the list of test tasks, create scenarios of use (with specific goals) that require participants to perform the identified tasks. Critical tasks can appear in more than one scenario. For repeated tasks, vary the task details to increase the generalizability of the results. When testing relatively complex systems, some scenarios should stay within specific parts of the system (e.g., typing and formatting a document) and others should require the use of different parts of the system (e.g., creating a figure using a spreadsheet program, adding it to the document, attaching the document to a note, and sending it to a specified recipient).

The complete specification of a scenario should include several items. It is important to document (but not to share with the participant) the required initial conditions so it will be easy to determine before a test session starts if the system is ready and the required ending conditions that define successful task completion (Howard, 2008; Howard and Howard, 2009). The written description of the scenario (presented to the participant) should state what the participant is trying to achieve and why (the motivation), keeping the description of the scenario as short as possible to keep the test session moving quickly. The scenario should end with an instruction for the action the participant should take upon finishing the task (to make it easier to measure task completion times). The descriptions of the scenario's tasks should not typically provide step-by-step instructions on how to complete the task but should include details (e.g., actual names and data) rather than general statements. For tasks in which users work with highly personalized data (email, calendar, financial), scenarios constructed with a participant's own real data can increase the validity of the study (Genov et al., 2009).

The order in which participants complete scenarios should reflect the way in which users would typically work and with the importance of the scenario, with important scenarios done first unless there are other less important scenarios that produce outputs that the important scenario requires as an initial condition. Not all participants need to receive the same scenarios, especially if there are different groups under study. The tasks performed by administrators of a Web system that manages subscriptions will be different from the tasks performed by users who are requesting subscriptions.

Here are some examples of scenarios:

- Frank Smith's business telephone number has changed to (896) 555-1234. Please change the appropriate address book entry so you have this new phone number available when you need it. When you have finished, please say "I'm done."
- You've just found out that you need to cancel a car reservation that you made for next Wednesday. Please call the system that you used to make the reservation (1-888-555-1234) and cancel it. When you have finished, please hang up the phone and say "I'm done."

Bailey et al. (2009) have described stopping a task after the first step as a means for assessing a large number of tasks in a relatively short period of time. Over a number of website studies, they found that if the first click of a task was correct, the likelihood of final task success was 0.87, whereas if the first click was incorrect, the likelihood of final success was 0.46. The more tasks covered in a usability test, the greater the likelihood of discovery of usability problems (Lindgaard and Chattratichart, 2007).

### 2.7.4 Procedure

The test plan should include a description of the procedures to follow when conducting a test session. Most test sessions include an introduction, task performance, posttask activities, and debriefing.

A common structure for the introduction is for the briefer (review Section 2.6) to start with the purpose of the test, emphasizing that its goal is to improve the product, not to test the participant. Participation is voluntary, and the participant can stop at any time without penalty. The briefer should inform the participant that all test results will be confidential. The participant should be aware of any planned audio or video recording. Finally, the briefer should provide any special instructions (e.g., TA instructions) and answer any other questions that the participant might have.

The participant should then complete any preliminary questionnaires and forms, such as a background questionnaire, an informed consent form (including consent for any recording, if applicable), and, if necessary, a confidential disclosure form. If the participant will be using a workstation, the briefer should help the participant make any necessary adjustments (unless, of course, the purpose of the test is to evaluate workstation adjustability). Finally, the participant should complete any prerequisite training. This can be especially important if the goal of the study is to investigate usability after some period of use (ease of use) rather than immediate usability (ease of learning).

The procedure section should indicate the order in which participants will complete task scenarios. For

each participant, start with the first task scenario assigned and complete additional scenarios until the participant finishes (or runs out of time). The procedure section should specify when and how to interact with participants, according to the type of study. This section should also indicate when it is permissible to provide assistance to participants if they encounter difficulties in task performance.

Normally, practitioners should avoid offering assistance unless the participant is visibly distressed. When participants initially request help at a given step in a task, refer them to documentation or other supporting materials if available. If that doesn't help, provide the minimal assistance required to keep the participant moving forward in the task, note the assistance, and score the task as failed. When participants ask questions, try to avoid direct answers, instead turning their attention back to the task and encouraging them to take whatever action seems right at that time. When asking questions of participants, it is important to avoid biasing the participant's response. Try to avoid the use of loaded adjectives and adverbs in questions (Dumas and Redish, 1999). Instead of asking if a task was easy, ask the participant to describe what it was like performing the task. Give a short satisfaction questionnaire (such as the ASQ; see Section 3.3 for details) at the end of each scenario.

After participants have finished the assigned scenarios, it is common to have them complete a final questionnaire, usually a standard questionnaire and any additional items required to cover other test- or product-specific issues. For standardized questionnaires, ISO lists the SUMI (Software Usability Measurement Inventory) (Kirakowski and Corbett, 1993; Kirakowski, 1996) and PSSUQ (Post-Study System Usability Questionnaire) (Lewis, 1995, 2002). In addition to the SUMI and PSSUQ, ANSI lists the QUIS (Questionnaire for User Interaction Satisfaction) (Chin et al., 1988) and SUS (System Usability Scale) (Brooke, 1996) as widely used questionnaires. After completing the final questionnaire, the briefer should debrief the participant. Toward the end of debriefing, the briefer should tell the participant that the test session has turned up several opportunities for product improvement (this is almost always true) and thank the participant for his or her contribution to product improvement. Finally, the briefer should discuss any questions that the participant has about the test session and then take care of any remaining activities, such as completing time cards. If any deception has been employed in the test (which is rare but can happen legitimately when conducting certain types of simulations), the briefer must inform the participant.

### 2.7.5   Pilot Testing

Practitioners should always plan for a pilot test before running a usability test. A usability test is a designed artifact and like any other designed artifact needs at least some usability testing to find problems in the test procedures and materials. A common strategy is to have an initial walkthrough with a member of the usability test team or some other convenient participant. After making the appropriate adjustments, the next pilot participant should be a more representative participant. If there

are no changes made to the design of the usability test after running this participant, the second pilot participant can become the first real participant (but this is rare). Pilot testing should continue until the test procedures and materials have become stable.

### 2.7.6   Number of Iterations

It is better to run one usability test than not to run any at all. On the other hand, "usability testing is most powerful and most effective when implemented as part of an iterative product development process" (Rubin, 1994, p. 30). Ideally, usability testing should begin early and occur repeatedly throughout the development cycle. When development cycles are short, it is a common practice to run, at a minimum, exploratory usability tests on prototypes at the beginning of a project, to run a usability test on an early version of the product during the later part of functional testing, and then to run another during system testing. Once the final version of the product is available, some organizations run an additional usability test focused on the measurement of usability performance benchmarks. At this stage of development, it is too late to apply information about any problems discovered during the usability test to the soon-to-be-released version of the product, but the information can be useful as early input to a follow-on product if the organization plans to develop another version of the product.

### 2.7.7   Ethical Treatment of Test Participants

Usability testing always involves human participants, so usability practitioners must be aware of professional practices in the ethical treatment of test participants. Practitioners with professional education in experimental psychology are usually familiar with the guidelines of the American Psychology Association (APA; see http://www.apa.org/ethics/), and those with training in human factors engineering are usually familiar with the guidelines of the Human Factors and Ergonomics Society (HFES) (see http://www.hfes.org/About/Code.html). It is particularly important (Dumas, 2003) to be aware of the concepts of informed consent (participants are aware of what will happen during the test, agree to participate, and can leave the test at any time without penalty) and minimal risk (participating in the test does not place participants at any greater risk of harm or discomfort than situations normally encountered in daily life). Most usability tests are consistent with guidelines for informed consent and minimal risk. Only the test administrator should be able to match a participant's name and data, and the names of test participants should be confidential. Anyone interacting with a participant in a usability test has a responsibility to treat the participant with respect.

Usability practitioners rarely use deception in usability tests. One technique in which there is potential use of deception is the WOZ method (originally, the OZ Paradigm) (Kelley, 1985; see also http://www.musicman.net/oz.html). In a test using the WOZ method, a human (the Wizard) plays the part of the system, remotely controlling what the participant sees happen in response to the participant's manipulations. This method

is particularly effective in early tests of speech recognition IVR systems because all the Wizard needs is a script and a phone (Sadowski, 2001). Often, there is no compelling reason to deceive participants, so they know that the system they are working with is remotely controlled by another person for the purpose of early evaluation. If there is a compelling need for deception (e.g., to manage the participant's expectations and encourage natural behaviors), this deception must be revealed to the participant during debriefing.

## 2.8  Reporting Results

There are two broad classes of usability test results, problem reports and quantitative measurements. It is possible for a test report to contain one type exclusively (e.g., the ANSI Common Industry Format has no provision for reporting problems, which led the National Institute of Standards and Technology to investigate a similar standard for formative test reports; see Theofanos and Quesenbery, 2005), but most usability test reports will contain both types of results. Høegh et al. (2006) reported that usability reports can have a strong impact on developers' understanding of specific usability problems, especially if the developers have also observed usability test sessions. Of particular interest to the developers was the list of specific usability problems and redesign proposals, consistent with the results of Capra (2007) and Nørgaard and Hornbæk (2009).

### 2.8.1  Describing Usability Problems

"We broadly define a usability defect as: Anything in the product that prevents a target user from achieving a target task with reasonable effort and within a reasonable time.... Finding usability problems is relatively easy. However, it is much harder to agree on their importance, their causes and the changes that should be made to eliminate them (the fixes)" (Marshall et al., 1990, p. 245).

The best way to describe usability problems depends on the purpose of the descriptions. For usability practitioners, the goal should be to describe problems in such a way that the description leads logically to one or more potential interventions (recommendations) that will help designers and developers improve the system under evaluation (Høegh et al., 2006; Hornbæk, 2010). Ideally, the problem description should also include some indication of the importance of fixing the problem (most often referred to as problem severity). For more scientific investigations, there can be value in higher levels of problem description (Keenan et al., 1999), but developers rarely care about these levels of description. They just want to know what they need to do to make things better while also managing the cost (both monetary and time) of interventions (Gray and Salzman, 1998).

The problem description scheme of Lewis and Norman (1986) has both scientific and practical merit because their problem description categories indicate, at least roughly, an appropriate intervention. They stated (p. 413) that "although we do not believe it possible to design systems in which people do not make errors, we do believe that much can be done to minimize the incidence of error, to maximize the discovery of the error, and to make it easier to recover from the error." They separated errors into mistakes (errors due to incorrect intention) and slips (errors due to appropriate intention but incorrect action), further breaking slips down into mode errors (which indicate a need for better feedback or elimination of the mode), capture errors (which indicate a need for better feedback), and description errors (which indicate a need for better design consistency). In one study using this type of problem categorization, Prümper et al. (1992) found that expertise did not affect the raw number of errors made by participants in their study, but experts handled errors much more quickly than novices. The types of errors that experts made were different from those made by novices, with experts' errors occurring primarily at the level of slips rather than mistakes (knowledge errors).

Using an approach similar to that of Lewis and Norman (1986), Rasmussen (1986) described three levels of errors: skill based, rule based, and knowledge based. Other classification schemes include Structured Usability Problem Extraction, or SUPEX (Cockton and Lavery, 1999), the User Action Framework, or UAF (Andre et al., 2000), and the Classification of Usability Problems (CUP) scheme (Vilbergsdóttir et al., 2006). The UAF requires a series of decisions, starting with an interaction cycle (planning, physical actions, assessment) based on the work of Norman (1986). Most classifications require four or five decisions, with interrater reliability [as measured with kappa ($\kappa$)] highest at the first step ($\kappa = 0.978$) but remaining high through the fourth and fifth steps ($\kappa > 0.7$).

Whether any of these classification schemes will see widespread use by usability practitioners is still unknown. For example, the CUP scheme requires some training for inexperienced evaluators to effectively use the scheme, even though a simplified version may be useful for developers and usability practitioners (Vilbergsdóttir et al, 2006). There is considerable pressure on practitioners to produce results and recommendations as quickly as possible. Even if these classification schemes see little use by practitioners, effective problem classification is a very important problem to solve as usability researchers strive to compare and improve usability testing methods.

### 2.8.2  Crafting Design Recommendations from Problem Descriptions

The development of recommendations from problem descriptions is a craft rather than a rote procedure. A well-written problem description will often strongly imply an intervention, but it is also often the case that there might be several ways to attack a problem. It can be helpful for practitioners to discuss problems and potential interventions with the other members of their team and to get input from other stakeholders as necessary (especially, the developers of the product). This is especially important if the practitioner has observed problems but is uncertain as to the appropriate level of description of the problem.

For example, suppose that you have written a problem description about a missing Help button in a

software application. This could be a problem with the overall design of the software or might be a problem isolated to one screen. You might be able to determine this by inspecting other screens in the software, but it could be faster to check with one of the developers.

The first recommendations to consider should be for interventions that will have the widest impact on the product. "Global changes affect everything and need to be considered first" (Rubin, 1994, p. 285). After addressing global problems, continue working through the problem list until there is at least one recommendation for each problem. For each problem, start with interventions that would eliminate the problem, then follow, if necessary, with other less drastic (less expensive, more likely to be implemented) interventions that would reduce the severity of the remaining usability problem. When different interventions involve different trade-offs, it is important to communicate this clearly in the recommendations. This approach can lead to two tiers of recommendations: those that will happen for the version of the product currently under development (short-term) and those that will happen for a future version of the product (long-term).

Molich et al. (2007) used results from CUE-4 to develop guidelines for making usability recommendations useful and usable. By their assessment, only 14 of 84 studied comments (17%) were both useful and usable. To address the weaknesses observed in the recommendations, they concluded:

- Communicate clearly at the conceptual level.
- Ensure that recommendations improve overall usability.
- Be aware of business or technical constraints.
- Solve the whole problem, not just a special case.

Nørgaard and Hornbæk (2009) conducted an exploratory study in which three developers assessed 40 usability findings presented using five feedback formats. The developers rated redesign proposals, multimedia presentations, and screen dumps as useful inputs, problem lists second, and scenarios as least helpful. "Problem lists seem best suited for communicating simple and uncontroversial usability problems for which no contextual information is needed" (p. 64). The preferred feedback formats provided strong contextual information. These results suggest that problem lists can be useful, but it is important to provide sufficient contextual information, if not possible through verbal description, then through associated redesign proposals, screen dumps, and multimedia presentations.

### 2.8.3   Prioritizing Problems

Because usability tests can reveal more problems than there are resources to address, it is important to have some means for prioritizing problems, keeping in mind that design process considerations (stage of development and cost-effectiveness) can also influence the specific usability changes made to a product (Hertzum, 2006). There are two approaches to prioritization that have appeared in the usability testing literature: (1) judgment

driven (Virzi, 1992) and (2) data driven (Lewis et al., 1990; Rubin, 1994; Dumas and Redish, 1999). The bases for judgment-driven prioritizations are the ratings of stakeholders in the project (such as usability practitioners and developers). The bases for data-driven prioritizations are the data associated with the problems, such as frequency, impact, ease of correction, and likelihood of usage of the portion of the product that was in use when the problem occurred. Of these, the most common measurements are frequency and impact (sometimes referred to as severity, although, strictly speaking, severity should include the effect of all of the types of data considered for prioritization). In a study of the two approaches to prioritization, Hassenzahl (2000) found a lack of correspondence between data-driven and judgment-driven severity estimates. This suggests that the preferred approach should be data driven.

The usual method for measuring the frequency of occurrence of a problem is to divide the number of occurrences within participants by the number of participants. A common method (Rubin, 1994; Dumas and Redish, 1999) for assessing the impact of a problem is to assign impact scores according to whether the problem (1) prevents task completion, (2) causes a significant delay or frustration, (3) has a relatively minor effect on task performance, or (4) is a suggestion. This is similar to the scheme of Lewis et al. (1990), in which the impact levels were (1) scenario failure or irretrievable data loss (e.g., the participant required assistance to get past the problem or caused the participant to believe the scenario to be properly completed when it was not), (2) considerable recovery effort (recovery took more than 1 min or the participant repeatedly experienced the problem within a scenario), (3) minor recovery effort (the problem occurred only once within a scenario with recovery time at or under 1 min), or (4) inefficiency (a problem not meeting any of the other criteria).

When considering multiple types of data in a prioritization process, it is necessary to combine the data in some way. A graphical approach is to create a problem grid with frequency on one axis and impact on the other. High-frequency, high-impact problems would receive treatment before low-frequency, low-impact problems. The relative treatment of high-frequency, low-impact problems and low-frequency, high-impact problems depends on practitioner judgment.

An alternative approach is to combine the data arithmetically. Rubin (1994) described a procedure for combining four levels of impact (using the criteria described above with 4 assigned to the most serious level) with four levels of frequency (4: frequency $\geq$ 90%; 3: 51–89%; 2: 11–50%; 1: $\leq$ 10%) by adding the scores. For example, if a problem had an observed frequency of occurrence of 80% and had a minor effect on performance, its priority would be 5 (a frequency rating of 3 plus an impact rating of 2). With this approach, priority scores can range from a low of 2 to a high of 8. If information is available about the likelihood that a user would work with the part of the product that enables the problem, this information would be used to adjust the frequency rating. Continuing the example, if the expectation is that only 10% of users would encounter the

problem, the priority would be 3 (a frequency rating of 1 for the 10% × 80%, or an 8% likelihood of occurrence plus an impact rating of 2).

A similar strategy is to multiply the observed percentage frequency of occurrence by the impact score. The range of priorities depends on the values assigned to each impact level. Assigning 10 to the most serious impact level leads to a maximum priority (severity) score of 1000 (which can optionally be divided by 10 to create a scale that ranges from 1 to 100). Appropriate values for the remaining three impact categories depend on practitioner judgment, but a reasonable set is 5, 3, and 1. Using those values, the problem with an observed frequency of occurrence of 80% and a minor effect on performance would have a priority of 24 (80 × 3/10). It is possible to extend this method to account for the likelihood of use using the same procedure as that described by Rubin (1994), which in the example resulted in modifying the frequency measurement from 80 to 8%. Another way to extend the method is to categorize the likelihood of use with a set of categories such as very high likelihood (assigned a score of 10), high likelihood (assigned a score of 5), moderate likelihood (assigned a score of 3), and low likelihood (assigned a score of 1) and multiply all three scores to get the final priority (severity) score (then optionally divide by 100 to create a scale that ranges from 1 to 100). Continuing the previous example with the assumption that the task in which the problem occurred has a high likelihood of occurrence, the problem's priority would be 12 (5 × 240/100). In most cases, applying the different data-driven prioritization schemes to the same set of problems should result in a very similar prioritization (but there has been no research published on this topic).

### 2.8.4 Working with Quantitative Measurements

The most common use of quantitative measurements is to characterize performance and preference variables by computing means, standard deviations, and ideally confidence intervals. Practitioners use these results to compare observed to target measurements when targets are available. When targets are not available, the results can still be informative, for example, for use as future target measurements or as relatively gross diagnostic indicators.

The failure to meet targets is an obvious diagnostic cue. A less obvious cue is an unusually large standard deviation. Landauer (1997) describes a case in which the times to record an order were highly variable. The cause for the excessive variability was that a required phone number was sometimes, but not always, available, which turned out to be an easy problem to fix. Because the means and standard deviations of time scores tend to correlate, one way to detect an unusually large variance is to compute the coefficient of variation by dividing the standard deviation by the mean (Jeff Sauro, personal communication, April 26, 2004) or the normalized performance ratio by dividing the mean by the standard deviation (Moffat, 1990). Large coefficients of variation (or, correspondingly, small normalized

performance ratios) are potentially indicative of the presence of usability problems.

## 3  STATISTICAL TOPICS

This section covers statistical topics in usability testing, including sample size estimation for problem discovery and measurement tests (both comparative and parameter estimation), confidence intervals based on $t$-scores and binomial confidence intervals, and standardized usability questionnaires. This chapter contains a considerable amount of information about statistical topics because statistical methods do not typically receive much attention in chapters on usability testing, and properly practiced, these techniques can be very valuable. On the other hand, practitioners should keep in mind that the most important factors that lead to successful usability evaluation are the appropriate selection of participants and tasks. No statistical analysis can repair a study in which you watch the wrong people doing the wrong activities.

### 3.1  Sample Size Estimation

The purpose of this section is to discuss the principles of sample size estimation for three types of usability test: population parameter estimation, comparative (also referred to as experimental), and problem discovery (also referred to as diagnostic, observational, or formative). This section assumes some knowledge of introductory applied statistics, so if you're not comfortable with terms such as *mean, variance, standard deviation*, $p$, $t$, and $Z$, refer to an introductory statistics text such as Walpole (1976) for definitions of these and other fundamental terms.

Sample size estimation requires a blend of mathematics and judgment. The computations are straightforward, and it is possible to make reasoned judgments (e.g., judgments about expected costs and precision requirements) for those values that the mathematics cannot determine.

#### 3.1.1  Sample Size Estimation for Parameter Estimation and Comparative Studies

Traditional sample size estimation for population parameter estimation and comparative studies depends on having an estimate of the variance of the dependent measure(s) of interest and an idea of how precise (the magnitude of the critical difference and the statistical confidence level) the measurement must be (Walpole, 1976). Once you have that, the rest is mathematical mechanics (typically, using the formula for the $t$-statistic).

You can (1) get an estimate of variance from previous studies using the same method (same or similar tasks and measures), (2) run a quick pilot study to get the estimate (e.g., piloting with four participants should suffice to provide an initial estimate of variability), or (3) set the critical difference you are trying to detect to some fraction of the standard deviation (Diamond, 1981). (See the following examples for more details about these different methods.)

Certainly, people prefer precise measurement to imprecise measurement, but all other things being equal, the more precise a measurement is, the more it will cost, and running more participants than necessary is wasteful of resources (Kraemer and Thiemann, 1987). The process of carrying out sample size estimation can lead usability practitioners and their management to a realistic determination of how much precision they really need to make their required decisions.

Alreck and Settle (1985) recommend using a "what if" approach to help decision makers determine their required precision. Start by asking the decision maker what would happen if the average value from the study was off the true value by 1%. Usually, the response would be that a difference that small would not matter. Then ask what would happen if the measurement were off by 5%. Continue until you determine the magnitude of the critical difference. Then start the process again, this time pinning down the required level of statistical confidence. Note that statistically unsophisticated decision makers are likely to start out by expecting 100% confidence (which is only possible by sampling every unit in the population). Presenting them with the sample sizes required to achieve different levels of confidence can help them settle in on a more realistic confidence level.

***Example 1: Parameter Estimation Given Estimate of Variability and Realistic Criteria*** This example illustrates the process of computing the sample size requirement for the estimation of a population parameter given an existing estimate of variability and realistic measurement criteria. For speech recognition applications, the recognition accuracy is an important value to track due to the adverse effects misrecognitions have on product usability. Thus, part of the process of evaluating the usability of a speech recognition product is estimating its accuracy. For this example, suppose that:

- Recognition variability (variance) from a previous similar evaluation: 6.35
- Critical difference ($d$): 2.5%
- Desired level of confidence: 90%.

The appropriate procedure for estimating a population parameter is to construct a confidence interval (Bradley, 1976). To determine the upper and lower limits of a confidence interval, add to and subtract the following from the observed mean:

$$d = \text{SEM} \times t_{\text{crit}} \tag{1}$$

where SEM is the standard error of the mean (the standard deviation, $S$, divided by the square root of the sample size, $n$) and $t_{\text{crit}}$ is the $t$-value associated with the desired level of confidence (found in a $t$-table, available in most statistics texts). Setting the critical difference to 2.5 is the same as saying that the value of SEM $\times$ $t_{\text{crit}}$ should be equal to 2.5. In other words, you do not want the upper or lower bound of the confidence interval to be more than 2.5 percentage points away from the observed mean, for a confidence interval width equal to 5.0.

Calculating the SEM depends on knowing the sample size, and the value of $t_{\text{crit}}$ also depends on the sample size, but you do not know the sample size yet. Iterate using the following method.

1. Start with the $Z$-score for the desired level of confidence in place of $t_{\text{crit}}$. For 90% confidence, this is 1.645. (By the way, if you actually *know* the true variability for the measurement rather than just having an estimate, you are done at this point because it is appropriate to use the $Z$-score rather than a $t$-score. However, you almost never know the true variability but must work with estimates.)

2. Algebraic manipulations based on the formula SEM $\times Z = d$ results in $n = Z^2 S^2/d^2$, which for this example is $n = (1.645^2)(6.35)/2.5^2$, which equals 2.7. Always round sample size estimates up to the next whole number, so this initial estimate is 3.

3. Now you need to adjust the estimate by replacing the $Z$-score with the $t$-score for a sample size of 3. For this estimate, the degrees of freedom (df) to use when looking up the value in a $t$ table is $n - 1$, or 2. This is important because the value of $Z$ will always be smaller than the appropriate value of $t$, making the initial estimate smaller than it should be. For this example, $t_{\text{crit}}$ is 2.92.

4. Recalculating for $n$ using 2.92 in place of 1.645 produces 8.66, which rounds up to 9.

5. Because the appropriate value of $t_{\text{crit}}$ is now a little smaller than 2.92 (because the estimated sample size is now larger, with $9 - 1$, or 8, degrees of freedom), recalculate $n$ again, using $t_{\text{crit}}$ equal to 1.86. The new value for $n$ is 3.515, which rounds up to 4.

6. Stop iterating when you get the same value for $n$ on two iterations or you begin cycling between two values for $n$, in which case you should choose the larger value. Table 2 shows the full set of iterations for this example, which ends by estimating the appropriate sample size as 5. Note that there is nothing in these computations that makes reference to the size of the population. Unless the size of the sample is a significant percentage of the total population under study (which is rare but correctable using a finite population correction), the size of the population is irrelevant. Alreck and Settle (1985) explain this with a soup-tasting analogy. Suppose that you are cooking soup in a one-quart saucepan and want to test if it is hot enough. You would stir it thoroughly, then taste a teaspoonful. If it were a two-quart saucepan, you would follow the same procedure—stir thoroughly, then taste a teaspoonful.

Diamond (1981) points out that you can usually get by with an initial estimate and one iteration because most researchers do not mind having a sample size that

**Table 2  Full Set of Iterations for Example 1**

|                 | Initial | 1     | 2     | 3     | 4     | 5     |
|-----------------|---------|-------|-------|-------|-------|-------|
| $t_{crit}$      | 1.645   | 2.92  | 1.86  | 2.353 | 2.015 | 2.132 |
| $t_{crit}^2$    | 2.71    | 8.53  | 3.46  | 5.54  | 4.06  | 4.55  |
| $S^2$           | 6.35    | 6.35  | 6.35  | 6.35  | 6.35  | 6.35  |
| $d$             | 2.5     | 2.5   | 2.5   | 2.5   | 2.5   | 2.5   |
| Estimated $n$   | 2.749   | 8.663 | 3.515 | 5.625 | 4.125 | 4.618 |
| Rounded up      | 3       | 9     | 4     | 6     | 5     | 5     |
| df              | 2       | 8     | 3     | 5     | 4     | 4     |

is a little larger than necessary. If the cost of each sample is high, though, it makes sense to iterate until reaching one of the stopping criteria. Note that the initial estimate establishes the lower bound for the sample size (3 in this example), and the first iteration establishes the upper bound (9 in this example).

**Example 2: Parameter Estimation Given Estimate of Variability and Unrealistic Criteria**  The measurement criteria in Example 1 were reasonable—90% confidence that the interval (limited to a total length of 5%) contains the true mean. This example shows what happens when the measurement criteria are less realistic, illustrating the potential cost associated with high confidence and high measurement precision. Suppose that the measurement criteria for the situation described in Example 1 were less realistic, with:

- Recognition variability from a previous similar evaluation: 6.35
- Critical difference ($d$): 0.5%
- Desired level of confidence: 99%

In that case, the initial $Z$-score would be 2.576, and the initial estimate of $n$ would be

$$n = \frac{(2.576^2)(6.35)}{0.5^2} = 168.549 \qquad (2)$$

which rounds up to 169. Recalculating $n$ with $t_{crit}$ equal to 2.605 ($t$ with 168 degrees of freedom) results in $n$ equal to 172.37, which rounds up to 173. (Rather than continuing to iterate, note that the final value for the sample size must lie between 169 and 173.) There might be some industrial environments in which usability investigators would consider 169–173 participants a reasonable and practical sample size, but they are rare. (On the other hand, collecting data from this number of participants or more in a mailed survey is common.)

**Example 3: Parameter Estimation Given No Estimate of Variability**  For both Examples 1 and 2, it does not matter if the estimate of variability came from a previous study or a quick pilot study. Suppose, however, that you do not have any idea what the measurement variability is, and it is too expensive to run a pilot study to get an initial estimate. This example

illustrates a technique (from Diamond, 1981) for getting around this problem. To do this, though, you need to give up the definition of the critical difference ($d$) in terms of the variable of interest and replace it with a definition in terms of a fraction of the standard deviation.

In this example, the measurement variance is unknown. To get started, the testers have decided that with 90% confidence they do not want $d$ to exceed half the value of the standard deviation. The measurement criteria are:

- Recognition variability from a previous similar evaluation: N/A
- Critical difference ($d$): 0.5$S$
- Desired level of confidence: 90%

The initial sample size estimate is

$$n = \frac{(1.645^2)(S^2)}{(0.5S^2)} = \frac{1.645^2}{0.5^2} = 10.824 \qquad (3)$$

which rounds up to 11. The result of the first iteration, replacing 1.645 with $t_{crit}$ for 10 degrees of freedom (1.812), results in a sample size estimation of 13.13, which rounds up to 14. The appropriate sample size is therefore somewhere between 11 and 14, with the final estimate determined by completing the full set of iterations.

**Example 4: Comparing a Parameter to a Criterion**  For an example comparing a measured parameter to a criterion value, suppose that you have a product requirement that installation should take no more than 30 min. In a preliminary evaluation, participants needed an average of 45 min to complete installation. Development has fixed a number of usability problems found in that preliminary study, so you are ready to measure installation time again using the following measurement criteria:

- Performance variability from the previous evaluation: 10.0
- Critical difference ($d$): 3 min
- Desired level of confidence: 90%

The interpretation of these measurement criteria is that you want to be 90% confident that you can detect

**Table 3 Full Set of Iterations for Example 4**

|  | Initial | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| $t_{crit}$ | 1.645 | 2.353 | 1.943 | 2.132 | 2.015 |
| $t_{crit}{}^2$ | 2.706 | 5.537 | 3.775 | 4.545 | 4.060 |
| $s^2$ | 10 | 10 | 10 | 10 | 10 |
| $d$ | 3 | 3 | 3 | 3 | 3 |
| $d^2$ | 9 | 9 | 9 | 9 | 9 |
| Estimated $n$ | 3.007 | 6.152 | 4.195 | 5.050 | 4.511 |
| Rounded up | 4 | 7 | 5 | 6 | 5 |
| df | 3 | 6 | 4 | 5 | 4 |

a difference as small as 3 min between the mean of the data gathered in the test and the criterion you are trying to beat. In other words, the installation will pass if the observed mean time is 27 min or less, because the sample size should guarantee an upper limit to the confidence interval that is no more than 3 min above the mean (as long as the observed variance is less than or equal to the initial estimate of the variance). The procedure for determining the sample size in this situation is the same as that of Example 1, shown in Table 3. The outcome of these iterations is a sample size requirement of 6 because the sample size estimates begin cycling between 5 and 6. Because you only care if you beat the criterion, you could perform a one-sided evaluation (Sauro and Lewis, 2012). For the same measurement criteria (but one sided), the initial value of $t_{crit}$ would be 1.282 and the recommended minimum sample size would be 4.

### Example 5: Sample Size for a Paired t-Test

When you obtain two comparable measurements from each participant in a test (a within-subjects design), you can assess the results using a paired $t$-test. Another name for a *paired t-test* is a *difference score t-test*, because the measurements of concern are the mean and standard deviation of the set of difference scores rather than the raw scores. Suppose that you plan to obtain recognition accuracy scores from participants who have dictated test texts into your product under development and a competitor's product [following all the appropriate experimental design procedures such as counterbalancing the order of presentation of products to participants; see a text such as Myers (1979) for guidance in experimental design], using the following criteria:

- Difference score variability from a previous evaluation: 5.0
- Critical difference ($d$): 2%
- Desired level of confidence: 90%

This situation is similar to that of Example 4 because the typical goal of a difference score $t$-test is to determine if the average difference between scores is statistically significantly different from zero. Thus, the usability criterion in this case is zero, and you want to be 90% confident that if the true difference between system accuracies is 2% or more, you will be able to detect it because the confidence interval for the difference scores will not contain zero. Table 4 shows the iterations for this situation, leading to a sample size estimate of 6.

### Example 6: Sample Size for a Two-Groups t-Test

Up to this point, the examples have all involved one group of scores and have been amenable to similar treatment. If you have a situation in which you plan to compare scores from two independent groups, things get a little more complicated. For one thing, you now have two sample sizes to consider, one for each group.

To simplify things in this example, assume that the groups are essentially equal (especially with regard to performance variability), which should be the case if the groups contain participants from a single population who have received random assignment to treatment conditions. In this case it is reasonable to believe that the sample size for both groups will be equal, which simplifies things. For this situation, the formula for the initial estimate of the sample size for each group is

$$n = \frac{2Z^2 S^2}{d^2} \qquad (4)$$

**Table 4 Full Set of Iterations for Example 5**

|  | Initial | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| $t_{crit}$ | 1.645 | 2.353 | 1.943 | 2.132 | 2.015 |
| $t_{crit}{}^2$ | 2.706 | 5.537 | 3.775 | 4.545 | 4.060 |
| $s^2$ | 5 | 5 | 5 | 5 | 5 |
| $d$ | 2 | 2 | 2 | 2 | 2 |
| $d^2$ | 4 | 4 | 4 | 4 | 4 |
| Estimated $n$ | 3.383 | 6.921 | 4.719 | 5.682 | 5.075 |
| Rounded up | 4 | 7 | 5 | 6 | 6 |
| df | 3 | 6 | 4 | 5 | 5 |

**Table 5  Full Set of Iterations for Example 6**

|                | Initial | 1     | 2     | 3     |
| -------------- | ------- | ----- | ----- | ----- |
| $t_{crit}$     | 1.645   | 1.943 | 1.833 | 1.86  |
| $t_{crit}^2$   | 2.706   | 3.775 | 3.360 | 3.460 |
| $s^2$          | 5       | 5     | 5     | 5     |
| $d$            | 2       | 2     | 2     | 2     |
| $d^2$          | 4       | 4     | 4     | 4     |
| Estimated $n$  | 6.765   | 9.438 | 8.400 | 8.649 |
| Rounded up     | 7       | 10    | 9     | 9     |
| df             | 6       | 9     | 8     | 8     |

Note that this is similar to the formula presented in Example 1, with the numerator multiplied by 2. After getting the initial estimate, begin iterating using the appropriate value for $t_{crit}$ in place of $Z$. For example, suppose that you needed to conduct the experiment described in Example 5 with independent groups of participants, keeping the measurement criteria the same:

- Estimate of variability from a previous evaluation: 5.0
- Critical difference ($d$): 2%
- Desired level of confidence: 90%

In that case, as shown in Table 5, iterations would converge on a sample size of nine participants per group, for a total sample size of 18.

This illustrates the well-known measurement efficiency of experiments that produce difference scores (within-subjects designs) relative to experiments involving independent groups (between-subjects designs). For the same measurement precision, the estimated sample size for Example 5 was six participants, one-third the sample size requirement estimated for this example.

Doing this type of analysis gets more complicated if you have reason to believe that the groups are different, especially with regard to variability of performance. In that case you would want to have a larger sample size for the group with greater performance variability in an attempt to obtain more equal precision of measurement for each group. Advanced market research texts (such as Brown, 1980) provide sample size formulas for these situations.

***Example 7: Making Power Explicit in the Sample Size Formula***  The power of a procedure is not an issue when estimating the value of a parameter, but it is an issue when testing a hypothesis (as in Example 6). In traditional hypothesis testing, there is a null ($H_0$) and an alternative ($H_a$) hypothesis. The typical null hypothesis is that there is no difference between groups, and the typical alternative hypothesis is that the difference is greater than zero. When the alternative hypothesis is that the difference is nonzero, the test is two-tailed because you can reject the null hypothesis with either a sufficiently positive or a sufficiently negative outcome. If you have reason to believe that you can predict the direction of the outcome, or if an outcome in only one

**Table 6  Possible Outcomes of a Hypothesis Test**

|                                      | Reality          |                |
| ------------------------------------ | ---------------- | -------------- |
| Decision                             | $H_0$ Is True    | $H_0$ Is False |
| Insufficient evidence to reject $H_0$ | Fail to reject $H_0$ | Type II error  |
| Sufficient evidence to reject $H_0$  | Type I error     | Reject $H_0$   |

direction is meaningful, you can construct an alternative hypothesis that considers only a sufficiently positive or a sufficiently negative outcome (a one-tailed test). For more information, see an introductory statistics text (such as Walpole, 1976).

When you test a hypothesis (e.g., that the difference in recognition accuracy between two competitive dictation products is nonzero), there are two ways to make a correct decision and two ways to be wrong, as shown in Table 6. Strictly speaking, you never accept the null hypothesis, because the failure to acquire sufficient evidence to reject the null hypothesis could be due to (1) no significant difference between groups or (2) a sample size too small to detect an existing difference. Rather than accepting the null hypothesis, you fail to reject it.

Returning to Table 6, the two ways to be right are (1) to fail to reject the null hypothesis ($H_0$) when it is true or (2) to reject the null hypothesis when it is false. The two ways to be wrong are (1) to reject the null hypothesis when it is true (type I error) or (2) to fail to reject the null hypothesis when it is false (type II error). Table 7 shows the relationship between these concepts and their corresponding statistical testing terms.

The formula presented in Example 6 for an initial sample size estimate was

$$n = \frac{2Z^2 S^2}{d^2} \tag{5}$$

In Example 6, the $Z$-score was set for 90% confidence (which means that $\alpha = 0.10$). To take power into account in this formula, you need to add another $Z$-score to the formula, the $Z$-score associated with the desired power of the test (as defined in Table 7). Thus, the formula becomes

$$n = \frac{2(Z_\alpha + Z_\beta)^2 S^2}{d^2} \tag{6}$$

Note that you should always use the one-sided value for $z_\beta$, regardless of whether you are conducting a

**Table 7  Statistical Testing Terms**

| Statistical Concept                          | Testing Term |
| -------------------------------------------- | ------------ |
| Acceptable probability of a type I error     | $\alpha$     |
| Acceptable probability of a type II error    | $\beta$      |
| Confidence                                   | $1 - \alpha$ |
| Power                                        | $1 - \beta$  |

**Table 8  Full Set of Iterations for Example 7**

|               | Initial | 1     | 2     | 3     |
|---------------|---------|-------|-------|-------|
| $t(\alpha)$   | 1.645   | 1.753 | 1.740 | 1.746 |
| $t(\beta)$    | 0.842   | 0.866 | 0.863 | 0.865 |
| $t$(total)    | 2.487   | 2.619 | 2.603 | 2.611 |
| $t$(total)$^2$| 6.18    | 6.86  | 6.78  | 6.81  |
| $S^2$         | 5       | 5     | 5     | 5     |
| $d$           | 2       | 2     | 2     | 2     |
| $d^2$         | 4       | 4     | 4     | 4     |
| Estimated $n$ | 15.5    | 17.2  | 16.9  | 17.04 |
| Rounded up    | 16      | 18    | 17    | 18    |
| df            | 15      | 17    | 16    | 17    |

one- or two-sided test (Diamond, 1981). So, what was the value for power in Example 6? When beta ($\beta$) equals 0.5 (in other words, when the power is 50%), the one-sided value of $z_\beta$ is zero, so $z_\beta$ disappears from the formula. Thus, in this example the implicit power was 50%. Suppose that you want to increase the power of the test to 80%, reducing $\beta$ to 0.2.

- Estimate of variability from a previous evaluation: 5.0
- Critical difference ($d$): 2
- Desired level of confidence: 90% (two-sided $Z_\alpha = 1.645$)
- Desired power: 80% (one-sided $Z_\beta = 0.842$)

With this change, the iterations indicate a sample size of 18 participants per group, for a total sample size of 36, as shown in Table 8. To achieve the stated goal for power results in a considerably larger sample size. Note that the stated power of a test is relative to the critical difference—the smallest effect worth finding. Either increasing the value of the critical difference or reducing the power of a test will result in a smaller required sample size.

### Appropriate Statistical Criteria for Industrial Testing

In scientific publishing, the usual criterion for statistical significance is to set the permissible type I error ($\alpha$) equal to 0.05. This is equivalent to seeking to have 95% confidence that the effect is real rather than random and is focused on controlling the type I error (the likelihood that you decide that an effect is real when it is random). There is no corresponding scientific recommendation for the type II error ($\beta$, the likelihood that you will conclude an effect is random when it is real), although some suggest setting it to 0.20 (Diamond, 1981). The rationale behind the emphasis on controlling the type I error is that it is better to delay the introduction of good information into the scientific database (a type II error) than to let erroneous information in (a type I error).

In industrial evaluation, the appropriate values for type I and II errors depend on the demands of the situation, whether the cost of a type I or II error would be more damaging to the organization. Because we are often resource constrained, especially with regard to

making timely decisions to compete in dynamic marketplaces, this chapter has used measurement criteria (such as 90% confidence rather than 95% confidence and fairly large values for $d$) that seek a greater balance between type I and II errors than is typical in work designed to result in scientific publications. Nielsen (1997) has suggested that 80% confidence is appropriate for practical development purposes. For an excellent discussion of this topic for usability researchers, see Wickens (1998). For other technical issues and perspectives, see Landauer (1997).

Another way to look at the issue is to ask the question, "Am I typically interested in small high-variability effects or large low-variability effects?" The correct answer depends on the situation, but in most usability testing, the emphasis is on the detection of large low-variability effects (either large performance effects or frequently occurring problems). You should not need a large sample to verify the existence of large low-variability effects. Some writers equate sample size with population coverage, but this is not true. A small sample size drawn from the right population provides better coverage than a large sample size drawn from the wrong population. The statistics involved in computing confidence intervals from small samples compensate for the potentially smaller variance in the small sample by forcing the confidence interval to be wider than that for a larger sample (specifically, the value of $t$ is greater when samples are smaller).

Coming from a different tradition than usability research, many market research texts provide rules of thumb recommending large sample sizes. For example, Aaker and Day (1986) recommend a minimum of 100 per group, with 20–50 for subgroups. For national surveys with many subgroup analyses, the typical total sample size is 2500 (Sudman, 1976). These rules of thumb do not make any formal contact with statistical theory and may in fact be excessive, depending on the goals of the study. Other market researchers (e.g., Banks, 1965, p. 252) do promote a careful evaluation of the goals of a study:

> It is urged that instead of a policy of setting uniform requirements for type I and II errors, regardless of the economic consequences of the various decisions to be made from experimental data, a much more flexible approach be adopted. After all, if a researcher sets himself a policy of always choosing the apparently most effective of a group of alternative treatments on the basis of data from unbiased surveys or experiments and pursues this policy consistently, he will find that in the long run he will be better off than if he chose any other policy. This fact would hold even if none of the differences involved were statistically significant according to our usual standards or even at probability levels of 20 or 30 percent.

Finally, Alreck and Settle (1985) provide an excellent summary of the factors indicating appropriate use of large and small samples. Use a large sample size when:

1. Decisions based on the data will have very serious or costly consequences.

2. The sponsors (decision makers) demand a high level of confidence.

3. The important measures have high variance.

4. Analyses will require dividing the total sample into small subsamples.

5. Increasing the sample size has a negligible effect on the cost and timing of the study.

6. Time and resources are available to cover the cost of data collection.

Use a small sample size when:

1. The data will determine few major commitments or decisions.

2. The sponsors (decision makers) require only rough estimates.

3. The important measures have low variance.

4. Analyses will use the entire sample or just a few relatively large subsamples.

5. Costs increase dramatically with sample size.

6. Budget constraints or time limitations limit the amount of data you can collect.

**Tips on Reducing Variance**  Because measurement variance is such an important factor in sample size estimation for these types of studies, it generally makes sense to attempt to manage variance (although in some situations, such management is out of a practitioner's control). Here are some ways to reduce variance:

- Make sure that participants understand what they are supposed to do in the study. Unless potential participant confusion is part of the evaluation (and it sometimes is), it can only add to measurement variance.

- One way to accomplish this is through practice trials that allow participants to get used to the experimental situation without unduly revealing study-relevant information.

- If appropriate, use expert rather than novice participants. Almost by definition, expertise implies reduced performance variability (increased automaticity) (Mayer, 1997). With regard to reducing variance, the farther up the learning curve, the better.

- A corollary of this is that if you need to include both expert and novice users, you should be able to get equal measurement precision for both groups with unequal sample sizes (fewer experts required than novices—which is good, because experts are typically harder than novices to recruit as participants).

- If appropriate, study simple rather than complex tasks.

- Use data transformations for measurements that typically exhibit correlations between means and variances or standard deviations. For example, frequency counts often have proportional means and variances (treated with the square-root transformation), and time scores often have proportional means and standard deviations (treated with the logarithmic transformation) (Myers, 1979; Sauro and Lewis, 2010).

- For comparative studies, use within-subjects designs rather than between-subjects designs whenever possible.

- Keep user groups as homogeneous as possible (but although this reduces variability, it can, simultaneously, pose a threat to a study's external validity if the test group is more homogenous than the population under study) (Campbell and Stanley, 1963).

Keep in mind that it is reasonable to use these tips only when their use does not adversely affect the validity and generalizability of the study. Having a valid and generalizable study is far more important than reducing variability.

**Tips for Estimating Unknown Variance**  Parasuraman (1986) described a method for estimating variability if you have an idea about the largest and smallest values for a population of measurements but do not have the information you need to actually calculate the variability. Estimate the standard deviation (the square root of the variability) by dividing the difference between the largest and smallest values by 6. This technique assumes that the population distribution is normal and then takes advantage of the fact that 99% of a normal distribution will lie in the range of plus or minus three standard deviations of the mean.

Nielsen (1997) surveyed 36 published usability studies and found that the mean standard deviation for measures of expert performance was 33% of the mean value of the usability measure (in other words, if the mean completion time was 100 s, the mean standard deviation was about 33 s). For novice user learning the mean standard deviation was 46%, and for measures of error rates the value was 59%.

Churchill (1991) provided a list of typical variances for data obtained from rating scales. Because the number of items in the scale affects the possible variance (with more items leading to more variance), the table takes the number of items into account. For five-point scales, the typical variance is 1.2–2.0; for seven-point scales it is 2.4–4.0; and for 10-point scales it is 3.0–7.0. Because data obtained using rating scales tends to have a more uniform than normal distribution, he advises using a number nearer the high end of the listed range when estimating sample sizes.

Measurement theorists who agree with Steven's (1951) principle of invariance might yell "foul" at this point because they believe that it is not permissible to calculate averages or variances from rating scale data. There is considerable controversy on this point (see, e.g., Lord, 1953; Nunnally, 1978; Harris, 1985). Data reported by Lewis (1993) indicate that taking averages and conducting $t$-tests on multipoint rating data provides far more interpretable and consistent results than the alternative of taking medians and conducting Mann–Whitney $U$-tests. When you make claims about the meaning of the outcomes of your statistical tests you do have to be careful not to act as if rating scale data are

interval data rather than ordinal data. An average rating of 4 might be better than an average rating of 2, but you cannot claim that it is twice as good (a ratio claim), nor can you claim that the difference between 4 and 2 is equal to the difference between 4 and 6 (an interval claim).

### 3.1.2 Sample Size Estimation for Problem Discovery (Formative) Studies

"Having collected data from a few test subjects—and initially a few are all you need—you are ready for a revision of the text" (Al-Awar et al., 1981, p. 34). "This research does not mean that all of the *possible* problems with a product appear with 5 or 10 participants, but most of the problems that are going to show up with one sample of tasks and one group of participants will occur early" (Dumas, 2003, p. 1098).

Although these types of general guidelines have been helpful, it is possible to use more precise methods to estimate sample size requirements for problem discovery usability tests (Turner et al., 2006). Estimating sample sizes for tests that have the primary purpose of discovering the problems in an interface depends on having an estimate of $p$, characterized as the average likelihood of problem occurrence or, alternatively, the problem discovery rate. As with comparative studies, this estimate can come from previous studies using the same method and similar system under evaluation or can come from a pilot study. For standard scenario-based usability studies, the literature contains large-sample examples that show $p$ ranging from 0.08 to 0.46 (Hwang and Salvendy, 2007, 2009, 2010; Lewis, 1994). For heuristic evaluations, the reported value of $p$ from large-sample studies ranges from 0.08 to 0.60 (Hwang and Salvendy, 2007, 2009, 2010; Nielsen and Molich, 1990). The well-known (and often misused and maligned) guideline that five participants are enough to discover 80% of problems available for discovery is true only when $p$ equals .275. As the reported ranges of $p$ indicate, there will be many studies for which this guideline (or any similar guideline) will not apply, making it important for usability practitioners to obtain estimates of $p$ for their usability studies.

When estimating $p$ from a small sample, it is important to adjust its initially estimated value because a small-sample estimate of $p$ (e.g., fewer than 20 participants) has a bias that results in potentially substantial overestimation of its value (Hertzum and Jacobsen, 2003). A series of Monte Carlo experiments (Lewis, 2001) have demonstrated that a formula combining Good–Turing discounting with a deflation procedure provides a reasonably accurate adjustment of initial estimates of $p$ ($p_{est}$), even when the sample size for that initial estimate has as few as two participants (preferably four participants, though, because the variability of estimates of $p$ is greater for smaller samples) (Lewis, 2001; Faulkner, 2003). This formula for the adjustment of $p$ is

$$P_{adj} = \frac{1}{2}\left[\left(p_{est} - \frac{1}{n}\right)\left(1 - \frac{1}{n}\right)\right] + \frac{1}{2}\left(\frac{p_{est}}{1 + GT_{adj}}\right) \tag{7}$$

where $GT_{adj}$ is the Good–Turing adjustment to probability space (which is the proportion of the number of problems that occurred once divided by the total number of different discovered problems). The $p_{est}/(1 + GT_{adj})$ component in the equation produces the Good–Turing adjusted estimate of $p$ by dividing the observed, unadjusted estimate of $p$ ($p_{est}$) by the Good–Turing adjustment to probability space. The $(p_{est} - 1/n)(1 - 1/n)$ component in the equation produces the deflated estimate of $p$ from the observed, unadjusted estimate of $p$ and $n$ (the sample size used to estimate $p$). The reason for averaging these two different estimates is that the Good–Turing estimator tends to overestimate the true value of $p$, and deflation tends to underestimate it. For more details and experimental data supporting the use of this formula for estimates of $p$ based on sample sizes from 2 to 10 participants, see Lewis (2001).

***Adjusting the Initial Estimate of p***    Because this is a procedure not yet in common use by practitioners, this section contains a detailed illustration of the steps used to adjust an initial estimate of $p$. To start with, organize the problem discovery data in a table (e.g., Table 9) that shows which participants experienced which problems. With four participants and eight observed problems, there are 32 cells in the table. The total number of problem occurrences is 16, so the initial estimate of $p$ ($p_{est}$) is 0.50 (16/32). Note that averaging the proportion of problem occurrence across participants or across problems also equals 0.50.

To apply the Good–Turing adjustment, count the number of problems that occurred with only one participant. In Table 9 this happened for three problems (problems 4, 6, and 8) out of the eight unique problems listed in the table. Thus, the value of $GT_{adj}$ is 0.375 ($\frac{3}{8}$), and the value of $p_{est}/(1 + GT_{adj})$ is 0.36 (0.5/1.375).

**Table 9  Hypothetical Results for a Problem–Discovery Usability Study**

| Participant | Problem | | | | | | | | Count | Proportion |
|---|---|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | | |
| 1 | × | | × | | × | | × | × | 5 | 0.63 |
| 2 | × | × | | | × | | × | | 4 | 0.50 |
| 3 | × | | × | × | × | | | | 4 | 0.50 |
| 4 | × | × | | | | × | | | 3 | 0.38 |
| Count | 4 | 2 | 2 | 1 | 3 | 1 | 2 | 1 | 16 | |
| Proportion | 1.00 | 0.50 | 0.50 | 0.25 | 0.75 | 0.25 | 0.50 | 0.25 | | 0.50 |

To apply the deflation adjustment, start by computing $1/n$, which in Table 9 is 0.25 ($\frac{1}{4}$). The value of ($p_{est}$ − $1/n$)(1 − $1/n$) is 0.19 [(0.25)(0.75)].

The average of the two adjustments produces $p_{adj}$, which in this example equals 0.28 ((0.36 + 0.19)/2). In this example, the adjusted estimate of $p$ is almost half of the initial estimate.

***Using the Adjusted Estimate of p***  Once you have an appropriate (adjusted) estimate for $p$, you can use the formula $1 − (1 − p)^n$ [derivable from both the binomial probability formula (Lewis, 1982, 1994) and the Poisson probability formula (Nielsen and Landauer, 1993)] for various values of $n$ from, say, 1 to 20, to generate the curve of diminishing returns expected as a function of sample size. It is possible to get even more sophisticated, taking into account the fixed and variable costs of the evaluation (especially the variable costs associated with the study of additional participants) to estimate when running an additional participant will result in costs that exceed the value of the additional problems discovered (Lewis, 1994).

The Monte Carlo experiments reported in Lewis (2001) demonstrated that an effective strategy for planning the sample size for a usability study is first to establish a problem discovery goal (e.g., 90% or 95%). Run the first two participants and, based on those results, calculate the adjusted value of $p$ using equation (7). This provides an early indication of the probable sample size required, which might estimate the final sample size exactly or, more likely, underestimate by one or two participants (but will provide an early estimate of the required sample size). Collect data from two more participants (for a total of four). Recalculate

the adjusted estimate of $p$ using equation (7) and project the required sample size using $1−(1−p)^n$. The estimated sample size requirement based on data from four participants will generally be highly accurate, allowing accurate planning for the remainder of the study. Practitioners should do this even if they have calculated a preliminary estimate of the required sample size from an adjusted value for $p$ obtained from a previous study.

Figure 1 shows the discovery rates predicted for problems of differing likelihoods of observation during a usability study. Several independent studies have verified that these types of predictions fit observed data very closely for both usability and heuristic evaluations (Lewis, 1994; Nielsen and Landauer, 1993; Nielsen and Molich, 1990; Virzi, 1990, 1992; Wright and Monk, 1991). Furthermore, the predictions work both for predicting the discovery of individual problems with a given probability of detection and for modeling the discovery of members of sets of problems with a given mean probability of detection (Lewis, 1994). For usability studies, the sample size is the number of participants. For heuristic evaluations, the sample size is the number of evaluators.

Table 10 shows problem detection sample size requirements as a function of problem detection probability and the cumulative likelihood of detecting the problem at least once during the study. The sample size required for detecting the problem twice during a study appears in parentheses. To use this information to establish a usability sample size, you need to determine three things:

1. What is the average likelihood of problem detection probability ($p$)? This plays a role

**Figure 1**  Predicted discovery as a function of problem likelihood.

**Table 10  Sample Size Requirements for Problem Discovery (Formative) Studies**

| Problem Occurrence Probability | Cumulative Likelihood of Detecting the Problem at Least Once (Twice) | | | | | |
|---|---|---|---|---|---|---|
| | 0.50 | 0.75 | 0.85 | 0.90 | 0.95 | 0.99 |
| 0.01 | 69 (168) | 138 (269) | 189 (337) | 230 (388) | 299 (473) | 459 (662) |
| 0.05 | 14 (34) | 28 (53) | 37 (67) | 45 (77) | 59 (93) | 90 (130) |
| 0.10 | 7 (17) | 14 (27) | 19 (33) | 22 (38) | 29 (46) | 44 (64) |
| 0.15 | 5 (11) | 9 (18) | 12 (22) | 15 (25) | 19 (30) | 29 (42) |
| 0.25 | 3 (7) | 5 (10) | 7 (13) | 9 (15) | 11 (18) | 17 (24) |
| 0.50 | 1 (3) | 2 (5) | 3 (6) | 4 (7) | 5 (8) | 7 (11) |
| 0.90 | 1 (2) | 1 (2) | 1 (3) | 1 (3) | 2 (3) | 2 (4) |

similar to the role of variance in the previous examples. If you do not know this value (from previous studies or a pilot study), you need to decide on the lowest problem detection probability that you want to (or have the resources to) tackle. The smaller this number, the larger the required sample size.

2.  What proportion of the problems that exist at that level do you need (or have the resources) to discover during the study (in other words, the cumulative likelihood of problem detection)? The larger this number, the larger the required sample size.

3.  Are you willing to take single occurrences of problems seriously or must problems appear at least twice before receiving consideration? Requiring two occurrences results in a larger sample size.

For values of $p$ or problem discovery goals that are outside tabled values, you can use the following formula [derived algebraically from Goal $= 1-(1-p)^n$] to compute the sample size required for a given problem discovery goal (taking single occurrences of problems seriously) and value of $p$:

$$n = \frac{\log(1 - \text{goal})}{\log(1 - p)} \qquad (8)$$

In the example from Table 9, the adjusted value of $p$ was 0.28. Suppose that the practitioner decided that the appropriate problem discovery goal was to find 97% of the discoverable problems. The computed value of $n$ is 10.6 ($\log(0.03)/\log(0.72)$, or $-1.522/-0.143$). The practitioner can either round the sample size up to 11 or adjust the problem discovery goal down to 96.3%-[$1-(1-0.28)^{10}$].

Lewis (1994) created a return-on-investment (ROI) model to investigate appropriate cumulative problem detection goals. It turned out that the appropriate goal depended on the average problem detection probability in the evaluation, the same value that has a key role in determining the sample size. The model indicated that if the expected value of $p$ was small (say, around 0.10), practitioners should plan to discover about 86% of the problems. If the expected value of $p$ was larger

(say, around 0.25 or 0.50), practitioners should plan to discover about 98% of the problems. For expected values of $p$ between 0.10 and 0.25, practitioners should interpolate between 87 and 97% to determine an appropriate goal for the percentage of problems to discover.

The cost of an undiscovered problem had a strong effect on the magnitude of the maximum ROI, but, contrary to expectation, it had only a minor effect on sample size at maximum ROI (Lewis, 1994). Usability practitioners should be aware of these costs in their settings and their effect on ROI (Boehm, 1981), but these costs have relatively little effect on the appropriate sample size for a usability study.

In summary, there is compelling evidence that the law of diminishing returns, based on the cumulative binomial probability formula, applies to problem discovery studies. To use this formula to determine an appropriate sample size, practitioners must form an idea about the expected value of $p$ (the average likelihood of problem detection) for the study and the percentage of problems that the study should uncover. Practitioners can use the ROI model from Lewis (1994) or their own ROI formulas to estimate an appropriate goal for the percentage of problems to discover and can examine data from their own or published usability studies to get an initial estimate of $p$ (which published studies to date indicate can range at least from 0.08 to 0.60). With these two estimates, practitioners can use Table 10 (or, for computations outside tabled values, the appropriate equations) to estimate appropriate sample sizes for their usability studies.

It is interesting to speculate that a new product that has not yet undergone any usability evaluation is likely to have a higher $p$ than an established product that has gone through several development iterations (including usability testing). This suggests that it is easier (takes fewer participants) to improve a completely new product than to improve an existing product (as long as that existing product has benefited from previous usability evaluation). This is related to the idea that usability testing is a hill-climbing procedure, in which the results of a usability test are applied to a product to push its usability up the hill. The higher up the hill you go, the more difficult it becomes to go higher, because you have already weeded out the problems that were easy to find and fix.

Practitioners who wait to see a problem at least twice before giving it serious consideration can see from Table 10 the sample size implications of this strategy. Certainly, all other things being equal, it is more important to correct a problem that occurs frequently than one that occurs infrequently. However, it is unrealistic to assume that the frequency of detection of a problem is the only criterion to consider in the analysis of usability problems. The best strategy is to consider problem frequency and other problem data (such as severity and likelihood of use) simultaneously to determine which problems are most important to correct rather than establishing a cutoff rule such as "fix every problem that appears two or more times."

Note that, in contrast to the results reported by Virzi (1992), the results reported by Lewis (1994) did not indicate any consistent relationship between problem frequency and impact (severity). It is possible that this difference was due to the difference in the methods used to assess severity [judgment driven in Virzi (1992); data driven in Lewis (1994)]. Thus, the safest strategy is for practitioners to assume independence of frequency and impact until further research resolves the discrepancy between the outcomes of these studies.

It is important for practitioners to consider the risks as well as the gains when using small samples for usability studies. Although the diminishing returns for inclusion of additional participants strongly suggest that the most efficient approach is to run a small sample (especially if $p$ is high, if the study will be iterative, and if undiscovered problems will not have dangerous or expensive outcomes), human factors engineers and other usability practitioners must not become complacent regarding the risk of failing to detect low-frequency but important problems.

One could argue that the true number of possible usability problems in any interface is essentially infinite, with an essentially infinite number of problems with nonzero probabilities that are extremely close to zero. For the purposes of determining sample size, the $p$ we are really dealing with is the $p$ that represents the number of discovered problems divided by the number of discoverable problems, where the definition of a discoverable problem is vague but almost certainly constrained by details of the experimental setting, such as the studied scenarios and tasks and the skill of the observer(s). Despite this vagueness and some recent criticism of the use of $p$ to model problem discovery (Caulton, 2001; Schmettow, 2008, 2009; Woolrych and Cockton, 2001), these techniques seem to work reasonably well in practice (Lewis, 2006; Turner et al., 2006).

***Examples of Sample Size Estimation for Problem Discovery (Formative) Studies*** This section contains several examples illustrating the use of Table 10 as an aid in selecting an appropriate sample size for a problem discovery study.

A. Given the following problem discovery criteria:
- Detect problems with an average probability of 0.25
- Minimum number of detections required: 1
- Planned proportion to discover: 0.90

The appropriate sample size is nine participants.

B. Given the same discovery criteria, except that the practitioner requires problems to be detected twice before receiving serious attention:
- Detect problems with an average probability of 0.25
- Minimum number of detections required: 2
- Planned proportion to discover: 0.90

The appropriate sample size would be 15 participants.

C. Returning to requiring a single detection, but increasing the planned proportion to discover to 0.99:
- Detect problems with an average probability of 0.25
- Minimum number of detections required: 1
- Planned proportion to discover: 0.99

The appropriate sample size would be 17 participants.

D. Given the following extremely stringent discovery criteria:
- Detect problems with an average probability of 0.01
- Minimum number of detections required: 1
- Planned proportion to discover: 0.99

The sample size required would be 459 participants (an unrealistic requirement in most settings, implying unrealistic study goals).

Note that there is no requirement to run the entire planned sample through the usability study before reporting clear problems to development and getting those problems fixed before continuing. These required sample sizes are total sample sizes, not sample sizes per iteration. The following testing strategy promotes efficient iterative problem discovery studies and is similar to strategies published by a number of usability specialists (Bailey et al., 1992; Fu et al., 2002; Jeffries and Desurvire, 1992; Kantner and Rosenbaum, 1997; Macleod et al., 1997; Nielsen, 1993; Rosenbaum, 1989).

1. Start with an expert (heuristic) evaluation or one-participant pilot study to uncover the obvious problems. Correct as many of these problems as possible before starting the iterative cycles with step 2. List all unresolved problems and carry them to step 2.

2. Watch a small sample of participants (e.g., three or four) use the system. Record all observed usability problems. Calculate an adjusted estimate of $p$ based on these results and reestimate the required sample size.

3. Redesign based on the problems discovered. Focus on fixing high-frequency and high-impact problems. Fix as many of the remaining problems as possible. Record any outstanding problems so they can remain open for all following iterations.

4.  Continue iterating until you have reached your sample size goal (or must stop for any other reason, such as running out of time).

5.  Record any outstanding problems remaining at the end of testing and carry them over to the next product for which they are applicable.

This strategy blends the benefits of large and small sample studies. During each iteration, you observe only three or four participants before redesigning the system. Therefore, you can quickly identify and correct the most frequent problems (which means that you waste less time watching the next set of participants encounter problems that you already know about). With five iterations, for example, the total sample size would be 15–20 participants. With several iterations you will identify and correct many less frequent problems because you record and track the uncorrected problems through all iterations.

Note that using this sort of iterative procedure affects estimates of $p$ as you go along. The value of $p$ in the system you end with should generally be lower than the $p$ you started with (as long as the process of fixing problems does not create as many other problems). For this reason it is a good idea to recompute the adjusted value of $p$ after each iteration.

### Evaluating Sample Size Effectiveness Given Fixed $n$

Suppose that you know you have time to run only a limited number of participants, are willing to treat a single occurrence of a problem seriously, and want to determine what you can expect to get out of a problem discovery study with that number of participants. If that number were 6, for example, examination of Table 10 indicates:

-   You are almost certain to detect problems that have a 0.90 likelihood of occurrence (it only takes two participants to have a 99% cumulative likelihood of seeing the problem at least once).

-   You are almost certain (between 95 and 99% likely) to detect problems that have a 0.50 likelihood of occurrence (for this likelihood of occurrence, the sample size required at 95% is 5 and at 99% is 7).

-   You have a reasonable chance (about 80% likely) of detecting problems that have a 0.25 likelihood of occurrence (for this likelihood of occurrence, the required sample size at 75% is 5 and at 85% is 7).

-   You have a little better than even odds of detecting problems that have a 0.15 likelihood of occurrence (the required sample size at 50% is 5).

-   You have a little less than even odds of detecting problems that have a 0.10 likelihood of occurrence (the required sample size at 50% is 7).

-   You are not likely to detect many of the problems that have a likelihood of occurrence of 0.05 or 0.01 (for these likelihoods of occurrence, the

sample sizes required at 50% are 14 and 69 respectively).

This analysis illustrates that although a problem discovery study with a sample size of 6 participants will typically not discover problems with very low likelihoods of occurrence, the study is almost certainly worth conducting.

Applying this procedure to a number of different sample sizes produces Table 11. The cells in Table 11 are the probability of having a problem with a specified occurrence probability happen at least once during a usability study with the given sample size $(1-(1-p)^n)$. Practitioners who are uncomfortable with sample size estimation procedures that implicitly assume a fixed number of problems available for discovery (Hornbæk, 2010) or are concerned with unmodeled variability of an averaged estimate of $p$ (Caulton, 2001; Schmettow, 2008; Woolrych and Cockton, 2001) can use Table 11 to plan their formative usability studies without those limitations.

### Estimating the Number of Problems Available for Discovery

Another approach to assessing sample size effectiveness is to estimate the number of undiscovered problems. Returning to the situation illustrated in Table 9, the adjusted estimate of $p$ is 0.28 with four participants and eight unique problems. The estimated proportion of problems discovered with those four participants is 0.73 $[1-(1-0.28)^4]$. If eight problems are about 73% of the total number of problems available for discovery, the total number of problems available for discovery (given the constraints of the testing situation) is about 11 (8/0.73). Thus, there appear to be about three undiscovered problems. With an estimate of only three undiscovered problems, the sample size of 4 is approaching adequacy.

Contrast this with the MACERR study described in Lewis (2001), which had an estimated value of $p$ of 0.16 with 15 participants and 145 unique problems. For this study, the estimated proportion of discovered problems at the end of the test was 0.927 $[1-(1-0.16)^{15}]$. The estimate of the total number of problems available for discovery was about 156 (145/0.927). With about 11 problems remaining available for discovery, it might be wise to run a few more participants.

On the other hand, with an estimated 92.7% of problems available for discovery extracted from the problem discovery space defined by the test conditions, it might make more sense to make changes to the test conditions (in particular, to make reasonable changes to the tasks) to create additional opportunities for problem discovery. This is one of many areas in which practitioners need to exercise professional judgment using the available tables and formulas to guide that judgment.

Note the use of the phrase "problems available for discovery." A given set of tasks and participants defines a pool of potentially discoverable usability problems from the set of all possible usability problems. Even within that restricted pool there will always be uncertainty regarding the "true" number of usability

**Table 11 Likelihood of Discovering Problems of Probability *p* at Least Once in a Study with Sample Size *n***

| *p* | N | | | | | | |
| --- | --- | --- | --- | --- | --- | --- | --- |
| | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| 0.01 | 0.02 | 0.03 | 0.04 | 0.05 | 0.06 | 0.07 | 0.08 |
| 0.05 | 0.10 | 0.14 | 0.19 | 0.23 | 0.26 | 0.30 | 0.34 |
| 0.10 | 0.19 | 0.27 | 0.34 | 0.41 | 0.47 | 0.52 | 0.57 |
| 0.15 | 0.28 | 0.39 | 0.48 | 0.56 | 0.62 | 0.68 | 0.73 |
| 0.25 | 0.44 | 0.58 | 0.68 | 0.76 | 0.82 | 0.87 | 0.90 |
| 0.50 | 0.75 | 0.88 | 0.94 | 0.97 | 0.98 | 0.99 | 1.00 |
| 0.90 | 0.99 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| *p* | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
| 0.01 | 0.09 | 0.10 | 0.10 | 0.11 | 0.12 | 0.13 | 0.14 |
| 0.05 | 0.37 | 0.40 | 0.43 | 0.46 | 0.49 | 0.51 | 0.54 |
| 0.10 | 0.61 | 0.65 | 0.69 | 0.72 | 0.75 | 0.77 | 0.79 |
| 0.15 | 0.77 | 0.80 | 0.83 | 0.86 | 0.88 | 0.90 | 0.91 |
| 0.25 | 0.92 | 0.94 | 0.96 | 0.97 | 0.98 | 0.98 | 0.99 |
| 0.50 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| 0.90 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| *p* | 16 | 17 | 18 | 19 | 20 | 25 | 30 |
| 0.01 | 0.15 | 0.16 | 0.17 | 0.17 | 0.18 | 0.22 | 0.26 |
| 0.05 | 0.56 | 0.58 | 0.60 | 0.62 | 0.64 | 0.72 | 0.79 |
| 0.10 | 0.81 | 0.83 | 0.85 | 0.86 | 0.88 | 0.93 | 0.96 |
| 0.15 | 0.93 | 0.94 | 0.95 | 0.95 | 0.96 | 0.98 | 0.99 |
| 0.25 | 0.99 | 0.99 | 0.99 | 1.00 | 1.00 | 1.00 | 1.00 |
| 0.50 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |
| 0.90 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 | 1.00 |

problems (Hornbæk, 2010). The technique described in this section is a way to estimate, not to guarantee, the likely number of discoverable problems.

***Some Tips on Managing p*** Because *p* (the average likelihood of problem discovery) is such an important factor in sample size estimation for usability tests, it generally makes sense to attempt to manage it (although in some situations such management is out of a practitioner's control). Here are some ways to increase *p*:

- Use highly skilled observers for usability studies.
- Use multiple observers rather than a single observer (Hertzum and Jacobsen, 2003).
- Focus evaluation on new products with newly designed interfaces rather than older, more refined interfaces.
- Study less skilled participants in usability studies (as long as they are appropriate participants).
- Make the user sample as heterogeneous as possible, within the bounds of the population to which you plan to generalize the results.
- Make the task sample as heterogeneous as possible.
- Emphasize complex rather than simple tasks.
- For heuristic evaluations, use examiners with usability and application-domain expertise (double experts) (Nielsen, 1992).

- For heuristic evaluations, if you must make a trade-off between having a single evaluator spend a lot of time examining an interface versus having more examiners spend less time each examining an interface, choose the latter option (Dumas et al., 1995; Virzi, 1997).

Note that some of the tips for increasing *p* are the opposite of those that reduce measurement variability.

### 3.1.3 Sample Sizes for Nontraditional Areas of Usability Evaluation

Nontraditional areas of usability evaluation include activities such as the evaluation of visual design and marketing materials. As with traditional areas of evaluation, the first step is to determine if the evaluation is comparative/parameter estimation or problem discovery.

Part of the problem with nontraditional areas is that there is less information regarding the values of the variables needed to estimate sample sizes. Another issue is whether these areas are focused inherently on detecting more subtle effects than is the norm in usability testing, which has a focus on large low-variability effects (and correspondingly small sample size requirements). Determining this requires the involvement of someone with domain expertise in these nontraditional areas. It seems, however, that even these nontraditional areas would benefit from focusing on the discovery of large

low-variability effects. Only if there were a business case which held that investment in a study to detect small, highly variable effects would ultimately pay for itself should you conduct such a study.

For example, in *The Survey Research Handbook*, Alreck and Settle (1985) point out that the reason that survey samples rarely contain fewer than several hundred respondents is due to the cost structure of surveys. The fixed costs of the survey include activities such as determining information requirements, identifying survey topics, selecting a data collection method, writing questions, choosing scales, composing the questionnaire, and so on. For this type of research, the additional or marginal cost of including hundreds of additional respondents can be very small relative to the fixed costs. Contrast this with the cost (or feasibility) of adding participants to a usability study in which there might be as little as a week or two between the availability of testable software and the deadline for affecting the product, with resources limiting the observation of participants to one at a time and the test scenarios requiring two days to complete. The potentially high cost of observing participants in usability tests is one reason why usability researchers have devoted considerable attention to sample size estimation, despite some assertions that sample size estimation is relatively unimportant (Wixon, 2003).

"Since the numbers don't know where they came from, they always behave just the same way, regardless" (Lord, 1953, p. 751). What potentially differs for nontraditional areas of usability evaluation is not the behavior of numbers or statistical procedures, but the researchers' goals and economic realities.

### 3.2   Confidence Intervals

A major trend in modern statistical evaluation has been a reduced focus on hypothesis testing and a move toward more informative analyses such as effect sizes and confidence intervals (Landauer, 1997). For most applied usability work, confidence intervals are more useful than effect sizes because they have the same units of measurement as the variables from which they are computed. Even when confidence intervals are very wide, they can still be informative, so practitioners should routinely report confidence intervals for their measurements (Sauro, 2006). Although 95% confidence is a commonly used level, confidence as low as 80% will often be appropriate for applied usability measurements (Nielsen, 1997).

### 3.2.1   Intervals Based on *t*-Scores

Formulas for the computation of confidence intervals based on *t*-scores are algebraically equivalent to those used to estimate required sample sizes for measurement-based usability tests, but isolate the critical difference (*d*) instead of the sample size (*n*):

$$d = \text{SEM} \times t_{\text{crit}} \qquad (9)$$

where SEM is the standard error of the mean (the standard deviation, *S*, divided by the square root of

the sample size, *n*) and $t_{\text{crit}}$ is the *t*-value associated with the desired level of confidence (found in a *t*-table, available in most statistics texts). (Practitioners who are concerned about departures from normality can perform a logarithmic transformation on their raw data before computing the confidence interval, then transform the data back to report the mean and confidence interval limits.)

For example, suppose a task in a usability test with seven participants has an average completion time of 5.4 min with a standard deviation of 2.2 min. The SEM is 0.83 ($2.2/7^{1/2}$). For 90% confidence and 6 ($n-1$) degrees of freedom, the tabled value of *t* is 1.943. The computed value of *d* is 1.6 [(0.83)(1.943)], so the 90% confidence interval is 5.4 ± 1.6 min.

As a second example, suppose that the results of a within-subjects test of the time required for two installation procedures showed that the mean of the difference scores (version A minus version B) was 2 min with a standard deviation of 2 min for a sample size of eight participants. The SEM is 0.71 ($2/8^{1/2}$). For 95% confidence and 7 ($n-1$) degrees of freedom, the tabled value of *t* is 2.365. The computed value of *d* is 1.7 [(0.71)(2.365)], so the 95% confidence interval is 2.0 ± 1.7 min (ranging from 0.3 to 3.7 min). Because the confidence interval does not contain a zero, this interval indicates that with $\alpha$ of 0.05 (where $\alpha$ is 1 minus the confidence expressed as a proportion rather than a percentage) you should reject the null hypothesis of no difference. The evidence indicates that version A takes longer than version B. The major advantage of a confidence interval over a significance test is that you also know with 95% confidence that the magnitude of the difference is probably no less than 0.3 min and no greater than 3.7 min. If the versions are otherwise equal, version B is the clear winner. If the cost of version B is greater than the cost of version A (e.g., due to a need to license a new technology for version B), the decision about which version to implement is more difficult but is certainly aided by having an estimate of the upper and lower limits of the difference between the two versions.

### 3.2.2   Binomial Confidence Intervals

As discussed above, confidence intervals constructed around a mean can be very useful. Many usability measurements, however, are proportions or percentages computed from count data rather than means. For example, the maximum-likelihood estimate of a usability defect rate for a specific problem is the proportion computed by dividing the number of participants who experience the problem divided by the total number of participants ($x/n$). There are other, potentially more accurate ways to estimate completion rates (Lewis and Sauro, 2006), such as the Laplace method [adding 1 to the numerator and denominator before computing the percentage, in other words, $(x + 1)/(n + 1)$], but for practical usability measurement, improving the point estimate of a percentage is less important than computing a binomial confidence interval.

The statistical term for a study designed to estimate proportions is a *binomial experiment*, because a given problem either will or will not occur for each trial

(participant) in the experiment. For example, a participant either will or will not install an option correctly. The point estimate of the defect rate is the observed proportion of failures (*p*). However, the likelihood is very small that the point estimate from a study is exactly the same as the true percentage of failures, especially if the sample size is small (Walpole, 1976). To compensate for this, you can calculate interval estimates that have a known likelihood of containing the true proportion (Steele and Torrie, 1960). You can use these binomial confidence intervals to describe the proportion of usability defects effectively, often with only a small sample (Lewis, 1996a). Cordes and Lentz (1986) and Lewis (1996a) provided BASIC programs for the computation of exact binomial confidence intervals. There are similar programs available at the website of the Southwest Oncology Group Statistical Center (SOGSC, 2004), the GraphPad website (GraphPad, 2004), and the Measuring Usability website (Sauro, 2004).

Some programs (Cordes and Lentz, 1986; Lewis, 1996a; SOGSC, 2004) produce binomial confidence intervals that always contain the exact binomial confidence interval. Other programs (GraphPad, 2004; Sauro, 2004) also produce a new type of interval called *approximate* binomial confidence intervals (Agresti and Coull, 1998). Exact and approximate binomial confidence intervals differ in a number of ways. An exact binomial confidence interval guarantees that the actual confidence is equal to or greater than the nominal confidence. An approximate interval guarantees that the average of the actual confidence in the long run will be equal to the nominal confidence, but for any specific test, the actual confidence could be lower than the nominal confidence. On the other hand, approximate binomial confidence intervals tend to be narrower than exact intervals. When sample sizes are large (*n* > 100), the two types of intervals are virtually indistinguishable. When sample sizes are small, though, there can be a considerable difference in the width of the intervals, especially when the observed proportion is close to 0 or 1. The exact interval often has an actual confidence closer to 99% when the nominal confidence is 95%, making it too conservative.

Monte Carlo studies that have compared exact and approximate binomial confidence intervals using standard statistical distributions (Agresti and Coull, 1998) and data from usability studies (Sauro and Lewis, 2005) generally support the use of approximate rather than exact binomial confidence intervals. When the actual confidence of an approximate binomial confidence interval is below the nominal level, the actual level tends to be close to the nominal level. For example, Agresti and Coull (1998, p. 125) found that the actual level for 95% approximate binomial confidence intervals using the adjusted-Wald method was never less than 89%:

In forming a 95% confidence interval, is it better to use an approach that guarantees that the actual coverage probabilities are *at least* .95 yet typically achieves coverage probabilities of about .98 or .99, or an approach giving narrower intervals for which the actual coverage probability could be less than .95 but

is usually quite *close* to .95? For most applications, we would prefer the latter.

This conclusion, that using approximate binomial confidence intervals will tend to produce superior decisions relative to the use of exact intervals, seems to apply to usability test data (Sauro and Lewis, 2005). If, however, it is critical for a specific test to achieve or exceed the nominal level of confidence, then it is reasonable to use an exact binomial confidence interval.

When using binomial confidence intervals, note that if the failure rate is fairly high, you do not need a very large sample to acquire convincing evidence of failure. In the first evaluation of a wordless graphic instruction (Lewis and Pallo, 1991), 9 of 11 installations (82%) were incorrect. The exact 90% binomial confidence interval for this outcome ranged from 0.53 to 0.97. This interval allowed us to argue that, without intervention, the failure rate for installation would be at least 53% (and more likely closer to the observed 82%).

This suggests that a reasonable strategy for binomial experiments is to start with a small sample size and record the number of failures. From these results, compute a confidence interval. If the lower limit of the confidence interval indicates an unacceptably high failure rate, stop testing. Otherwise, continue testing and evaluating in increments until you reach a specified level of precision or you reach the maximum sample size allowed for the study.

This method can rapidly demonstrate with a small sample that a usability defect is unacceptably high if the criterion is low and the true defect rate is high. Although the confidence interval will be wide (50 percentage points in the graphic symbols example), the lower limit of the interval may be clearly unacceptable. When the true defect rate is low or the criterion is high, this procedure may not work without a large sample size. The decision to continue sampling or to stop the study should be determined by a reasonable business case that balances the cost of continued data collection against the potential cost of allowing defects to go uncorrected.

You cannot use this procedure with small samples to prove that a success rate is acceptably high. With small samples, even if the defect percentage observed is zero or close to 0%, the interval will be wide, so it will probably include defect percentages that are unacceptable. For example, suppose that you have run five participants through a task and all five have completed the task successfully. The 90% confidence interval on the percentage of defects for these results ranges from 0 to 45%, with a 45% defect rate almost certainly unacceptable. If you had 50 out of 50 successful task completions, the 90% binomial confidence interval would range from 0 to 6%, which would indicate a greater likelihood of the true defect rate being close to 0%. The moral of the story is that it is relatively easy to prove (requires a small sample) that a product is unacceptable, but it is difficult to prove (requires a large sample) that a product is acceptable.

## 3.3 Standardized Usability Questionnaires

Standardized satisfaction measures offer many advantages to the usability practitioner. Specifically,

standardized measurements provide objectivity, replicability, quantification, economy, communication, and scientific generalization (Nunnally, 1978). Comparisons of the reliability of standardized versus ad hoc (home-grown) usability questionnaires consistently favor the use of standardized instruments (Hornbæk, 2006; Hornbæk and Law, 2007; Sauro and Lewis, 2009). The first published standardized usability questionnaires appeared in the late 1980s (Chin et al., 1988; Kirakowski and Dillon, 1988). Questionnaires focused on the measurement of computer satisfaction preceded these questionnaires (e.g., the Gallagher Value of MIS Reports Scale and the Hatcher and Diebert Computer Acceptance Scale) (see LaLomia and Sidowski, 1990, for a review), but these questionnaires were not applicable to scenario-based usability tests.

The most widely used standardized usability questionnaires are the QUIS (Chin et al., 1988), the SUMI (Kirakowski and Corbett, 1993; Kirakowski, 1996), the PSSUQ (Lewis, 1992, 1995, 2002), and the SUS (Brooke, 1996). The most common application of these questionnaires is at the end of a test (after completing a series of test scenarios). The ASQ (Lewis, 1991b) is a short three-item questionnaire designed for administration immediately following the completion of a test scenario. The ASQ takes less than a minute to complete. The longer standard questionnaires typically have completion times of less than 10 min (Dumas, 2003).

The primary measures of standardized questionnaire quality are reliability (consistency of measurement) and validity (measurement of the intended attribute) (Nunnally, 1978). There are several ways to assess reliability, including test–retest and split-half reliability. The most common method for the assessment of reliability is coefficient $\alpha$, a measurement of internal consistency. Coefficient $\alpha$ can range from 0 (no reliability) to 1 (perfect reliability). Measures that can affect a person's future, such as IQ tests or college entrance exams, should have a minimum reliability of 0.90 (preferably, reliability greater than 0.95). For other research or evaluation, measurement reliability in the range of 0.70–0.80 is acceptable (Nunnally, 1978; Landauer, 1997).

A questionnaire's validity is the extent to which it measures what it claims to measure. Researchers commonly use the Pearson correlation coefficient to assess criterion-related validity (the relationship between the measure of interest and a different concurrent or predictive measure). These correlations do not have to be large to provide evidence of validity. For example, personnel selection instruments with validities as low as 0.30 or 0.40 can be large enough to justify their use (Nunnally, 1978). Another approach to validity is content validity, typically assessed through the use of factor analysis (which also helps questionnaire developers discover or confirm clusters of related items that can form reasonable subscales).

Regarding the appropriate number of scale steps, it is true that more scale steps are better than fewer scales steps, but with rapidly diminishing returns. The reliability of individual items is a monotonically increasing function of the number of steps (Nunnally, 1978). As the number of scale steps increase from 2 to 20, the increase in reliability is very rapid at first but tends to level off at about 7. After 11 steps there is little gain in reliability from increasing the number. The number of steps in an item is very important for measurements based on a single item but is less important when computing measurements over a number of items (as in the computation of an overall or subscale score).

### 3.3.1 QUIS

The QUIS (Shneiderman, 1987; Chin et al., 1988; see also http://lap.umd.edu/QUIS/) is a product of the Human–Computer Interaction Lab at the University of Maryland. Its use requires the purchase of a license. Chin et al. (1988) evaluated several early versions of the QUIS (Versions 3–5). They reported an overall reliability (coefficient $\alpha$) of 0.94 but did not report any subscale reliability.

The QUIS is currently at Version 7. This version includes demographic questions, an overall measure of system satisfaction, and 11 specific interface factors. The QUIS is available in two lengths, short (26 items) and long (71 items). The items are nine-point scales anchored with opposing adjective phrases (such as "confusing" and "clear" for the item "messages which appear on screen").

### 3.3.2 CUSI and SUMI

The Human Factors Research Group (HFRG) at University College Cork published their first standardized questionnaire, the Computer Usability Satisfaction Inventory (CUSI), in 1988 (Kirakowski and Dillon, 1988). The CUSI was a 22-item questionnaire containing two subscales: affect and competence. Its overall reliability was 0.94, with 0.91 for affect and 0.89 for competence.

The HFRG replaced the CUSI with the SUMI (Kirakowski and Corbett, 1993; Kirakowski, 1996), a questionnaire that has six subscales: global, efficiency, affect, helpfulness, control, and learnability. Its 50 items are statements (such as "The instructions and prompts are helpful") to which participants indicate that they agree, are undecided, or disagree. The SUMI has undergone a significant amount of psychometric development and evaluation to arrive at its current form. The results of studies that included significant main effects of system, SUMI scales, and their interaction support its validity (McSweeney, 1992; Wiethoff et al., 1992). The reported reliabilities of the six subscales (measured with coefficient $\alpha$) are:

- Global: 0.92
- Efficiency: 0.81
- Affect: 0.85
- Helpfulness: 0.83
- Control: 0.71
- Learnability: 0.82

One of the greatest strengths of the SUMI is the database of results that is available for the construction of interpretive norms. This makes it possible for practitioners to compare their results with those of similar products and tasks [as long as there are similar products and tasks in the database; Cavallin et al. (2007) reported a significant effect of tasks on SUMI scores]. Another strength is that the SUMI is available in different

languages (such as UK English, American English, Italian, Spanish, French, German, Dutch, Greek, and Swedish). Like the QUIS, practitioners planning to use SUMI must purchase a license for its use (which includes questionnaires and scoring software). For an additional fee, a trained psychometrician at the HFRG will score the results and produce a report.

### 3.3.3  SUS

Usability practitioners at Digital Equipment Corporation (DEC) developed the SUS in the mid-1980s (Dumas, 2003). The 10 five-point items of the SUS provide a unidimensional (no subscales) usability measurement that ranges from 0 to 100. In the first published account of the SUS, Brooke (1996) stated that the SUS was robust, reliable, and valid but did not publish the specific reliability or validity measurements. With regard to validity, "it correlates well with other subjective measures of usability (e.g., the general usability subscale of the SUMI)" (Brooke, 1996, p. 194). According to Brooke (1996, p. 194), "the only prerequisite for its use is that any published report should acknowledge the source of the measure." The standard SUS consists of the following 10 items (odd-numbered items worded positively; even-numbered items worded negatively):

1. I think that I would like to use this system frequently.
2. I found the system unnecessarily complex.
3. I thought the system was easy to use.
4. I think that I would need the support of a technical person to be able to use this system.
5. I found the various functions in this system were well integrated.
6. I thought there was too much inconsistency in this system.
7. I would imagine that most people would learn to use this system very quickly.
8. I found the system very cumbersome to use.
9. I felt very confident using the system.
10. I needed to learn a lot of things before I could get going with this system.

To use the SUS, present the items to participants as five-point scales numbered from 1 (anchored with "Strongly disagree") to 5 (anchored with "Strongly agree"). If a participant fails to respond to an item, assign it a 3 (the center of the rating scale). After completion, determine each item's score contribution, which will range from 0 to 4. For positively worded items (1, 3, 5, 7, and 9), the score contribution is the scale position minus 1. For negatively worded items (2, 4, 6, 8, and 10), it is 5 minus the scale position. To get the overall SUS score, multiply the sum of the item score contributions by 2.5. Thus, SUS scores range from 0 to 100 in 2.5-point increments.

Since its initial publication, research on the SUS has led to some proposed changes in the original wording of the items. Finstad (2006) and Bangor et al. (2008)

recommend the use of the word "awkward" rather than "cumbersome" in item 8. The original SUS items refer to "system," but substituting the word "product" or the use of the actual product name in place of "system" seems to have no effect on SUS scores (Lewis and Sauro, 2009), but, of course, substitutions should be consistent across the items.

An early assessment of the SUS indicated reliability (assessed using coefficient $\alpha$) of 0.85 (Lucey, 1991). More recent estimates of SUS reliability indicate the reliability of the SUS is somewhat higher (0.91 from Bangor et al., 2008; 0.92 from Lewis and Sauro, 2009). Tullis and Stetson (2004) indirectly provided additional evidence of SUS reliability when they found that of five methods for assessing satisfaction with usability, the SUS was the quickest to converge on the "correct" conclusion regarding the usability of two websites as a function of sample size, where "correct" meant a significant $t$-test consistent with the decision reached using the total sample size.

In addition to being highly reliable, recent studies have shown evidence of the validity of the SUS. Bangor et al. (2008) reported that the SUS was sensitive to differences among types of interfaces and as a function of changes made to a product and showed concurrent validity (a significant correlation of 0.806 between the SUS and a single seven-point rating of user friendliness). Lewis and Sauro (2009) also found the SUS to be sensitive.

Another recent finding is that the SUS, long assumed to be a unidimensional measure, actually appears to have two components (Borsci et al., 2009; Lewis and Sauro, 2009), with items 1, 2, 3, 5, 6, 7, 8, and 9 aligning with a factor named "Usable" (coefficient $\alpha = 0.91$) and items 4 and 10 aligning with "Learnable" (coefficient $\alpha = 0.70$). Practitioners who use the SUS can continue doing so, but in addition to working with the overall SUS score, they can easily decompose it into its Usable and Learnable components, extracting additional information from their data with very little effort.

### 3.3.4  PSSUQ and CSUQ

The PSSUQ is a questionnaire designed for the purpose of assessing users' perceived satisfaction with their computer systems. It has its origin in an internal IBM project called SUMS (System Usability MetricS), headed by Suzanne Henry in the late 1980s. A team of human factors engineers and usability specialists working on SUMS created a pool of seven-point scale items based on the work of Whiteside et al. (1988) and from that pool selected 18 items to use in the first version of the PSSUQ (Lewis, 1992). Each item was worded positively, with the scale anchors "strongly agree" at the first scale position (1) and "strongly disagree" at the last scale position (7). A "not applicable" (NA) choice and a comment area were available for each item [see Lewis (1995) for examples of the appearance of the items].

The development of the Computer System Usability Questionnaire (CSUQ) followed the development of the first version of the PSSUQ. Its items are identical to those of the PSSUQ except that their wording is

appropriate for use in field settings or surveys rather than in a scenario-based usability test, making it, essentially, an alternative form of the PSSUQ. For a discussion of CSUQ research and comparison of the PSSUQ and CSUQ items, see Lewis (1995).

An unrelated series of IBM investigations into customer perception of usability revealed a common set of five usability characteristics associated with usability by several different user groups (Doug Antonelli, personal communication, January 5, 1991). The 18-item version of the PSSUQ addressed four of these five characteristics (quick completion of work, ease of learning, high-quality documentation and online information, and functional adequacy) but did not address the fifth (rapid acquisition of productivity). The second version of the PSSUQ (Lewis, 1995) included an additional item to address this characteristic, bringing the total number of items up to 19.

Lewis (2002) conducted a psychometric evaluation of the PSSUQ using data from several years of usability studies (primarily studies of speech dictation systems, but including studies of other types of applications). The results of a factor analysis on these data were consistent with earlier factor analyses (Lewis, 1992, 1995) used to define three PSSUQ subscales: system usefulness (SysUse), information quality (InfoQual), and interface quality (IntQual). Estimates of reliability were also consistent with those of earlier studies. Analyses of variance indicated that variables such as the specific study, developer, state of development, type of product, and type of evaluation significantly affected PSSUQ scores. Other variables, such as gender and completeness of responses to the questionnaire, did not. Norms derived from the new data correlated strongly with norms derived from earlier studies.

Significant correlation analyses indicated scale validity (Lewis, 1995). For a sample of 22 participants who completed all PSSUQ and ASQ items in a usability study (Lewis et al., 1990), the overall PSSUQ score correlated highly with the sum of the ASQ ratings that participants gave after completing each scenario [$r(20) = 0.80, p = 0.0001$]. The overall PSSUQ score correlated significantly with the percentage of successful scenario completions [$r(29) = -0.40, p = 0.026$]. SysUse [$r(36) = -0.40, p = 0.006$] and IntQual [$r(35) = -0.29, p = 0.08$] also correlated with the percentage of successful scenario completions.

One potential criticism of the PSSUQ has been that some items seemed redundant and that this redundancy might inflate estimates of reliability. Lewis (2002) investigated the effect of removing three items from the second version of the PSSUQ (items 3, 5, and 13). With these items removed, the reliability of the overall PSSUQ score (using coefficient $\alpha$) was 0.94 (remaining very high), and the reliabilities of the three subscales were:

- SysUse: 0.90
- InfoQual: 0.91
- IntQual: 0.83

All of the reliabilities exceeded 0.80, indicating sufficient reliability to be valuable as usability measurements

(Anastasi, 1976; Landauer, 1997). Thus, the third (and current) version of the PSSUQ has 16 seven-point scale items (see Table 12 for the items and their normative scores).

Note that the scale construction is such that lower scores are better than higher scores and that the means of the items and scales all fall below the scale midpoint of 4. With the exception of item 7 ("The system gave error messages that clearly told me how to fix problems"), the upper limits of the confidence intervals are below 4. This shows that practitioners should not use the scale midpoint exclusively as a reference from which they would judge participants' perceptions of usability. Rather, they should also use the norms shown in Table 12 (and comparison with these norms is probably more meaningful than comparison with the scale midpoint).

The way that item 7 stands out from the others indicates:

- It should not surprise practitioners if they find this in their own data.
- It is a difficult task to provide usable error messages throughout a product.
- It may well be worth the effort to focus on providing usable error messages.
- If practitioners find the mean for this item to be equal to or less than the mean of the other items in InfoQual (assuming that they are in line with the norms), they have been successful in creating better-than-average error messages.

The consistent pattern of relatively poor ratings for InfoQual versus IntQual [seen across all the studies; for details and complete normative data, see Lewis (2002)] suggests that practitioners who find this pattern in their data should not conclude that they have poor documentation or a great interface. Suppose, however, that this pattern appeared in the first iteration of a usability evaluation and the developers decided to emphasize improvement to the quality of their information. Any subsequent decline in the difference between InfoQual and IntQual would be evidence of a successful intervention.

Another potential criticism of the PSSUQ is that the items do not follow the typical convention of varying the tone of the items so that half of the items elicit agreement and the other half elicit disagreement (Swamy, 2007). The rationale for the decision to align the items consistently was to make it as easy as possible for participants to complete the questionnaire. With consistent item alignment, the proper way to mark responses on the items is clearer, potentially reducing response errors due to participant confusion. Also, the use of negatively worded items can produce a number of undesirable effects (Barnette, 2000; Ibrahim, 2001; Sauro and Lewis, 2011), including problems with internal consistency and factor structure. The setting in which balancing the tone of the items is likely to be of greatest value is when participants do not have a high degree of motivation for providing reasonable and honest responses (e.g., in clinical and educational settings).

**Table 12 PSSUQ Version 3 Items, Scales, and Normative Scores (99% Confidence Intervals)[a]**

| | | Norm (99% CI) | | |
| --- | --- | --- | --- | --- |
| Item/Scale | Item Text/Scale Scoring Rule | Lower Limit | Mean | Upper Limit |
| Q1 | Overall, I am satisfied with how easy it is to use this system. | 2.60 | 2.85 | 3.09 |
| Q2 | It was simple to use this system. | 2.45 | 2.69 | 2.93 |
| Q3 | I was able to complete the tasks and scenarios quickly using this system. | 2.86 | 3.16 | 3.45 |
| Q4 | I felt comfortable using this system. | 2.40 | 2.66 | 2.91 |
| Q5 | It was easy to learn to use this system. | 2.07 | 2.27 | 2.48 |
| Q6 | I believe I could become productive quickly using this system. | 2.54 | 2.86 | 3.17 |
| Q7 | The system gave error messages that clearly told me how to fix problems. | 3.36 | 3.70 | 4.05 |
| Q8 | Whenever I made a mistake using the system, I could recover easily and quickly. | 2.93 | 3.21 | 3.49 |
| Q9 | The information (such as on-line help, on-screen messages and other documentation) provided with this system was clear. | 2.65 | 2.96 | 3.27 |
| Q10 | It was easy to find the information I needed. | 2.79 | 3.09 | 3.38 |
| Q11 | The information was effective in helping me complete the tasks and scenarios. | 2.46 | 2.74 | 3.01 |
| Q12 | The organization of information on the system screens was clear. | 2.41 | 2.66 | 2.92 |
| Q13 | The interface[b] of this system was pleasant. | 2.06 | 2.28 | 2.49 |
| Q14 | I liked using the interface of this system. | 2.18 | 2.42 | 2.66 |
| Q15 | This system has all the functions and capabilities I expect it to have. | 2.51 | 2.79 | 3.07 |
| Q16 | Overall, I am satisfied with this system. | 2.55 | 2.82 | 3.09 |
| *SysUse* | Average items 1–6. | 2.57 | 2.80 | 3.02 |
| *InfoQual* | Average items 7–12. | 2.79 | 3.02 | 3.24 |
| *IntQual* | Average items 13–15. | 2.28 | 2.49 | 2.71 |
| *Overall* | Average items 1–16. | 2.62 | 2.82 | 3.02 |

*Source*: Lewis (2002).
[a] SysUse, system usefulness; InfoQual, information quality; IntQual, interface quality; CI, confidence interval. Scores can range from 1 (strongly agree) to 7 (strongly disagree), with lower scores better than higher scores.
[b] The ''interface'' includes those items that you use to interact with the system. For example, some components of the interface are the keyboard, the mouse, the microphone, and the screens (including their graphics and language).

Obtaining reasonable and honest responses is rarely a problem in most usability testing settings.

Additional key findings and conclusions from Lewis (2002) were:

- There was no evidence of response styles (especially, no evidence of extreme response style) in the PSSUQ data.
- Because there is a possibility of extreme response and acquiescence response styles in cross-cultural research (Baumgartner and Steenkamp, 2001; Clarke, 2001; Grimm and Church, 1999; van de Vijver and Leung, 2001), practitioners should avoid using questionnaires for cross-cultural comparison unless that use has been validated. Other types of group comparisons with the PSSUQ are valid because any effect of response style should cancel out across experimental conditions.
- Scale scores from incomplete PSSUQs were indistinguishable from those computed from complete PSSUQs. These data do not provide information concerning how many items a participant might ignore and still produce reliable

scale scores. They do suggest that, in practice, participants typically complete enough items to produce reliable scale scores.

The similarity of psychometric properties across the various versions of the PSSUQ, despite the passage of time and differences in the types of systems studied, provides evidence of significant generalizability for the questionnaire, supporting its use by practitioners for measuring participant satisfaction with the usability of tested systems. Due to its generalizability, practitioners can confidently use the PSSUQ when evaluating different types of products and at different times during the development process. The PSSUQ can be especially useful in competitive evaluations (for an example, see Lewis, 1996b) or when tracking changes in usability as a function of design changes made during development. Practitioners and researchers are free to use the PSSUQ and CSUQ (no license fees), but anyone using them should cite the source.

### 3.3.5 ASQ

The ASQ (Lewis, 1991b, 1995) is an extremely short questionnaire (three seven-point scale items using

the same format as the PSSUQ). The items address three important aspects of user satisfaction with system usability: ease of task completion ("Overall, I am satisfied with the ease of completing the tasks in this scenario"), time to complete a task ("Overall, I am satisfied with the amount of time it took to complete the tasks in this scenario"), and adequacy of support information ["Overall, I am satisfied with the support information (on-line help, messages, documentation) when completing tasks"]. The overall ASQ score is the average of responses to these three items.

Because the questionnaire is short, it takes very little time for participants to complete, an important practical consideration for usability studies. Measurements of ASQ reliability (using coefficient $\alpha$) have ranged from 0.90 to 0.96 (Lewis, 1995). A significant correlation between ASQ scores and successful scenario completion [$r(46) = -0.40$, $p < 0.01$] in Lewis et al. (1990; analysis reported in Lewis, 1995) provided evidence of concurrent validity. Like the PSSUQ and CSUQ, the ASQ is available for free use by practitioners and researchers, but anyone using the ASQ should cite the source.

### 3.3.6   One-Question Posttask Usability Questionnaires

Sauro and Dumas (2009) compared three one-question rating types in a study with 26 participants, 5 tasks, and 2 software applications. The types were a Likert scale, a usability magnitude estimation (UME) judgment, and a subjective mental effort question (SMEQ). The SMEQ was a 150-point online slider scale with anchors at various points (e.g., "Not at all hard to do" at 0; "Tremendously hard to do" at about 113). The Likert type was an item that stated "Overall, this task was:" followed by seven radio buttons anchored on the left with "Very Easy" and on the right with "Very Difficult." All three types successfully distinguished between the applications, but the Likert and SMEQ types were more sensitive with small sample sizes and were easy to learn and quick to execute. For paper-based questionnaires, the Likert type would be the most effective. For online questionnaires, the Likert and SMEQ are about equally effective.

## 4   WRAPPING UP

### 4.1   Getting More Information about Usability Testing

This chapter has provided fundamental and some advanced information about usability testing, but there is only so much that you can cover in a single chapter. For additional chapter-length treatments of the basics of usability testing, see Nielsen (1997), Dumas (2003), and Dumas and Salzman (2006). There are also three well-known books devoted to the topic of usability testing: Dumas and Redish (1999), Rubin (1994), and Barnum (2002).

Dumas and Redish (1999) was the first of these book-length treatments of usability testing, making the content and references somewhat dated. The 1999 copyright date is a bit misleading, as the body of the book has not changed since its 1993 edition. The 1999 edition does include a new preface and some updated reading recommendations and provides excellent coverage of the fundamentals of usability testing.

Like Dumas and Redish (1999), the content and references of Rubin (1994) are out of date. It, too, covers the fundamentals of usability testing (which have not really changed for 25 years) very well and contains many useful samples of a variety of testing-related forms and documents.

Barnum (2002) is more recent but, at the time of writing this chapter, is almost 10 years old. It has a companion website (www.ablongman.com/barnum/) that includes sample reports and usability laboratory resources.

The most recent book on usability testing is the second edition of Rubin's *Handbook of Usability Testing*, coauthored with Dana Chisnell (Rubin and Chisnell, 2008). It also has a companion website (www.wiley.com/go/usabilitytesting).

Tullis and Albert's (2008) *Measuring the User Experience: Collecting, Analyzing and Presenting Usability Metrics* is a book-length treatment of usability measurement, with a companion website at www.measuringux.com.

Sauro and Lewis (2012) is a book-length treatment of statistical methods for usability testing and other user research applications.

For late-breaking developments in usability research and practice, there are a number of annual conferences that have usability evaluation as a significant portion of their content. Companies making a sincere effort in the professional development of their usability practitioners should ensure that their personnel have access to the proceedings of these conferences and should support attendance at one or more of these conferences at least every few years. These major conferences are:

- Usability Professionals Association (www.upassoc.org/)
- Human–Computer Interaction International (www.hci-international.org/)
- ACM Special Interest Group in Computer–Human Interaction (www.acm.org/sigchi/)
- Human Factors and Ergonomics Society (hfes.org/)
- INTERACT (held every two years; see, e.g., www.interact2005.org/)

### 4.2   Usability Testing: Yesterday, Today, and Tomorrow

It seems clear that usability testing (both summative and formative) is here to stay and that its general form will remain similar to the forms that emerged in the late 1970s and early 1980s. The last 30 years have seen the introduction of more usability evaluation techniques and some consensus (and some continuing debate) on the conditions under which to use the various techniques, either alone or in combination (Al-Wabil and Al-Khalifa, 2009; Hornbæk, 2010; Jarrett et al., 2009).

In the last 20 years, usability researchers have made significant progress in the areas of standardized usability questionnaires and sample size estimation for formative usability tests. More recently, there has been significant advancement in large-sample remote usability testing (Albert et al., 2010). Also, given its emerging focus on commercial self-service, it is reasonable to anticipate standardized usability questionnaires for the Internet (Bargas-Avila et al., 2009; Lascu and Clow, 2008), with extensions to address Internet-specific factors such as trust and other elements of customer satisfaction from the marketing research literature (Safar and Turner, 2005).

As we look to the future, usability practitioners should monitor the continuing research taking place in the scientific study of usability (Gillan and Bias, 2001). Of particular interest are the various proposed extensions of usability beyond effectiveness, efficiency, and satisfaction to include factors such as hedonics, aesthetics, safety, and flexibility (Bevan, 2009; Bødker and Sundblad, 2008; Hornbæk, 2006; Sonderegger and Sauer, 2010). If we expand the definition of usability in these ways, then do we risk obscuring the fundamental concept of usability?

In the meantime, practitioners will continue to perform usability tests, exercising professional judgment as required. Usability testing is not a perfect usability evaluation method in the sense that it does not guarantee the discovery of all possible usability problems, but it does not have to be perfect to be useful and effective. It is, however, important to understand its strengths, limitations, and current leading practices to ensure its proper (most effective) use.

# CHAPTER 47

# USER REQUIREMENTS COLLECTION AND ANALYSIS

**Dieter Spath, Fabian Hermann, Matthias Peissner and Sandra Sproll**
**Fraunhofer Institute for Industrial Engineering IAO**
**Stuttgart, Germany**

## 1  INTRODUCTION

Software and interactive system development is for markets and users. To get good products which people want to buy and use, much information is needed: information about user goals and tasks, needs, preferences, and wishes as well as specific information about functions or user interface solutions that are desirable, attractive, and efficient, all part of expressed *requirements*. The use of requirements in design and development projects ensures sufficient information flow between users and markets on the one hand and system developers and designers on the other. Developers use these guidelines to plan, focus, and evaluate their work. System designers use requirements as a valuable source of inspiration to come up with new solutions. Additionally, requirements play a key role in the level of project management. They are used to explain the project goals, plan the project, invite tenders, specify contracts, and so on. Thus, requirement specifications help to coordinate different project stakeholders and partners such as clients and contractors, different units, and end users. One common approach to getting a project started is to deliver an initial system outline by compiling a set of requirements, which is then elaborated on to a more precise technical requirements document (Davis, 1993).

Many of the project stakeholders who document, use, or work with requirements are often also *sources* of requirements. In particular, technical or marketing departments define requirements of all kinds, often again relying on diverse input channels. Informal channels include user and customer contacts in sales, support, and help desks as well as user organizations and Web-based product feedback. Results from market research

or product management are often more formalized and thus can deliver general input for the definition of product features or detailed requirements and ideas for functionalities and user interface solutions.

Different levels of detail and scope of requirements and their different usages in the engineering processes have been discussed extensively, yielding a set of typical distinctions. An ongoing International Organization for Standardization (ISO) activity on system and software engineering uses the terms *user needs* and *user requirements*. In working draft ISO/IEC WD 25064 user needs are defined as "factors or conditions necessary for a user to achieve desired results" (ISO, 2010a, p. IV). User requirements, however, are "statements that provide the basis for design and evaluation of interactive systems to meet some or all of the identified user needs" (cf. ISO/IEC WD 25065; ISO, 2010b). This concept reflects the fact that user requirements are often formulated in terms of system features whereas user needs take a more general, user-centered perspective. In ISO/IEC WD 25065, diverse subtypes of requirements are distinguished: typical ergonomic aspects such as task-related and usability requirements, but also user characteristics, information about the context, or compatibility with standards is subsumed here. In software engineering (e.g., Sommerville, 2004), user requirements are seen as high-level descriptions typically formulated in natural language. They are separated from s*ystem requirements*, which are seen as more specific information resulting from an analysis phase: They are detailed specifications of system features, functions, or design solutions. Finally, the demarcation is not strict. In general, the term "user requirements" implies that the user's needs

and interests are in focus, even if technical or design solutions are specified.

A well-established distinction (e.g., ISO/IEC 24765; ISO,2009; Sommerville, 2004) is made between *functional* requirements describing system functionalities and services and *non-functional* requirements that specify quality aspects of the product (e.g., reliability, performance, usability). Nonfunctional requirements that relate to the development process, for example, delivery or procedure, serve the purpose of organizing the cooperation of an ordering and a contracting party.

## 2 METHODS AND APPROACHES FOR USER REQUIREMENTS COLLECTION

For the collection and analysis of user requirements, a number of methods have been established. These methods aim at systematically identifying user needs and specifying contextual conditions which need to be considered when designing user-friendly and efficient interactive systems.

The methods described in the following sections cover only a selection of the many requirements methods which are used in industry today. Other commonly used methods include stakeholder interviews (see, e.g., Fowler and Mangione, 1990) and extant systems analysis (Kirwan and Ainsworth, 1992), which applies well-established usability evaluation methods to existing, often competitive systems in order to identify user habits and expectations, typical problems of use, and best practice design approaches.

### 2.1 Task Analysis

Analyzing typical users' tasks and activities is often regarded as a first step toward understanding the user requirements of an interactive system. For instance, to understand the usage concerns of a specific workplace, the activities of this workplace are explored: What are the personal and organizational goals of individuals and groups in a workplace? What actions do they carry out to achieve these goals?

A popular approach for analyzing activities is hierarchical task analysis (HTA). In a HTA (e.g., Annett et al., 1971), the most relevant user tasks are identified and organized into a hierarchy. Tasks are broken down into subtasks, then operations and actions. HTA can be applied to physical tasks and break them down to a fine level of detail with atomic actions such as pressing a key. But HTA can be applied also to complex cognitive tasks such as planning and decision making. As a result, the task components are graphically represented in a structure chart. HTA entails identifying tasks, categorizing them, identifying the subtasks, and checking the overall accuracy of the model (Crystal and Ellington, 2004). Traditional task analysis assumes that there is one correct and complete description of a user task, and it aims at comprising the description consistently (Carroll, 2002).

The step-by-step transformation of a complex activity into an organized set of successive choices and actions is seen as the central strength of HTA (Rosson and Carroll, 2002). Thus, the resulting hierarchy can be analyzed in terms of completeness, complexity, and consistency.

Besides HTA, there are many other techniques for task analysis [see Kirwan and Ainsworth (1992) for an overview]. Although the techniques differ considerably in terms of focus and specific procedure, their contribution to user requirements analysis is quite the same. A detailed description of the interaction between a human and an interactive system serves as a framework for further analyses. For each step in the task completion process, human capabilities and limitations can be identified, and information needs or other enabling conditions can be specified. Thus, task analysis does not directly end in a set of user requirements, but it provides a detailed understanding and knowledge of user tasks and interactions from which requirements can be discovered.

### 2.2 Ethnography

Task analysis techniques focus on very specific aspects in human work. Some techniques focus more on the observable activities, whereas others highlight the cognitive processes in task completion. In contrast, ethnographic methods take a more holistic perspective. Ethnography developed from work in anthropology which focuses primarily on cultural aspects of humans and aims at understanding humans living within a social group, including rules, practices, and conventions (Spinuzzi, 2000). Ethnography is based on the idea that humans are best understood in the fullest possible context, including their environment and the improvements they make to it. Therefore, ethnographic methods are strong in developing a thick, rich multilayered representation of a user's work or communication habits. Originally, the focus of ethnography was on describing and interpreting cultural aspects, rather than using it as a design method (Blomberg, 1995). Nevertheless, many researchers have used ethnography to gather information for design work (e.g., Blomberg, 1995; Nardi, 1993; Nardi and O'Day, 1999). Many examples of the use of ethnography were concerned with the development of complex computer systems (e.g., Viller and Sommerville, 1999; Wales et al., 2002; D'Souza and Greenstein, 2003). These authors assess ethnography to be an effective approach for obtaining insights into individual work patterns and into the ways technology works within organizations.

In ethnographic studies, the researcher spends an extended period—months or even years—studying the users within their environment. The observation includes the users' behaviors and interactions between users and between users and devices (Martin et al., 2006). The research focuses on learning without preconceived ideas or questions. The main goal is to get immersed into an environment over time, record observations, and obtain insights which emerge from patterns they find in their observations (Spinuzzi, 2000). One prominent example using ethnography is the study of Sommerville et al. (1994) which describes the design process for a new air traffic control computer system. In this study, researchers spent several months

observing the controllers' behaviors and interactions and reading their manuals.

In contrast to the systematic approaches of task analysis, ethnography is exploratory and open ended with emphasis upon discovery. Therefore, it is often especially suitable for identifying unmet or ill-met user needs (cf. Martin et al., 2006). By recording verbal and nonverbal behavior, certain aspects of the environment and usage situation can be identified which are not even obvious to the users themselves (Martin et al., 2006). According to D'Souza and Greenstein (2003, p. 263), "this results in discovering latent needs—those needs of which a user is not aware, that when met, bring a high level of satisfaction."

Ethnographic methods can provide extremely detailed insights into an environment. However, it is also intrusive, time consuming, and therefore extremely expensive. Spinuzzi (2000) indicates it takes 6–12 months for an ethnography study in which researchers observe users working, attending meetings, and so on. Moreover, data analysis is quite costly given the huge amount of gathered data which is mainly qualitative. Therefore, in human–computer interaction (HCI), ethnography is often considered to be impractical as a requirements collection method in design projects, at least in its purest form (Martin et al., 2006).

## 2.3 Contextual Inquiry

Contextual inquiry (CI) is an ethnographic study refined to suit the needs of industrial system design projects in HCI (Holtzblatt and Beyer, 1993). It starts from the assumption that task analysis and self-reports in interviews and discussions often lack important context information. People tend to rationalize their behavior (Ericsson and Simon, 1993) and describe their activities in a prescribed or most typical version. According to Rosson and Carroll (2002), it is important to focus also on tacit or "unofficial" knowledge when collecting and analyzing user requirements. They state that a lot of the users' knowledge is unconscious until users carry out activities or are confronted with their behavior. However, tacit knowledge is considered to be valuable as it often contains the "fixes" and "enhancements" developed informally to address the problems. Thus, CI is a method for probing the end users' conscious and unconscious knowledge in the field.

CI was developed as a field method from the realms of psychology, anthropology, and sociology (Darroch and Silvers, 1982) in connection with the larger design method contextual design (Beyer and Holtzblatt, 1998), where it can be used throughout the development cycle. Thereby, it is often used to gather requirements for a variety of products and systems. Like ethnographic research methods, CI supports an understanding of current practices as a basis for developing a system model that fits users' requirements (Holtzblatt and Jones, 1993). But CI adapts "ethnographic methods to fit the time and resource constraints of engineering" (Holtzblatt and Beyer, 1993, p. 93). Thereby, CI involves collecting detailed information about user activities by observing and interviewing the users while they actually carry out their activities in their normal environments. The goal is to understand how and why something is done or why something is not done (Beyer and Holtzblatt, 1998). The main questions on which to focus include: What is the user's work? What tools are currently used? What works well and why? What are the problems that should be addressed with the new technology? (Holtzblatt and Jones, 1993).

CI is based on four principles guiding the adoption and adaption of the technique to get valuable data:

1. The first and most basic requirement of CI is the principle of data gathering in the *context* of users' work. According to Beyer and Holtzblatt (1998), the key to getting good data is to go where the work happens and observe it while it happens. The context enables us to gather ongoing experiences rather than summary experiences. This is different from the data you get from, for example, questionnaires, because people usually tend to summarize and give overall impressions with one or two highlights. However, we are interested in the detailed structure of work. Furthermore, the context enables us to gather concrete data rather than abstract data, because it is based on in-the-moment experiences (Raven and Flanders, 1996). Concrete data help to identify requirements.

2. *Partnership* describes the relationship between the person performing the CI and the user working together as equals. The goal is to make them collaborators in understanding and exploring work issues. The conversation about work helps the user to become aware of aspects that were formerly invisible (Beyer and Holtzblatt, 1998). By alternating between watching and probing, a true partnership develops in which both partners identify requirements and think about design solutions (Chin et al., 1997; Beyer and Holtzblatt, 1998).

3. For requirement analysis it is necessary to use the language of the respective domain when describing the gathered data. Therefore, an *interpretation* of the observations in terms of their implication about work structure is essential (Beyer and Holtzblatt, 1998).

4. In CI, a clear *focus* steers the conversation. The focus—a perspective or set of concerns—supports the interviewer in keeping the conversation on the central topics. Unlike a structured interview, CI does not constrain the flexibility to follow a promising pathway in a conversation that might not have been in the list of questions (Raven and Flanders, 1996).

According to Beyer and Holtzblatt (1998), the most common structure for CI is the contextual interview. The interview takes place in a one-on-one interaction lasting for 2–3 h. The user performs typical tasks and discusses it with the interviewer. The typical structure includes the following steps:

1. The *conventional interview*, gathering summary data, aims to get to know the users and their issues. After explaining the procedure, the interviewer gets an overview of the work and asks for opinions about relevant tools.

2. The *transition* is the phase where the interviewer explains the rules of a contextual interview, that is, the user is observed while doing his or her work and interrupted by the interviewer whenever something is interesting.

3. The *contextual interview* is the phase where contextual data are gathered. Following the principles of context, partnership, interpretation, and focus, the interviewer is the apprentice, observing and taking notes, asking questions, and suggesting interpretations of behavior.

4. The *wrap-up* occurs at the end of the interview, when the interviewer summarizes his or her understanding of the work structures and tools. The user should finally correct and elaborate on the understanding.

To sum up, CI can be described as a systematic adaption of ethnography for the design of interactive systems. CI is considered to be a discovery method directed at eliciting user requirements (Wixon et al., 2002). It aims at understanding users' needs and requirements by observing and interviewing them in their real environments. The strength of the method is its high external validity. Formal and informal knowledge of the user can serve as the basis for the identification of user requirements.

## 2.4 Focus Groups

Conducting focus groups is a highly accepted method for involving users in the collection and analysis of user requirements (Garmer et al., 2004). The technique is used to identify user needs at early concept stages, to explore product attributes and features required by users and their relative importance, or to identify contextual problems (Martin et al., 2006). Kuniavsky (2003, p. 201) describes focus groups as "an excellent technique for uncovering what people think about a given topic. . . . They reveal what people perceive to be their needs, which is crucial when determining what should be part of an experience and how it should be presented."

Krueger and Casey (2000) describe focus groups in terms of five typical characteristics: (1) People with (2) certain characteristics (3) provide qualitative data (4) in a focused discussion (5) to develop an understanding of a topic of interest, for example, typical usage structures and evolving user needs and requirements:

1. Focus groups typically involve 5–10 people. A focus group should not be run with fewer participants in order to support lively discussions and have a variety of perspectives represented (Nielson, 1993). If there are more than 12 participants, the focus group could fragment into subgroups, for example, by sharing information only with neighbors (Krueger and Casey, 2000).

2. Participants in focus groups have certain characteristics that are important to the research questions. The researcher has to think of "Who can provide the type of information needed?" Participants should be similar regarding the aspects of interest, for example, homogeneity of partic-

ipants is determined by the research questions (Krueger and Casey, 2000). In general, homogeneity supports communication between group members, while heterogeneity provides wider perspective and innovation (Levine and Moreland, 1998; Stewart et al., 2006).

3. Focus groups provide qualitative data. The researcher aims to compare and contrast opinions across several groups. In an inductive process the researcher intends to develop an understanding of user needs and requirements based on discussions rather than coming to one conclusion (Krueger and Casey, 2000).

4. The discussion in focus groups has a clear focus on the topic of interest. Therefore, the set of questions is predetermined, phrased, and arranged in a natural, logical sequence. Usually, a session begins with more general questions getting people to think and talk. As the session continues, questions become more focused, gathering the most useful information near the end (Krueger and Casey, 2000). The moderator has to keep the discussion on track without inhibiting the free flow of ideas (Nielson, 1993). Questions should be easy, clear, and short, usually open ended, and include only dimensions of interest (Krueger and Casey, 2000).

5. Krueger and Casey (2000) point out that a focus group is aimed not at developing an understanding of a topic in terms of overall consensus but rather at understanding user needs and requirements in terms of the feelings and thoughts of the participants. Different opinions among group members help the researcher to identify how and why particular ideas are embraced or rejected (Stewart et al., 2006).

A focus group is a technique (Nielson, 1993) to explore user needs (Caplan, 1990; Greenbaum, 1998). While the moderator follows a preplanned questioning route, from a users' perspective, a session should feel free floating (Nielson, 1993). Through the interaction between the participants, focus groups generate spontaneous reactions and valuable ideas (Caplan, 1990). The interactive environment of a focus group help the members to ponder, reflect, and listen to experiences of others and compare their own personal reality to that of others (Krueger and Casey, 2000).

Focus groups are restricted to what the participants are aware of and what they can recall and articulate (Martin et al. 2006). Martin et al. (2006) suggest focus groups to be complemented by observations of relevant situations in order to gather information about user needs and requirements that cannot be articulated. To sum up, focus groups can collect user needs and requirements quickly and with relatively low cost. They provide an opportunity to interact directly with the users and gather a lot of data in the users' own words. Focus groups are an appropriate technique for different user groups (Stewart et al., 2006). A major challenge is the analysis and interpretation of the recorded data in order to specify user requirements appropriately.

## 2.5  Scenario Analysis

Scenarios have been used as a powerful design tool throughout the entire design process of an interactive system. Scenarios can facilitate all design activities by providing a lightweight way of creating and reusing usage situations (Carroll, 2000).

In this context a scenario is a description that contains actors, background information about the actors and their environments and goals, and sequences of actions or events (Go and Carroll, 2003). Scenarios are stories which are shared among various stakeholders. They can be expressed in various media and forms, for example, textual narratives, storyboards, video mock-ups, or scripted prototypes. In HCI, scenarios typically illustrate user tasks and interactions in a story format (Go and Carroll, 2006).

It is easier for end users and other stakeholders to relate to real-life examples rather than to abstract descriptions of the functions provided by the system. Moreover, scenarios facilitate the communication between designers and users as they can act as a vehicle of knowledge (Go and Carroll, 2003). For these reasons, it can be quite useful to develop a set of scenarios as a starting point for collecting and eliciting user requirements (cf. Sommerville, 2004).

Scenario-based design (SBD) (Caroll, 2002; Rosson and Carroll, 2002) is a systematic approach to ensuring that interaction design will remain focused on the needs and concerns of users throughout the entire design process. In SBD, new designs are developed on the basis of rich and participatory descriptions of all stakeholders and on the basis of a systematic analysis of current usage environments. SBD starts with scenario-based requirements analysis (SBRA), as described by Rosson and Carroll (2002) and illustrated in Figure 1.

At the beginning of the SBRA, analysts compose a *root concept* which describes the project vision and rationale, the assumptions that guide the development process and the initial analysis of project stakeholders in order to develop a shared understanding of the project's high-level goals (Rosson and Carroll, 2002).

In the subsequent *field studies,* current practise and activities that will be transformed by the future system are analyzed based on the root concept. Special attention is given to the needs and concerns of all stakeholders (Rosson and Carroll, 2002). Techniques of qualitative research, such as task observation and recording (Diaper, 1989) and stakeholder interviews or artefacts analysis, are employed.

Then, the collected data is discussed in several *summary* representations: Stakeholder profiles summarize general characteristics of each group and stakeholder diagrams show the relation among the different groups. Another summary documents the tasks of each stakeholder group. Also, tools and artefacts as well as general project themes are summarized (Rosson and Carroll, 2002). During this process, task analysis methods such as hierarchical task analysis (Shepard, 1989) and methods similar to the affinity diagram in contextual design (Beyer and Holzblatt, 1998) are valuable.

*Problem scenarios* tell stories of current practice by describing activities in the problem domain. They contain summary information on identified stakeholders, their key tasks and tools, and the artefacts they use. In a creative process, scenarios are developed. These scenarios are often entirely fictional but are based on real-world characters or observed episodes.

According to Rosson and Carroll (2002), the themes and relationships implicit in a scenario can be made more explicit by analyzing them in *claims*. A claim is seen as a description of trade-offs, that is, pros and

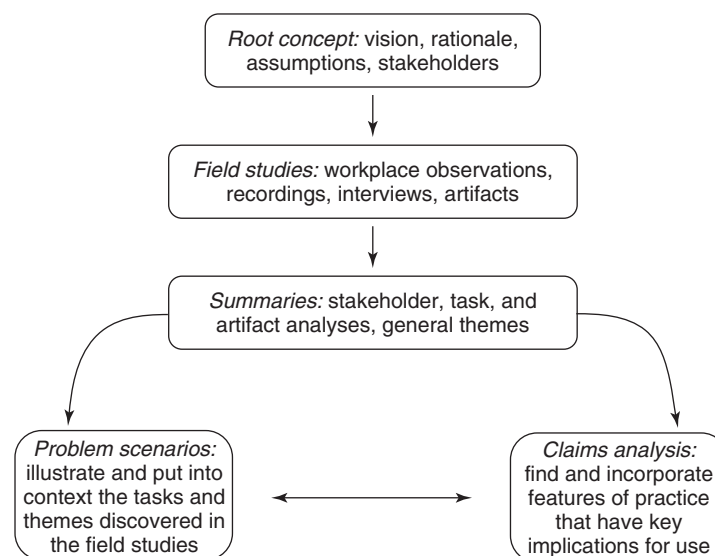

**Figure 1**  Overview of SBRA. (Rosson and Carroll, 2002.)

cons related to specific usability concerns (Go and Carroll, 2006). During requirement analysis, claims are analyzed by identifying features of a scenario that have significant positive or negative consequences for system use. A consequence is some impact on a person's ability to perform a task or enjoy the interaction (Rosson and Carroll, 2002). By explicitly stating the advantages and disadvantages of a specific feature, claims analysis provides a balanced view of both problems and opportunities. During requirements analysis, usually there is a tendency to focus on difficulties of current practice (Bødker, 1991; Nardi, 1996). The methodology of claim analysis ensures that well-working aspects of the current situation are also considered and serve as a basis for the new design (Rosson and Carroll, 2002).

Scenarios can serve as a vehicle for analyzing and specifying requirements and for supporting their transition into the next development phases. In contrast to other methods and formats with the same purposes, scenarios are written from a system's point of view and in a concrete, process-oriented way (Go and Carroll, 2004). Hooper and Hsia (1982) used scenarios in one of the earliest works as prototypes for representing the system for selected sequences of events. The users can simulate the real operations of a system and thus identify their actual needs and requirements. Whereas scenarios seem to provide significant advantages in communication concerns, they are criticized for their shortcomings in completeness and precision (cf. Diaper, 2002). Even an interactive system of average complexity can hardly be fully covered by a manageable number of interaction scenarios. For requirements analysis this means that the actual selection of scenarios will heavily influence and sometimes bias the set of requirements which can be identified. Diaper (2002) also criticizes the common strategy of defining scenarios in a very general (i.e., high level of abstraction) and vague (i.e., lack of detail) manner which allows for different interpretations and therefore misunderstandings in the requirements and design process.

### 2.6 Cultural Probes

"Cultural Probes" (Gaver et al., 1999) have become a prominent approach in interactive system design for exploring design spaces and learning more about user needs by engaging with future users in their situational contexts (e.g., Boehner et al., 2007; Boettcher, 2006; Crabtree et al., 2003; Gaver et al., 2004). Cultural probes originated in artist design and have been used in a number of innovate design projects (e.g., Presence project, and Equator IRC) to primarily inspire design activity (Blythe et al., 2003).

Gaver et al. (1999) introduced cultural probes to address a common dilemma in projects developing interactive products and services for unfamiliar user groups. This design-led approach (Gaver et al., 2004) meets the challenges of both understanding local cultures so that the design fits relevant needs and context aspects and ensuring that the design is not constrained by focusing on needs that are already understood. The aim is to lead discussions toward unexpected user needs and ideas. Unlike traditional approaches, Gaver et al. (1999)

intended to develop an approach for designing for pleasure, rather than for utility, that is, attention is directed to "playful" aspects and activities that are "meaningful and valuable" for humans, in contrast to production and efficiency (Gaver, 2001). Peoples' lives should be enriched in new and pleasurable ways by new technologies. The focus is on new understandings of technology by exploring experiences and functions beyond the norm. New pleasures, new forms of sociability, and unexpected user requirements can be discovered. Cultural probes elicit information of members of a user group and shed light on users' social, emotional, and aesthetic values and habits (Blythe et al., 2003).

Gaver et al. (2004) consider the probes as collections of evocative tasks provoking inspirational responses from the user groups. Thereby, cultural probes are packages of materials given to the participants. The participants use these materials to tell about their lives over a period of time and return the probes to the researchers. Within a probe package, participants can find postcards with images on the front or questions at the back about attitudes towards their lives, environments, or technology (e.g., "Tell us about your favorite device"), maps where they can mark zones (e.g., the zone where they would go to meet people), a camera to take pictures (e.g., of their home, their clothes, something desirable), or a photo album and media diary (e.g., for illustrating their past, current life, or anything meaningful). In this way, fragmentary data are gathered over a period of time providing subjective but inspirational glimpses into the lives and situational contexts of the participants (Boettcher, 2006).

Rather than defining a final set of requirements, the "inspirational data" gathered with the cultural probes stimulate the designers' imagination (Gaver et al., 1999). What should be reached is not an objective view of users' needs but a more impressionistic account of their desires and needs. Against the background that knowledge has limits, Gaver et al. (2004, p. 53) even stress that their "approach values uncertainty, play, exploration, and subjective interpretation as ways of dealing with those limits." Summarizing cultural probe data and using these data for classical requirements analysis seems to contradict Gaver's intentions. He argues against "asking specific questions" and "rationalizing" the probes and "summarizing returns" as this will lead to a loss of valuable information (Gaver et al., 2004). Nevertheless, methods were developed from moving cultural probe data toward classical requirements engineering considering subjectivity and interpretation [e.g., inclusion of agent-oriented software engineering (AOSE) in the cycle of cultural probe observation to production (Boettcher, 2006)].

## 3  ANALYSIS AND MANAGEMENT OF USER REQUIREMENTS

Most of the above-mentioned approaches deliver results that describe the user's needs, situations, and contexts in depth. Their goal is to give a vivid impression of the users and opportunities to assist them with the technology. In this way perhaps partial but valid information is

delivered which can inspire and guide the design work. Many user-oriented approaches do not claim to provide systematic requirements engineering: For example, Gaver et al. (2004) explicitly state that a systematic set of requirements is not delivered in the sense that working through the list will guarantee a satisfying product. In complex product development, user requirements will be integrated in systematic engineering approaches (e.g., Boettcher, 2006) to solve typical problems (e.g., Aurum and Wohlin, 2005; Kotonya and Sommerville, 1998; ISO, 2010b): User requirements must be balanced and negotiated with stakeholders; trade-offs, inconsistencies, and ambiguities must be solved; abstract goals must be elaborated to feasible design and technical solutions; priorities must be determined in case of restricted time and budget; and requirements must be traceable and validated.

### 3.1 Documentation Formats

A first step in working with user requirements is to record them in a standardized way. If empirical results serve as an input, for example, from interviews or observations, standardized documentation is a great first step in the interpretation and reduction of data. In most cases, raw empirical data will not have the quality needed to support decisions of developers, designers, managers, and whoever else uses the requirements documentation. Diverse standards formulate quality aspects for well-formed requirements and documents [e.g. Institute of Electrical and Electronics Engineers/American National Standards Institute (IEEE/ANSI) 830-1998]. ISO/IEC WD 25065 (ISO, 2010b) recommends a clear syntax to ensure the suitability for design and the verifiability of a user requirement. Different levels of abstraction are suggested, from the presence or absence of a particular system feature to quantifiable measurements, that is, in terms of user behavior, system response times, and so on.

A requirements specification document in practice may comprise diverse formats and types of information. Textual and narrative formats are often used in the beginning of projects while in later stages of the requirements elaboration more formalized formats may be used (Kotonya and Sommerville, 1998). In particular, functional requirements can be specified in task-based formats such as use cases. In addition to the differences, many approaches have some writing guidelines in common: for example, avoid giving detailed information on technical realization or user interface design but focus on user goals and system responsibility to achieve them (see, e.g., Constantine and Lockwood, 1999; Beyer & Holtzblatt, 1998).

Narrative formats such as *problem scenarios* and *claims* in scenario-based-design (see above) do not follow these recommendations. They do not specify features of a particular system, as their primary goal is to express user requirements by describing the needs and opportunities in the current situation. Similarly, *user stories* (e.g., Ramsin and Paige, 2008) are narrative descriptions of use situations. They are characterized by low levels of detail and should be as short as possible (Cohn, 2004). User stories should give an overall picture of the users' needs and values of the functionality as well as estimate development efforts but avoid giving too much information (e.g., on interaction flows). Again, the format reflects the status and role of requirements in the particular approach, in this case agile development (see below).

In contrast to narrative formats, *use cases* typically describe functional requirements in a more detailed manner. They focus on tasks and have a formal syntax, often as diagrams and tables. Typically, use cases comprise a task or function title and a sequence of system–user interactions. Use case models are mostly procedurally structured so that within a use case other sub–use cases can be called conditionally or unconditionally [e.g., the prominent format of Unified Modeling Language (UML) use cases in the unified process; Booch et al., 1998]. Some approaches stress the relation to other models in the software development process, such as the link of essential use cases (Constantine and Lockwood, 1999) to view models in graphical user interfaces. Many other task-related formats also follow a formalized syntax (e.g., using task diagrams).

### 3.2 User Requirements in Engineering Processes

In software engineering, the management of requirements is a central aspect described in all established development process models. Requirements are always the starting point in a project, but often requirements are changing or need to be detailed during the process. Since the beginning of formalized process descriptions, the question of how to deal with that problem in complex system development was discussed and "waterfall"-like development with successive steps was criticized as inappropriate (Royce, 1970).

Process models mostly define sequential phases of activities but foresee controlled steps back in order to correct or substantiate requirements specifications or other previous project results. Typically, an initial phase is dedicated to the collection, analysis, and documentation of requirements. In earlier models, iterations to change them are treated as rather exceptional cases (e.g., in object modeling technique; Rumbaugh et al., 1991). So-called evolutionary or incremental approaches (Bunse and von Knethen, 2008) implement preplanned iterations of analysis, development, prototype, and risk reviews (e.g., the spiral model; Boehm, 1988). In the iterations, different increments of the software system are focused, covering different parts of requirements. Incremental development often incorporates a step-by-step refinement of requirements. In the first phase ("inception") of the unified process (Booch et al., 1998), for example, only overall requirements on the business level are identified. The majority of requirements should be specified only in the second phase ("elaboration").

Together with iterative refinement, many process models build on prototyping in order to solve the problem of initially imprecise or unclear requirements. While requirements leave freedom for design, prototypes are concrete and can be used for evaluation and validation also for customers and users. This also is one of the

core ideas in human-centered design (ISO, 2010c), the central approach to implement usability engineering in software development. Human-centered design involves end users throughout the entire software development process by means of evaluations of system prototypes. In repeated iterations, requirements (and system design) are then refined on the basis of evaluation results.

Iterative and other "traditional" software development processes have been criticized as being inefficient for volatile projects dealing with fast-changing organizations, markets, and technologies. Predefined iterations are regarded as inflexible. Extensive specifications for requirements are considered to cause unjustifiable efforts of adapting, updating, and communication (see, e.g., Batra, 2009; Sillitti and Succi, 2005. Since the late 1990s, *agile software engineering approaches* such as extreme programming (Beck, 2003), Scrum (Schwaber, 2004), and Crystal (Cockburn, 2004) have tried to overcome these problems by focusing on communication and cooperation (Jiang and Eberlein, 2008). The "lightweight" management of requirements plays a key role in achieving the goal of effective processes: Lean description formats, in particular user stories, are used in the early phases to get an overall picture of the users' needs and values of a functionality and to estimate development efforts. Later, they are refined and elaborated as necessary by customers and users. By gathering information not before needed, no dispensable efforts are spent, and the current situation of the project is always considered. In Scrum, the project roles dealing with requirements are defined: A *product owner* representative of the customer is responsible for prioritizing requirements and passing them on to the executing team who decides which requirements to take and when. This approach of lean requirement documentation to reduce efforts and ensure direct, well-fitting information flow is still under discussion. While the potential strengths are obvious, it appears that the great responsibility of project stakeholders to ensure continuous and sound input also bears risk, for example, for requirements retention (Kelly, 2010).

## 4   CONCLUSIONS

Collecting and analyzing user requirements comprise the first and important step in the process of developing an interactive system. A deep understanding of contextual conditions and forces, user tasks and activities, and user needs is a major precondition for designing successful and user-friendly systems.

This chapter has presented a selection of methods for user requirements collection and analysis. The differences between the methods described here reflect different approaches and perspectives which can be taken in the early phases of system development. Task analysis is a very well-structured and analytical approach which fits directly into traditional engineering processes. It focuses on user activities, whereas other methods emphasize the importance of physical, organizational, and social contexts and environments (e.g., ethnography, contextual inquiry). These methods have a more

sociocultural origin. Methods such as scenario analysis have their strengths in supporting an easy communication between project stakeholders. Compared to more analytical approaches, these narrative methods can establish a vivid impression of use scenarios while they make it more difficult to cover requirements in a concise and complete manner. Cultural probes go one step further. Their purpose is not a complete or structured set of requirements. Cultural probes are appreciated for their exploratory and playful character, which supports inspiration and stimulates the designers' imagination. Requirements collection methods also differ in the extent to which they involve end users and rely on empirical data. In most cases, a combination of more analytical/theoretical (e.g., task analysis, scenario analysis) and empirical methods such as focus groups or contextual inquiries will yield best results.

To achieve the best value of collected and analyzed requirements, requirements must be effectively incorporated into the design and development process. The formats, in which requirements are delivered into the design process, highly influence the potential uptake by other project members. This chapter has discussed different formats from narrative to formal descriptions. From a modern perspective which appreciates lean and agile processes, it is not a question of preference between detailed formal descriptions and narratives but rather a question of when (in the development process) to use which format. In the early phases of the project, narrative user stories can support a common understanding of high-level objectives and general user needs. Later in the process, more elaborate and formal requirements descriptions will be needed in order to inform detailed design and development activities. The management of user requirements in today's development processes faces the challenge of permanent changes and refinements. Iterative design optimizations have to be supported and reflected on by iterative refinements on the level of user requirements.

## 1 INTRODUCTION

Virtually all users have encountered examples of good and bad sites in their interactions with the World Wide Web. Poor Web designs often lead to user frustration because users cannot easily access the information they are seeking, and this frustration may cause them to abandon the site. Having users abandon a site is undesirable in almost any case, as it defeats the purpose of disseminating information or providing services on the Web. Moreover, abandonment of a site is particularly harmful to e-businesses because it results in the loss of potential customers. Organizations that are successful in developing a good website and maintaining it will thus have a competitive edge over their rivals.

The first question to ask when designing a website should be: What is the goal of the website? Is the site's goal to sell the most widgets that company XYZ produces? Is it to provide a resource where scientific information relating to a certain topic can be found? Or, is it to be an entertainment site that users can visit in their recreation time? Although the task of posing this question may be simple, the answer is critical for determining the nature of the website as well as for driving the design and evaluation process for the site (see, e.g., Vu et al.,

2011). Clearly defining the goals for the website helps the designer focus on those aspects that are important to attaining the goal and determining the emphasis that is to be placed on each component.

Several basic types of websites are commonly encountered (Irie, 2004): information dissemination, portal, social networking/community, search, e-commerce, company information, and entertainment. Each of these types of websites is designed for specific purposes or goals and has characteristics unique to achieving those goals:

- News/information dissemination
  - *Goal*: to provide users with news or information
  - *Characteristic*: mostly text based, with minor graphics; simple and consistent navigation
  - *Example*: www.npr.com—NPR is a website that provides information about noncommercial news, talk, and entertainment programs.
- Portal
  - *Goal*: to provide links to other websites or resources
  - *Characteristic*: mostly uniform resource locator (URL) links, with minor descriptions of

the linked resources; usually organized alphabetically or by a keyword or theme

- *Example*: www.merlot.org—The Multimedia Educational Resource for Learning and Online Training (MERLOT) website provides free access to online learning materials for faculty and students of higher education.

- Social networking/community/communication
  - *Goal*: to provide a medium that promotes the community and provides opportunity for communication and interaction among users
  - *Characteristic*: usually in the form of message boards or chat rooms
  - *Example*: www.facebook.com—Facebook is a social networking site that allows individuals to set up profile pages to connect and share information with other people in their life.

- Search
  - *Goal*: to facilitate retrieval of specific information or resources
  - *Characteristic*: usually in the form of a search engine; the returned results page resembles a portal
  - *Example*: www.google.com—The Google website consists of a search engine that allows users to find information relating to a variety of topics.

- E-commerce
  - *Goal*: to allow companies to sell products or services; to allow users to purchase products or services
  - *Characteristic*: usually consists of a searchable catalog of products; must include a mechanism for secure online monetary transactions
  - *Example*: www.amazon.com—Amazon is a website that sells books and other products to users.

- Company/organization/product information
  - *Goal*: to provide specific information about a company, organization, or product
  - *Characteristic*: emphasis on company's or product's image/logo
  - *Example*: www.apple.com—The Apple website features products and services provided by the company, such as the iPhone4 and iPad.

- Entertainment
  - *Goal*: to provide pleasant interactions or entertainment resources for users
  - *Characteristic*: usually places emphasis on aesthetics; games and videos
  - *Example*: www.d-9.com—The District 9 website features video trailers and advertisement for the movie.

Once the goal for the website has been established, the next step is to determine what content should be placed in the site (Liao et al., 2010). It is important to distinguish content from aesthetics. Content design focuses primarily on the substance or information that is contained in the website, whereas aesthetics design focuses primarily on making the site visually pleasant or enjoyable. A good website can be informative as well as pretty and creative, which means that designing for content and aesthetics is not mutually exclusive. However, because the goal of many websites is to provide some type of service, it is usually more important to design for content than for aesthetics.

## 2 WEBSITE CONTENT

Websites should be designed with the end users in mind at all times because the sites are intended to support user activities (Proctor and Vu, 2010). The design process for Web interfaces proceeds in a manner similar to traditional usability engineering life cycles, which include a requirements analysis phase, a design, testing, and development phase, and an installation phase (see, e.g., Mayhew, 2011). It is important to note that design, evaluation, and development are iterative processes. That is, the design of the website should be evaluated as it is being developed so that usability problems can be identified and fixed. However, for ease of presentation, Web design issues are covered in this section and Section 3 of the chapter, and Web evaluation techniques are covered separately in Section 4.

### 2.1 Components of a Website

There are several major components of a website: its content, architecture and organization, the presentation of the content, and the programming logic that is used to integrate the content and its presentation within the site's structure. Content design and presentation can be broken down even further into specific components, such as page design, navigation, use of multimedia, search design, and URL design (see, e.g., Nielsen, 2000). On the recommendation of the World Wide Web Consortium (W3C), the international organization that creates Web standards [HyperText Markup Language (HTML), Extensible Markup Language (XML), etc.], Web designers have begun to programmatically separate content from presentation as much as possible. The main reason for this change is to build more flexibility into websites. When content is separated from presentation, it allows the content to be rendered on many different devices (e.g., mobile devices), displayed in many different formats (e.g., different color schemes), and changed quickly and easily. Separating content from presentation requires that the designer provide proper structure for content by marking it up with appropriate HTML tags (e.g., <p>) and employ cascading style sheets (CSSs) for presentation. The separation of content from presentation is also necessary for creating accessible websites because assistive technologies use the structural HTML tags to convey information to the user and present the content in accessible formats. Examples of how the same content marked up with identical HTML tags can be presented in many different ways with CSSs are available at the CSS Zen Garden (http://www.csszengarden.com/).

One way to determine the process involved in website design is to look at common design practices.

Newman et al. (2003; see also Newman and Landay, 2000) conducted a study in which 11 expert website designers were interviewed about various Web design projects to determine the practices in which Web designers customarily engage during the design process. They identified several specific areas to which the expert designers referred when describing the design process of a website:

- *Information design* includes identifying and grouping content so that individual components can be integrated and organized into a coherent whole.
- *Navigation design* includes methods for users to move through or access different parts of the website.
- *Graphics design* includes how to present individual pieces of information or content visually to the users (e.g., through images).
- *Information architecture* includes how to combine the information and navigation components so that the entire website functions as a unified entity.
- *User interface design* refers to designing and evaluating the usability of the website, including its informational and navigational components.

Although the areas listed above emphasize the major ones of concern for Web design, as identified by several Web design experts, there is some degree of overlap between the different areas. Newman et al. (2003) noted that most of the time the designers indicated that work in the areas of information design and navigation design preceded work on the graphics design. Because the Web consists of many individual components, designers should use the goal of the website to determine which components are more critical than others.

## 2.2 Content Preparation

The Web provides a medium for exchange of information and services to a global audience. Because of the potential impact that the Web can have on the success of an organization or company, it is important to have an effective content design that promotes the goals of the website. Unfortunately, it is often the case that websites are not designed in an effective manner. For example, although the goal of an e-commerce website is to sell the products, one study showed that users were not able to find specific items on e-commerce websites 36% of the time (Nielsen et al., 2000). After ten years, though, the situation does not seem to have improved much. The Web analytics firm iperceptions (2010) reported, in a survey of immediate postexperience feedback from over 400,000 e-commerce users, that 47% of users could not find what they were looking for at a site. If users cannot find an item, they cannot buy it. Thus, e-commerce websites that are designed to structure and organize their content in a manner that promotes the ease with which users can locate specific items will have a competitive edge over rival websites designed to achieve the same goal.

Content preparation refers to the processes involved in determining the information for the website to convey and how to organize, structure, and present that information so that it can be retrieved easily and efficiently when needed. Proctor et al. (2002b) summarized four major areas that Web designers should emphasize for content preparation [see also Proctor et al. (2003) and Liao et al. (2010)]. These areas include:

1. *Knowledge elicitation*: determining what type of information should be conveyed
2. *Structure and organization of information*: determining the best method to structure and organize information
3. *Retrieval of information*: determining the best methods for helping users search and retrieve information
4. *Presentation of information*: determining the medium in which information should be presented to the user

## 2.3 Knowledge Elicitation

When designing for the Web, knowledge should be elicited from two classes of users: experts and end users (Proctor et al., 2002b). Experts in Web design can provide valuable information, including (1) how to organize and present information in a manner that is consistent with human information-processing capabilities, (2) the functions and features that good websites should possess, (3) methods for enhancing the website's efficiency or effectiveness; and so on. The information that end users provide is usually not expert advice regarding how to design a website, but rather, information that is intended to help designers understand (1) the computing skills or level of knowledge of the end users; (2) the users' mental models, or representations, of the content that is contained in the website; (3) the specific pieces of information that users need when performing a task; and so on. Another way to characterize the different information provided by experts and end users is that end users reveal the type of information needed by them to achieve their goals, whereas experts determine how to organize and present that information in the most effective manner.

### 2.3.1 Eliciting Knowledge from Experts

A lot of information can be gained about how to design for the Web from interviewing experts and observing their work. Interviews are a well-known knowledge elicitation technique (e.g., Shadbolt and Burton, 1995) and can be one of the best methods for obtaining in-depth data from experts. In the study by Newman et al. (2003) mentioned earlier, expert designers were interviewed extensively to obtain information about their thought processes and involvement during an entire design process. The experts were asked to walk the interviewer through each phase of the project, showing examples of their "work in progress" if possible. Newman et al. report in detail the steps involved in creating a tutorial for a suite of computer-aided design (CAD) tools that can be accessed through the intranet

within a company or through the Internet remotely. The key steps identified by the expert are as follows:

1. *Discovery phase*: gathering background information about the project to determine the project scope, goals, and timeline for completion
2. *Design exploration phase*: generating sketches of initial variations of the design, including how the content will be structured, the individual pages, navigation, and the interaction sequence
3. *Design refinement phase*: creating high-fidelity mock-ups of the site, including the home page and second-level pages that can be accessed from the home page; choosing a limited set of the mock-up designs for further refinement and development; selecting a single refined mock-up to prototype in HTML
4. *Production phase*: writing up guidelines for the prototype so that a design team can turn the prototype into a working product

As illustrated by Newman et al.'s (2003) study, interviews from experts and observation of artifacts of their work can provide valuable information about the design process. However, there are numerous other methods that can be used to elicit knowledge from experts. Many of these techniques are described by Proctor et al. (2002b) and include the following:

- *Verbal Protocol Analysis*. Analysis of an expert's problem-solving strategies through examining the verbal protocols, obtained by having the experts "think aloud" as they solve problems or reflect on their thought processes when reviewing recordings of their performance during a problem-solving task.

- *Group Task Analysis*. Analysis of a group of experts' joint depiction about how a specific task is represented and processed. Usually, a flowchart is used to depict the individual steps required for performing a specific task.

- *Narratives and Scenarios*. Analysis of information contained in stories or narratives that experts tell about their activities. They often reveal valuable information about the goals of a particular task and the sequence of actions and events that lead to particular decisions and outcomes.

- *Critical Incident Reports*. Analysis of critical incidents that tested a person's expertise for the insight they provide into the processes involved an expert's decision making and reasoning when an unexpected or unusual event occurs.

When interviewing design experts is not feasible, a designer should refer to published papers and chapters on specific Web design issues of interest written by experts in the field [see Ratner (2003), Bidgoli (2004), and Vu and Proctor (2011) for edited volumes on the Internet and Web design]. Dorn and Guzdial (2010) found that, in addition to traditional books, technical reports, and information exchange between colleagues, Web designers often consult the Web to obtain sample

codes/demos and to gain access to learning materials such as online walkthroughs/tutorials, forums/blogs, podcasts, and so on.

When it comes to evaluating expertise, one question that can be asked is: Who is the expert (Flach, 2000)? Should websites be designed according to the wishes of the expert designers or are the end users the expert in this case? After all, the end users are the people for whom the website is intended. Most Web professionals would agree that the input of the end users is important when designing a website and evaluating its effectiveness. However, the end users should not be allowed to direct the design process because the features they desire for the website may be hard to implement or may lead to a less than optimal design when all factors are considered.

Below, different techniques for eliciting knowledge from end users are discussed. Many of these methods and techniques are used in the exploratory phases of Web design to understand the end users and their goals, representations of the task, likes and dislikes, and preferences. As a result, the term *understanding the user* is used to refer to this process rather than *knowledge elicitation* (see, e.g., Volk et al., 2011).

### 2.3.2 Understanding the User

The Web affords the opportunity for a site to be accessed anywhere, anytime, and with various devices (e.g., computer, laptop, personal data assistant, and cell phone). As a result, in initial or exploratory phases of Web design, it is important to obtain background information about the targeted user population, including the users' cognitive and physical capabilities, the tasks that they are likely to perform, the information needed to perform those tasks, and their roles and responsibilities (Stanney et al., 1997). For example, if the website is targeted for use by older adults, it is recommended that designers avoid using colors from the short-wavelength end of the visual spectrum (i.e., blue and green) and increase the resolution of elements on the screen so that the items can be seen more easily (Bitterman and Shalev, 2004). Moreover, different types of users may need to access different parts of the website. For example, an e-commerce merchant may want to access the U.S. Postal Service's website to request or print out mailing labels or to schedule a package pickup, whereas both the merchant and the consumer may access the site to track a package. Because different users have unique goals, the website must be designed to accommodate the tasks that the different user groups want and need to perform.

There are many different types of methods that can be employed to understand the users (see Kuniavsky, 2008; Proctor et al., 2002b; Volk et al., 2011, for reviews). Most of these methods are aimed at obtaining information regarding what users need to complete their task on the website, along with users' preferences for the site's options and features. Below are brief descriptions of the major methods, along with their goals and characteristics.

***Interviews***   As with experts, end users can be interviewed to obtain in-depth knowledge about their characteristics, opinions, and preferences. There are two

main types of interviews: structured and unstructured. In a structured interview, the interviewer asks the users questions from a prearranged list. In an unstructured interview, the interviewer allows users to express their thoughts on a topic freely. Structure and unstructured are two ends of a continuum. Most interviews fall somewhere in between these two ends, with the interviewer asking general questions, but the direction of the interview is dependent on the user's answers. Interviews of end users provide a large amount of qualitative data in which the evaluators often organize into topics or perform a content analysis of the data to identify themes and categories of information. The interviewers should try to avoid imposing their beliefs or opinions during the process. Caution must be taken when framing the questions to avoid biasing the users' answers, and at least two different evaluators should code the data to ensure that their interpretations of the answers match to some degree.

**Surveys and Questionnaires** Surveys and questionnaires consist of questions used to gather information about a user (e.g., How old are you? How often do you make online purchases?), obtain users' likes and dislikes [e.g., On a scale of 1 (do not like it at all) to 10 (like it a lot), indicate how much you like pop-up windows], and preferences (e.g., Do you prefer a dark font color on a light background or a light font color on a dark background?). Some advantages of using surveys and questionnaires include (1) obtaining data from a large sample in different demographic areas or specified user groups (e.g., previous customers or persons on an email list) is relatively easy (there are now many online survey service providers, e.g., SurveyMonkey.com), (2) the data can be obtained in a relatively short period of time, (3) if there are no open-ended questions, the data can be coded and summarized relatively easily, and (4) data from questionnaires and surveys can also be used to develop user profiles (see Kuniavsky, 2008). However, some disadvantages of using surveys and questionnaires include (1) not all targeted users chose to fill them out and submit their answers; (2) it may be difficult to verify the identity of the participants who submit their answers through the Web; (3) if the default code for "no response" on an item is not coded as such, the default value may be mistaken as the user's response rather than no response; (4) the framing of questions may affect the validity of the results; and (5) users' judgments and preferences may not correlate with their actual performance.

**Focus Groups** Unlike surveys and questionnaires, focus groups consist of a smaller number of users (usually, 5–10) but allow the users to interact with one another when discussing and evaluating different aspects or issues of the design. Problems and concerns about the website that may not have been identified by a single user can emerge during the group's interactions. A moderator usually directs the group to ensure that everyone participates and stays on the task so that all the topics wanting to be covered will get covered and that no single participant dominates the session. Proctor et al.

(2002b) noted that focus groups are best used to attain high-level goals, such as generating a list of functions or features for a product. Focus groups yield large amounts of qualitative data that must be organized and summarized. As with the previous methods, focus groups also suffer from the fact that the design judgments and preferences produced by the group may not correspond to designs that benefit performance. Furthermore, since the tasks and interface are evaluated in a context different from what the user is likely to experience during "real" use of the website, issues identified in the focus group may not always be of items of major concern.

**Naturalistic Observation** Observation and nonparticipatory contextual inquiries reflect more naturalistic techniques for understanding users. These methods rely on observing users' everyday interactions with the website in their natural surroundings and provide researchers with background information about the context in which a product is being used. This can be done by having researchers observe users performing Web tasks from "afar." It is important that the evaluator remain unnoticed, so that users' natural behaviors can be observed. Often, it is difficult for evaluators to remain unobtrusive. However, this can be done through the use of one-way mirrors or video cameras. Connecting rooms with one-way mirrors are often found in usability labs (described later) but do not capture the users in their natural environment unless they access the website in public locations (e.g., a library). Video cameras (or Web cameras) can be set in public locations to observe users. However, it is important that these cameras not be visible to users because they may change their interaction pattern if they know that they are being observed. Because data from observational methods are based on the users' actions, the conflict between users' verbal report and their actions is no longer an issue. However, it is often difficult for the observer to remain unnoticed, and the data obtained from the observer may reflect his or her biases and/or interpretation of the observed events.

**Ethnographic Studies** With ethnographic studies, which emerged from the field of anthropology, the researcher seeks to understand the users by immersing himself or herself in the targeted users' culture or work environment (Millen, 2000). The goal of the researcher is to become a natural member of the group so that he or she will be able to understand the views of the user groups and work with them to design products that meet their needs. Ethnographic studies can yield a customer–partner relationship that results in an effective medium for identifying the users' needs (Volk et al., 2011). However, there are many drawbacks to ethnographic methods as well. Ethnographic studies take a long time to conduct, suffer from the same disadvantages of interpretation and bias as other methods based on self-report or observational data, and may not result in general guidelines for product designs since the data are based on a very specific group of people.

**User Diary** The user diary allows the user to observe and record, in a diary, his or her actions with a product over a period of time. A typical diary study involves

asking participants to keep a diary of their daily activities with the product for a few days or weeks. However, Rieman (1993) noted that is often inconvenient for participants to keep a diary for more than two weeks. The diary method is based on a real-time tracking system. Diary logs can reveal qualitative data such as "critical incidents" that have occurred as well as descriptive data such as the time spent on each task. The disadvantage of traditional diary methods is that they rely on the conscientiousness of the participants, which may result in diaries of different qualities. Participants may forget to log the activities, may log information that they think the evaluators want, or provide vague or general summaries. However, with the availability of wireless connections, an online or video diary can be obtained by wearing a wireless video camera or Web camera that records the users' interaction with different websites. The video diary circumvents the traditional problems of users waiting until a convenient time to enter the data in their diary.

***Web Server Log Files***   A benefit of collecting data about website usage is that the site itself can be used as a data collection tool because the actions of the users are recorded as the users interact with the website. Server logs can provide designers valuable information about existing websites, such as "who" is visiting the site, the pages within the site that the users visit and the order in which those pages are accessed, how long the user spends looking at a particular page, and what items users search for (Pearrow, 2000). The benefits of evaluating data from log files are that a large amount of data can be obtained from users who access the site and the data collection process does not interfere with the users' interaction with the site. However, because information irrelevant to the design goals is logged, it may be difficult to sort through log files and important variables of interest may not have been logged. Zeng and Duan (2011) describe a technique for analyzing user activity such as clicking (analyzing mouse click sequences), selection (collecting Web postings), and propagation (estimating where users are likely to go). These activities can then be used in models to capture user Web behaviors.

### 2.3.3   Summary

This section summarized the major methods that are used to determine the processes involved in the website's design life cycle and how to extract the content to be conveyed by the website from experts and end users. Although these knowledge elicitation methods can yield substantial insight and data regarding the knowledge, expertise, and characteristics of designers and end users, the main drawback is that the methods rely on self-report data. Self-report data are vulnerable because there are well-known biases in self-reports (e.g., Isaacs, 1997), not all cognitive processes can be articulated clearly [see Anderson (1982) for a discussion of declarative versus procedural knowledge], analysis is based on the interpretation of the evaluators (see Proctor et al., 2002b; Volk et al., 2011), and users' preferences and judgments may not correlate with their performance (e.g., Bailey, 1993; Nielsen, 2001; Vu and Proctor, 2003).

### 2.4   Structuring and Organizing the Content

Once designers have identified or elicited the content that needs to be conveyed, they must structure and organize it in a manner that will allow effective presentation and retrieval of that information. It is important for designers to plan carefully how to structure and organize the content to be conveyed by the website because poor design of the information architecture leads to poor usability (Nielsen, 2000; iperceptions, 2010), making the website more difficult to use and less enjoyable to the end user. To create a good website, designers should be familiar with the following concepts (e.g., Chou, 2002):

- *Organizational schemes*: how the information is organized (e.g., by name, date, type, association).
- *Organizational structure*: how the website is structured (e.g., hierarchical structure) and the programming logic that is used to access, retrieve, and present different pieces of information.
- *Labeling*: how specific items are referred to. Labels should be used consistently throughout the website.
- *Navigation*: how to set paths that allow users to find their way through the website.

### 2.4.1   Organizational Schemes

One simple, yet successful method that can be used to determine relationships between fixed sets of categories is concept, or card, sorting. In a concept-sorting task, users are given cards that contain concept words and are asked to organize these words into discrete categories based on the relationships between the words. Users are often also asked to come up with a global label for each pile, or category, and then the categories can be used to determine how the various concepts should be organized (see, e.g., Vaughan et al., 2001). Tullis and Albert (2008) describe how a matrix of perceived distances can be created to capture the relation between pairs of cards. Pairs of cards grouped into the same pile would receive a value of 1 and those not grouped together would receive a value of 0 in the matrix. After the matrix has been completed, then statistical analyses such as hierarchical cluster analysis or multidimensional scaling can be applied to extract measures of similarity between the items on the cards. There are many other sophisticated methods for organizing and structuring content for the Web (see Proctor et al., 2002b), some of which are described briefly below.

***Objects/Actions Interface Model***   (Shneiderman, 1997) This model focuses on decomposing complex information found in websites into manageable hierarchies of objects (e.g., networks) and actions (e.g., searching). Specifically, the designers should focus on how the objects and actions are represented in the task and interface. For example, an e-commerce site may consist of individual objects such as pencils and paper. These objects can be aggregated into classes such as school supplies or stationery. Similarly, users can perform individual actions in the site, such as clicking on

a hyperlink to get from one page to another, or aggregate actions, such as scanning a list of different types of office supplies to find and link to a specific category of supplies. To link the objects and actions into the Web interface, designers can use common metaphors (e.g., a file cabinet) to organize objects and "handles" (e.g., pull-down menu) or a magnifying glass to represent an action (zooming feature) or type of action that can be performed. Hadar and Leron (2008) noted that although object-oriented program is useful, it can be for designers to learn how to use object-orienting programming and put it into practice due to difficulties in translating intuition into design parameters.

***Ecological Interface Design*** (Vicente and Rasmussen, 1992) This design process emphasizes that the way in which information is represented in a good display depends on the users' knowledge level and the type of behavior in which the users' engage. The ecological interface design is built on two concepts from cognitive engineering: the abstraction hierarchy and the skills–rules–knowledge behavior framework. The abstraction hierarchy is a multilevel knowledge representation framework that can be used to identify the information content and structure of the Web interface. The skills–rules–knowledge framework is used to distinguish the three modes of behaviors of users (Rasmussen, 1986). *Skill-based behavior* arises when users interact with a system on a regular basis and routine commands can be performed "automatically." *Rule-based behavior* occurs when users are confronted with a novel situation but can apply rules to solve them that they have learned previously. *Knowledge-based behavior* arises when a completely unfamiliar event occurs and the user must invoke his or her problem-solving skills to continue the task. By understanding the behavioral mode and constraints placed on the end user, the goal of ecological interface design is to organize and structure the information in the most meaningful manner to display to the user.

***Latent Semantic Analysis*** (Landauer et al., 2007) This analysis provides a valuable tool for organizing and structuring conceptual knowledge based on the relatedness of the items. Latent semantic analysis considers the frequencies with which words occur in various contexts. Each word then occupies a position in the semantic space based on a large corpus of text and is linked with other words through common labels or features. Words that are more highly associated are represented closer in space. Latent semantic analysis can be used as a tool to structure and organize information because it can easily determine similarity relationships between words, sentences, or larger text units. For example, Katsanos et al. (2008) used latent semantic analysis and other clustering algorithms to develop an AutoCardSorter tool for automating the data collection and analysis of card-sorting tasks.

***Extensible Markup Language*** XML is a markup language that provides designers with the option of tagging the content with standard markup indicators (e.g., </TITLE>) as well as new indicators that may

not have been used before. XML provides a mechanism to impose standards or constraints on how the content is specified so that it can be stored, retrieved, and organized easily.

***Use of the Semantic Web*** The Semantic Web (http://www.w3.org/2001/sw/) provides a framework to transform documents written in natural language into machine-readable form. The machine-readable annotations can be used to for organizing and retrieving Web content. There are several tools available for creating Semantic Web markups (see Michaelis et al., 2011).

### 2.4.2 Labeling

Labels are used extensively on the Web to represent particular pieces of information or categories of information. Labels are usually keywords or short descriptors that highlight the type of content that the user will encounter when accessing information categorized by the label. Category labels can be assigned manually by the designer or can be generated automatically or by computer programs. Qin (2004) recommends consulting existing encyclopedias and reference books in the domain in which the website is being created so that the designer can be familiar with the classification schemes already being used. Designers can also use key terms or keywords from indexes of books in the domain to familiarize themselves with the vocabulary and ontology with which the end users are also familiar.

Labels are used to identify different components of the website, including:

1. *Page Titles*. Every page of a website has a title. Coming up with a good label and description for the page is critical because "you get 40 to 60 characters to explain what people will find on your page. Unless the title makes it absolutely clear what the page is about, users will never open it" (Nielsen, 2000, p. 123).

2. *Headings*. Heading labels are used to signal to the user what content is forthcoming as he or she scans or scrolls down a Web page. Because many users tend to skim a Web page when looking for information rather than reading the content carefully, a good heading will alert the user to pay attention to the forthcoming material. To help make headings as easily to skim as possible, it is important to place keywords to the front of the heading when possible. Headings should also be easily distinguishable from the rest of the text on the screen (see http://www.usability.gov/pdfs/chapter9.pdf).

3. *Hyperlinks*. Hyperlinks take users to other places inside or outside the website. Hyperlinks have brief labels that inform users about the content that they will access by clicking on the link (e.g., if the link is to a file) or information about where the link will take them (e.g., if the link is taking users to another page). Hyperlinks should be made self-explanatory so that users do not have to guess where they will be going by clicking on them (Pearrow, 2000).

4. *Images*. There are many images that can be displayed on a website. When using images, ALT (alternative) tags should be used so that a textual label or description of the image can be displayed to the user when the image cannot be seen (e.g., text-based browser). Von Ahn and Dabbish (2004) introduced a method of labeling images with a computer game called ESP. The ESP game has a pair of users' guess labels for images until a match is obtained between the pair. They found that, on average, 3.89 labels are agreed upon each minute by participants in the game. The quality of these labels was validated by independent tests of search precision and comparison with descriptors generated by participants in an experiment. Coming up with good labels for the images can help produce more efficient image search as well as organization of the images.

5. *Icons*. Icons are symbolic representations of items, actions, or concepts. A good icon conveys an appropriate label for the content. In addition to visual icons, earcons (or auditory icons) are also being used on the Web (see Altinsoy and Hempel, 2011). All icons should include a descriptive label so that they can be indexed and referred to. The label should also be displayed to the users when a cursor is placed over the icon in case the user has trouble identifying the meaning of the icon.

It is important that the same item and/or category within a website be given the same label consistently throughout the website. It may confuse users, for example, to refer to the search feature as "search" in one part of the website and "find" in another part of the site. The label should also be representative of the type of information that it is linked to and should be a term that is recognized by the end users. By producing good labels for the individual components of the website, the designer should have an easier time organizing and structuring the content. Kantor (2003b) suggests the following guidelines for coming up with good labels:

- Never assume that users are familiar with the acronyms, programs, and jargon that the company or designer may use or that they are familiar with how the site is structured.
- Be consistent.
- Use labels that are familiar to users.

### 2.4.3  Organizational Structure

To design an information architecture for a website successfully, the designer must take into account the goals and purpose of the website, the nature of the information that needs to be conveyed, and the type of information that is needed to perform a particular task. The organizational structure refers to the physical structuring of information based on its relationship with other components of the site. The most common types of organizational structures are hierarchical, network, linear, and database oriented (Kantor, 2003a).

*Hierarchical Structures*   Most websites are organized using some type of hierarchical structure. Basically, this structure consists of a high-level, or global, category and is branched into subcategories underneath it (see Figure 1a). The subcategories can be broken down into smaller components until the elemental objects are reached. Sometimes, hierarchical structures are represented as tree diagrams. Shneiderman's (1997) objects–action interface model is based on a hierarchical organization. Hierarchical organizations are good because they represent how users naturally link concepts and categories together. Kantor (2003a) notes that although categories within the hierarchy should be both inclusive (provide all the relevant data) and exclusive (fit into only one category), this is rarely the case in practice because information can be categorized in a variety of ways. When designing hierarchies, the designer must also take into account the issue of breadth (how much should be included in each level) and depth (how deep the levels should go). Tullis et al. (2011) concluded from a review of several studies examining the breadth-versus-depth issue that breadth wins over depth in complex or ambiguous situations and in simple situations depth wins over breadth.

*Linear Structures*   Linear information structures connect pieces of information serially and do not allow for branching of information as hierarchical structures do (see Figure 1c). In essence, linear structures have depth and no breadth. A linear structure is most appropriate for organizing and structuring information that should be accessed in order (e.g., step-by-step instructions or alphabetical listing of items). Linear structures can be embedded into a larger hierarchical structure. For example, the index of an online book can be structured hierarchically according to the first letter (A–Z) of the keywords or concepts, but the concepts themselves can be organized linearly or alphabetically under the first letters.

*Networked Structures*   The Web itself is organized using networked structures. With this organization, users can move around the information architect by clicking on *hyperlinks* (see Figure 1b). The hyperlink can transport the user to an area of the website that does not have to be adjacent to their starting point. This structure is useful for organizing information that is related to but does not necessarily fall into the same category. For example, when searching for specific items such as dishes or plates on an e-commerce site, the results returned could include links to other kitchenware, such as cutlery sets.

*Database Structures*   Information within a website can also be organized and stored in a database structure (see Figure 1d). Database structures usually rely heavily on a search feature that allows users to retrieve the information. For example, the catalog website for a library may use a database structure in which users search for information within well-defined categories (e.g., call number, author, title, and date).

The type of structure used to design a website should reflect the purpose and context of the site as well as
**Figure 1**   (*a*) Hierarchical, (*b*) networked, (*c*) linear, and (*d*) database structures.

the type of tasks the site is designed to support. It is also important to note that websites do not have to be organized solely in terms of one type of structure. Hybrid structures can be developed to support the specific needs of the users or for specific tasks that are performed within the website.

### 2.4.4   Navigation

Once the structure of the website is determined, designers must focus on the navigation system that allows users to access the content from different areas of the site. Navigation through a website is usually implemented through the use of hyperlinks that connect one Web page to another or a search engine that returns results that are relevant to the keyword or terms that a user enters. Because issues relating to information search are discussed in the following section, the primary emphasis of this section will be on navigation. A navigation scheme provides users with a set of paths that allow them to move through a website, such as from the homepage to a specific section of the site.

***Avoiding Getting Users Lost***   Because a website can contain a huge amount of information that is distributed throughout the site, the content needs to be structured in a simple manner that is intuitive to the users. If users become overwhelmed by the information or if the site is structured poorly, users can get lost in

a website. Once the user is lost, he or she must either start over from the beginning or abandon the task. The former adds to the time needed to complete the task, and the latter results in failure of the task.

One way to help users navigate through a website is to communicate the structure of the site to them (Proctor et al., 2002b). If users understand the nature of how the site is structured and organized, they may be able to navigate through it more easily and quickly. Some techniques that can help communicate the structure of the site to users include:

1. *Site Maps*. An outline of the website illustrates how the various sections and individual pages are organized within the site and where they are located.
2. *Interactive Navigation Displays*. Interactive navigation displays provide users with a graphical display of their current position within a website and provide information about how the users got there, how they can get back to a previously visited page, and where they can go next. For example, navigational breadcrumbs are trails of hyperlinked page titles usually located at the top of each page that shows the users how they arrived at the current page. Users can click on the hyperlinks of pages visited previously to move back.

3. *Obvious and Consistent Major Navigation Controls*. Navigation controls for the major sections should be placed in prominent locations on each page of the site. The navigational controls should also be located in the same place on each page so the user can know where to find them (Najjar, 2001). Usually, navigation controls are placed on the top or left side of the screen (Pearrow, 2000). If the page links to lower levels, navigational controls to access those levels should also be placed on the page.

4. *Avoidance of Orphan Pages*. Make sure that users are not stranded when they click on a link that transports them to a page that does not link back to the site. If the link is to an external Web page, warn the user that he or she is leaving the site and/or have the linked page open in a separate window.

5. *Mark for Links Visited*. Separate pages that users have visited from ones that they have not by using different colors for the links. Most websites tend to use the color blue to indicate active hyperlinks that have not been visited and purple or burgundy to mark hyperlinks that lead to visited pages. Halverson and Hornof (2004) showed that differentiating visited and unvisited hyperlinks by color can improve search performance by narrowing the search space.

6. *Back Button and History*. Users use the back button to leave a page approximately two-thirds of the time (see Dix and Shabir, 2011), especially as a means to correct mistakes, to avoid being stuck at a "dead end," and to explore or browse the site. Because the back button is used often, users should be allowed the option of returning to a site visited previously by clicking on the back button. The history feature provided by the Web browser is also a means for users to return to a site visited previously. Because history logs can be set to record the navigation paths for long periods of time (i.e., days and months), it is important to give informative page titles so that users can find the page again when scanning the history log.

**Presenting Navigation Options**    Tullis et al. (2011) provided a summary of several different techniques that are being used for presenting navigation options, including:

- *List of Static Links*. A list of links leads to subsections on sequential pages.
- *Index or Table of Contents Layout*. Links are organized by topics in tables or by columns and rows.
- *Expanding and Contracting Outlines*. Links can expand when clicked to reveal subsections or contract to hide them.
- *Pull-Down Menus*. Heading links result in a pull-down menu of subsections either beneath the heading or to its side.

Tullis et al. concluded that users' performance was better when the navigation controls were presented with simple static listing of links or index/table of contents organization rather than with dynamic techniques.

### 2.4.5   Summary

Many methods can be used to connect or link various parts of a site so that it becomes a unified whole. As aforementioned, the most common technique is the use of hyperlinks. When a hyperlink is activated by clicking on it, the user is moved automatically to a different Web page. Although users can move throughout the site serially by relying on hyperlinks on successive pages, they can take shortcuts or jump from one section of the website to another by using the search function of the site and accessing the links returned.

## 3   PRESENTATION OF AND ACCESS TO INFORMATION

### 3.1   Retrieval of Information

The search function is one of the most important elements of a home page and should be placed in a location that allows users to find it easily. Why is the search feature so important? The answer is simple. Users like to use the search feature to locate information that is of interest to them. According to a survey by the Pew Internet & American Life Project (2009a), 88% of American Internet users find information by using a search engine, and 50% do so daily (2009b). In fact, the Pew Internet & American Life Project survey (2009a) found that searching for information is one of the most common online activities carried out by Internet users, second only to sending/reading email (89%). A summary of statistics by SearchEngineWatch.com (2009) indicated that in August 2009 the three major search engines were Google (with 6,986,580 searches), Yahoo! (with 1,726,060 searches), and MSN/WindowsLive/Bing (with 1,156,415 searches).

Although there has been much research about search engine designs for the Web [see Kammerer and Gerjets (2011) for a review], the focus in this chapter is on local search engines designed for searching within a particular website. One benefit of designing a search function for a particular website is that the content that has to be located and retrieved is much smaller than that on the entire World Wide Web. However, many issues and techniques involved in designing global search engines for searching the Web are applicable to designing search features for an individual website.

Users can engage in two types of behavior when searching for information: browsing and keyword search (Chen et al., 1997). *Browsing* refers to the act of scanning, reviewing, or skimming the contents of a Web page to find interesting or relevant information. *Keyword searching* refers to the process of entering a keyword, term, or phrase into a search engine in an attempt to find a particular piece of information. Of course, these two searching behaviors are not mutually exclusive. For example, even if users engage in keyword searching,

they are likely to browse the returned results page to find a particular link to which they want to go.

### 3.1.1 Browsing for Information

Browsing is a strategy used by beginners when they do not know exactly what they are looking for. However, even more experienced Web users tend to engage in browsing behavior when they are exploring or investigating a topic. Because there is much information that a website can contain, browsing may not be a very efficient way to look for information in the website. Moreover, if a website is large, users can get sidetracked by the various links that they encounter even when they have a purpose for their search. Fang et al. (2005) summarized several types of browsing behaviors that reflect goal-directed or nondirected search behavior:

1. *Search-Oriented Browsing*. Directed search aimed at accomplishing a specific goal. *Example:* looking for a specific section or link in an e-commerce website that contains information about laptop computers.

2. *Reviewing or General-Purpose Browsing*. Scanning through and reviewing information or Web pages related to the users' general goals but not necessarily needed to accomplish a specific task. *Example:* browsing through the electronics section of an e-commerce website to determine what different types of computer products are available and reading information about them.

3. *Scanning Browsing*. Scanning through information without reviewing it. *Example:* scanning the headings on the home page of a website to find interesting topics.

4. *Serendipitous Browsing*. Just looking to see what is in the website, without a specific goal but with the possibility that the user may stumble into something of interest.

### 3.1.2 Keyword Search

Keyword search reflects more goal-directed behavior. That is, users are looking for a particular piece of information at the website that is relevant to attaining their goals. Keyword search is conducted through a website's search engine, in which users enter a query and results matching the query or relevant to it are returned. Keyword search gives users direct access to Web pages within the site without navigating through it serially. Kammerer and Gerjects (2011) proposed a framework for characterizing text searches on the Web that includes four stages: formulation, action, review of results, and refinement. In the first stage, users determine the information for which they want to search. At this stage the information can be a topic such as "Web design," a product such as the "ipad," or even a question such as "What is a Web mashup?" After formulating the search term, users enter the action stage where they click on the "search" button. After the search results are displayed, users enter the review phase in which they evaluate whether the displayed results are relevant and decide which result or results to further review (i.e.,

which website to visit, documents to open, etc.) If users do not find what they need or decide that too many results are displayed, then the refinement stage begins where alternative search terms are considered in order to narrow the results. Keyword search can be more efficient than browsing if the search engine is powerful (i.e., does not return many irrelevant results) because if multiple refinements have to be made, the search may become too time consuming. In the following sections, users' keyword search behaviors are reviewed.

***Finding the Search Function***   For users to use the search function of the site, they must be able to find it. Thus, the search feature should be represented in a manner that will be recognized by users and located in a place where users expect to find the search feature. The former point is captured in Nielsen et al.'s (2000) study, in which "users told us that when they looked for the search function, they looked for 'one of the little boxes.' Tabs and links to a separate Search page just didn't work for them" (p. 7). Search features are often located at the top or bottom of a Web page and should be placed on every Web page so that users can have the option of performing a search instead of browsing through the contents or returning to the home page.

***Simple versus Advanced Search***   *Simple search* refers to search engines that primarily use keywords to find information, and *advanced search* engines allow additional filters. Many advanced search features include Boolean operators (OR and AND). Eastman and Jansen (2003) noted that 90% of Web searches used extremely simple queries and only 10% used advanced query options. They conducted a study examining the effectiveness of searches with and without advanced operators on global search engines and found that the use of advanced operators did not result in significantly better results. Furthermore, Nielsen (2000) reported that users have trouble with Boolean operators because they often confuse AND with OR and vice versa. Given that a majority of users have trouble with advanced search, the website's default search feature should be a simple search, providing an option for advanced search for users who want to use the feature.

***Fast and Accurate Search***   A good search feature or engine should be fast and accurate. Speed refers to how long a user has to wait before the results returned are displayed. Users tend to rate speed as an important factor affecting their preference for a website. For example, users in Lightner's (2003) survey on preferences for e-commerce sites indicated that navigation speed and buying speed were the third and fourth characteristics that determined their overall satisfaction. Thus, the search feature for a website should provide fast, high-quality results. The speed at which a search can be performed depends on the size of the search space and the power of the search engine, and the quality of the information retrieved depends on the precision of the engine (see, e.g., Kobayashi and Takeda, 2000). *Precision* can be defined simply as the proportion of the number of relevant documents retrieved by the search over the number of relevant documents in the search space. The use of

wide search boxes can improve the quality of the search because it allows more room for users to type more descriptive words that will help result in better matches (Nielsen, 2000).

***Dictionaries and Thesauruses*** Typographical errors (typos) occur when users enter keywords or terms into a search engine. Dictionaries can be used to help correct typos. When dictionaries are used to correct a user's spelling, users should be notified of it (Proctor et al., 2002b). For example, before results are returned, a message can be presented indicating that there were "no matches for one-bedroom apartments, did you mean one-bedroom apartments instead?" By notifying the user that the search engine noted a potential typo and corrected it, users will understand why they are receiving the results that are being displayed. Different users may also use different words to describe the same item, so including a thesaurus can help users find items that are stored in the website even if it does not exactly match the label that was assigned to the item.

***Better Indexing of Terms*** Queried terms are usually matched against index terms in order to find matches. Inclusion of a thesaurus will help avoid the problem of different people using different terms to describe the same item. Metatags can also be used to index Web pages within a site. Metatags allow designers to specify additional keywords for a Web page that is indexed. It is very labor intensive to create good metatags for a Web page, but the investment in creating them may be worthwhile because global search engines can use metatags to lead users to the Web page. However, not all search engines support metatags (Sullivan and Sherman, 2001).

***Using Relevance to Rank the Presentation of Results*** Search engines for a site usually return a list of Web pages that "match" the queried topic. Usually, short descriptions of the Web page are provided underneath or next to the hyperlink that will point the user to the page itself. Depending on the nature of the website, many Web pages can match the queried topic. Because users do not typically read or skim all the results that are returned, the linked Web pages should be ordered according to their judged relevance to the queried topic to help users locate the desired information quickly. There are many tools and algorithms that have been developed for determining relevance (see Kobayashi and Takeda, 2000; Fang et al., 2005).

***Allowing Users to Return to the Results Page*** When a user follows a link to a Web page listed on the results page, it may or may not be the particular Web page for which the user is looking. Thus, users should always be allowed to link back to the results page or navigate backward (use the back button of the browser) to return to the results page. When users return to the results page, links visited should be made distinct from new links to show the user where they have been and new Web pages that they have not visited. As noted in Section 2.4.4, blue links should be used to designate unvisited sites and purple or burgundy links to mark sites that have been visited.

### 3.1.3 Summary

The search feature of a website is important because users are prone to use search features to locate information. If users cannot find what they are looking for, they may abandon a website. The search feature should be in the form of a "box" and should include algorithms that return relevant results quickly.

## 3.2 Information Presentation

Successful structuring and organization of the components in a website will lead to more efficient navigation and search of information. The next step is to determine the best methods to present to users the information included in a website. Effective presentation of information is critical because it allows the user to extract the relevant information that they need to accomplish their goals. Fogg et al. (2003) conducted a survey in which 2684 participants evaluated the credibility of websites. They found that the "look" of the website was more important than any other factor in determining the credibility of the site. In fact, 46.1% of the comments received were devoted to issues of presentation and design, including the visual design, layout, color schemes, and so on. Because designers of the website built it, they have a good understanding of where everything is located and know why the information is presented in the manner that it is. However, some designers may fail to recognize that just because the organization and presentation of information is intuitive to them does not mean that it will be intuitive to the end users. Subsequent sections are devoted to the topic of information presentation at the global level and page level and how to present information in a manner that is accessible to users or different cultures and to users with disabilities.

### 3.2.1 Global Site Design

***Simplicity, Straightforwardness, and Easiness*** Information presented in a website should be made simple and straightforward (Nielsen, 2000). This will help the users locate the information they are looking for and will aid in the ease with which they can use the website. Although fancy designs may be aesthetically pleasing, they may distract users or "hide" relevant features or information presented in the site. In the spirit of parsimony, the simplest design that includes all the relevant and important features and information is probably the best.

***Browsers and Other User Agents*** It is important to know what types of browsers users will be using to access the site and to present information in a manner that meets the requirements of the browser. If the information is presented in a manner not supported by the browser (e.g., frames and flash), the user will not be able to see it. The most common browsers should be taken into account when designing the presentation of information. According to the Web analytics firm Net Market Share (2010a), the most commonly used browsers are Internet Explorer, Firefox, Chrome, and Safari. However, browser usage trends are constantly changing and designers should consult the most current data available whenever

they are working on a website. Designers also need to note that the same website may look different when accessed by different browsers (see, e.g., Figure 2). Furthermore, because newer versions of these browsers are released periodically, designers should present the information to accommodate the requirements not only of current versions but of back versions as well. Nielsen (2000) analyzed statistics of browser versions and noted that only about 2% of users per week upgrade or change to a newer version of a browser when moving from version 1 to 2 or 2 to 3 and only 1% from version 3 to 4. Thus, it seems appropriate to keep one year or more behind the latest browser. At the very least, it is important to design for the most used versions of the most popular browser: Internet Explorer. Internet Explorer versions 6.0, 7.0, and 8.0 are each used more often than all other browsers except for Firefox (Net Market Share, 2010b), and each has its own quirks in how it renders Web pages.

It is also important to keep in mind other user agents that users will use to connect to the Web. Users are no longer limited to accessing the Web from their desktops and laptops but can access the Web from many devices, including cell phones, personal data assistants, and ipads. Furthermore, accessing the Internet via mobile devices is becoming more prevalent. A survey by the Pew Internet & American Life Project found that 32% of Americans have at one time used a mobile device to access the Internet (a substantial increase from 24% in 2007), and 19% use the Internet on a mobile device on a daily basis (up from 11% in 2007; Horrigan, 2009). Thus, when designing the format of the Web page, designers should take into account mobile devices in addition to traditional computer monitors. Major factors to consider when designing Web pages to be accessed on mobile devices are that the display is only a small fraction of what is available on computer monitors (which have gotten bigger over the years due to decreases in cost) and the small or special input mechanisms (keypad or touchscreen) text entry, navigation, and information selection (Xu and Fang, 2011).

**Scrolling and Paging** Web designers often struggle with how much information should be presented on a given page of a website. Information that is presented in large amounts becomes lengthy and takes up a lot of space, and users are likely to have to scroll down the page to read or review the entire content of the page. Users do not like to scroll, so some designers recommend placing important or critical information "above the fold," within the space that can be viewed without scrolling (e.g., Pearrow, 2000). To avoid having to scroll, information can be decomposed into smaller chunks and presented on different pages. Users can access the information on the next page by clicking on a link or forward button. This method does not require users to scroll but does require them to page through the information serially (although some sites allow users to "jump" pages by providing links to numbered pages that represent the chronology of the information).

Baker (2003) found that it took participants 19 s longer to read paged text than scrolled text, but there was no significant difference in the level of comprehension between the two groups. He also found that users took 55 s longer to search for information in paged text than in scrolled text. Thus, it may be better to place all the information on a single page and require users to scroll than to break up the information across different pages. However, Tullis et al. (2011) noted that home pages and navigation pages should be kept short. One reason why these two types of pages should be kept short is that they have the goal of pointing users to the information that they need rather than being the source of that information.

The scrolling referred to above involves vertical scrolling or moving down a page by scrolling. However, if the website is designed to be too wide, users may have to scroll horizontally to see the information at the "edges." In general, it is recommended that horizontal scrolling should be avoided unless the task involves item comparison, in which case horizontal scrolling may facilitate the task (see Najjar, 2001).

**Secondary and Pop-Up Windows** *Secondary windows* are windows that open up with the Web page or information that users request, whereas *pop-up windows* are usually Web pages, advertisements, or information that "pops up" or appears without the users' request. Pop-up windows are usually considered annoying by users and should not be implemented in a website. Moreover, Fogg et al. (2003) indicated that "pop-up ads were widely disliked and typically reduced perceptions of site credibility" (p. 7). Secondary windows, on the other hand, can be used appropriately to present information since users are requesting the information and the information is not being imposed on them. Secondary windows are especially helpful for presenting additional information such as online help or detailed product information (see Tullis et al., 2011). When a second window is being used to present additional information, users should be notified of its use by presenting the secondary window in a smaller size that does not occlude the original screen or by prompting the user that another window will be opened to display the requested information.

**Frames** Frames divide the browser screen into distinct parts, each of which can be navigated and scrolled through independently. Frames can be particularly useful for displaying information that needs to be visible while the user scrolls down a page (see Dix and Shabir, 2011). For example, providing navigational tools in a separate frame allow users to access them even when the user scrolls "below the fold" of the content material in another frame (see Figure 3). However, frames have drawbacks. First, not all browsers support the use of frames. Frames can also make the website or pages from the website harder to find by search engines because the page that sets the frame is indexed instead of the content page (see Wisman, 2004). Finally, there can be problems with bookmarking and printing content from websites with frames because the page that sets the frame is the one that is often marked or printed or the last framed accessed is printed.

**Figure 2** (*continued*)

***URL Design*** URLs are Web addresses that direct the users to the desired Web page. The URL of a website starts with the prefix "http://"; however, some Web servers will load the page without the prefix. After the prefix are the letters "www" for World Wide Web, followed by a domain name and specific page titles, if there are any.

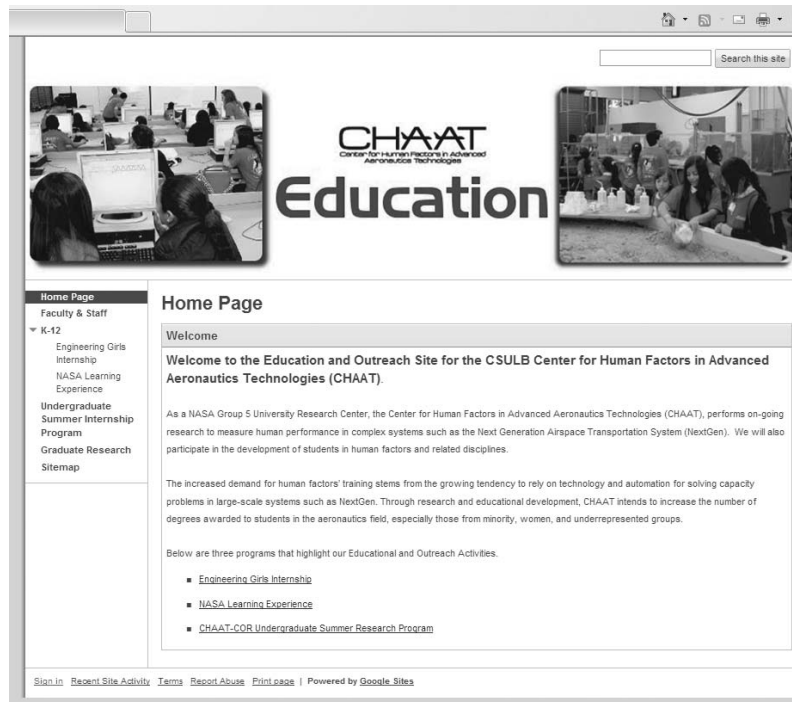
Nielsen (2000) noted that the domain name is the most important component of the URL because if users can recall or guess the correct domain name, they can get to the home page and find their way to specific information from there. Because URLs must be specified completely accurately, Nielsen recommends that they be made as


**Figure 3**  Example of a website that uses frames for navigational controls.

short as possible, with common words, all lowercase letters, and without any special characters. Because some users will choose to "cut and paste" URLs into browsers (e.g., from a referral in an e-mail) or link to a specific URL, it is important that the URL not be broken (e.g., by inserting a return break at the end to "wrap" the URL). As mentioned earlier, one problem with a frame is that it breaks the URL, making it difficult or impossible for users to bookmark the specific Web page.

*Error Messages*    There are many possible reasons for errors to occur. Some of these errors may be due to the Web browser that the user is using whereas others can be due to the design of a specific website. Lazar and Huang (2002) examined error messages for Web browsers and noted that many error messages are confusing and difficult for users to understand. Although the designer cannot control the error messages produced by the Web browser, care should be taken in error messages returned by the individual website. For example, if the website asks the user to enter the date in a specific format such as MM\DD\YYYY, but the user enters the date as MM\DD\YY, the error message returned should not be something obscure such as "PAGE ERROR: INVALID REFERENCE, NOT SET TO AN INSTANCE OF THE REFERENCE" but should indicate the error so that the user can fix the problem. A better error message would be: "FORMAT FOR DATE IS NOT VALID, PLEASE ENTER DATE IN THE FORM OF MM\DD\YYYY" (see also Figure 4). This message specifically tells the user that the date field is incorrect

rather than making the user guess what is meant by "INVALID REFERENCE," as in the former error message example. Several Web pages have also been designed to mark the field or entry in which the error was made to help users find where the error occurred.

### 3.2.2   Page Design

*Home Page Design*    The home page is usually, but not always, the first page that a user encounters when entering a website. If users access specific pages in the site (e.g., from a hyperlink on a global search engine's results page or from another website), they should be allowed to have direct access to the home page through a link or "home" button. The home page should communicate the site's purpose, include information about the site or organization hosting the site, and contain navigation functions to major subsections of the site. Nielsen and Tahir (2002) examined the usability of 50 websites' home pages and suggested 113 guidelines for designing usable home pages. From these, Nielsen created a list of the top 10 guidelines for home page usability (Table 1).

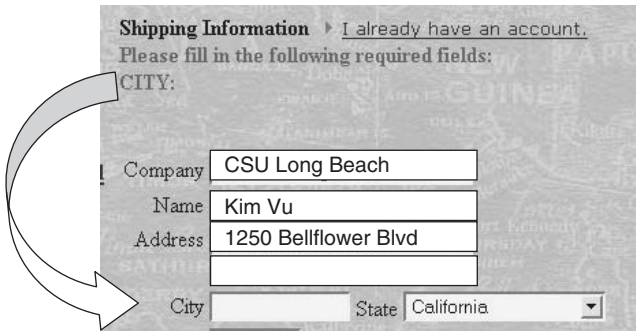
*Page Layout*    The layout of the page should be designed in a manner consistent with users' expectations. For example, the home page link or logo linking to the home page is usually located at the top-left corner of the page, navigational links are located at the left column of the page, and the main content is located in the center. Guidelines and standards have been developed to try to make Web pages more consistent, and user testing


**Figure 4**   Example of a good error message on a website.

**Table 1  Top 10 Guidelines for Home Page Usability**

| Home Page Design Guidelines |
| --- |
| 1.  Include a one-sentence tagline. |
| 2.  Write a window title with good visibility in search engines and bookmark lists. |
| 3.  Group all corporate information in one distinct area. |
| 4.  Emphasize the site's top high-priority tasks. |
| 5.  Include a search input box. |
| 6.  Show examples of real site content. |
| 7.  Begin link names with the most important keyword. |
| 8.  Offer easy access to recent home page features. |
| 9.  Don't overformat critical content, such as navigation areas. |
| 10.  Use meaningful graphics. |

*Source*: Based on Jakob Nielsen's Alertbox, available at http://www.useit.com. Readers should visit useit.com to read more details about the guidelines.

has shown some layouts to be more effective than others. Tullis et al. (2011) conducted a thorough review of research relating to page layout issues and recommended the following based on the literature:

- *Use a fluid layout rather than a fixed layout.* A fixed layout does not change with the size of the browser window, whereas a fluid layout adjusts the elements to the browser window as well as the printed page.
- *Use a medium level of white space.* White space can be used to reduce clutter, although too much white space may increase the time needed for users to locate items if it causes a need to scroll down to see information.
- *Place items in locations where users are likely to expect them.* Because the Web has been around for some time, users have become aware of what a "typical" Web page should look like.

**Links**   Links are important elements of a Web page because users can use the links to go to other Web pages that are connected to the current one. There are two types of links, text-based links and image/icon links.

The mouse cursor changes shape when it is placed over an active text or image link. Text-based links are usually marked by highlighting the text on a website in color and underlining it. Visited and unvisited links should be distinguished clearly to help users know where they have been. Using different colors to mark visited and unvisited links helps reduce search time (Halverson and Hornof, 2004), but care should be taken as to which color to use. Halverson and Hornof showed that search time is increased when red-text links are present on a Web page.

Icon or image-based links are graphics or pictures that link to another page when they are clicked. It is important to make links distinctive from nonlinks so that users know by looking at the image or icon what they can and cannot click on to take them to another Web page, rather than having to place their cursor over each item to find which is an active link. An image link is particularly useful when it provides a visual representation of the information requested or the item or product available from the website. Because text-based links usually download faster than image- or icon-based links since they are smaller in size, thumbnail image links can be used to lead users to an enlarged picture or image to reduce page load times when many images are presented on a page (e.g., a returned search page).

Portals, websites that are intended to provide links to other websites or online resources, often display many links on a single page. Because portals consist of a framework and supporting technologies for integrating multiple systems into a single interface, it has the ability to aggregate content from multiple sources and still provide users with a unifying look and feel to the information (Eisen, 2011). One question that arises is how many links should be displayed on a page. Bernard et al. (2002) had participants locate specific links on a search engine's result page for which the number of links returned was 100, with the number of links present on each page being 10, 50, or 100. Task completion time was shortest for the page with 50 links and longest for the page with 10 links. Users rated the 10- and 50-link-per-page formats roughly equal in terms of how easy it was to find information on the page and in terms of being professional looking but showed a slightly greater preference for the layout of 50 links to a page.

***Text versus Graphics and Images***    Text is the most common method used to convey information. This is especially true since there are some Web browsers that do not support graphics, and skilled users may know how to turn off the graphics mode in browsers that support them. Thus, the question of interest is whether graphics should be used with the text and, if so, what combination of text and graphics is optimal. Sears et al. (2000) found that all participants in their study indicated that websites that contained graphics were more attractive than those that contained only text. Although the use of graphics and animation can distract users, some types of information can be conveyed better by a "picture" than by words (see, e.g., Plaue et al., 2004). Sears et al. conducted an experiment examining a version of the 1997 Microsoft website that was modified to make the site self-contained (i.e., not linked externally) and a simplified version of the site (animations were removed and graphics simplified, graphical links were transformed to text links, etc.). They found that users were able to find desired information more easily with the original site than with the simplified site. Thus, there does not seem to be a problem with including some graphics in a website, as long as ALT tags or labels are used to indicate what the graphics are supposed to be in browsers that do not support them.

Graphics should not be used gratuitously, though, because they tend to be large in size, slowing the download time. As described in the next section, slow download times often frustrate users. The use of graphics and images is important to many e-commerce sites because users often want to see the product. Because search results from an e-commerce site tend to return many products that fit the queried item, including detailed images of each product may not be possible. In this case, small thumbnails of the image should be provided, with the option for users to access a more detailed version of the image if desired.

***Animation***    Animation can be applied to graphics to mimic real-life movement. Animation is frequently used as an attention getter in Web pages (Nielsen, 2000; Lazar, 2003). People are particularly sensitive to movement in the peripheral visual field due to the human sensory and perceptual system (see Chapter 3). Nielsen indicated that the use of animation is good for the purposes of (1) demonstrating continuity, transitions, or changes over time; (2) illustrating three-dimensional structures; and (3) attempting to attract attention. However, it has been shown that having animation present on the screen decreases performance on other tasks (e.g., Zhang, 2000). Zhang had participants perform an identification task in which users had to report the number of times the target information (i.e., strings of letters) appeared in an $8 \times 10$ table of a Web page. On the page containing the search array, animation was presented randomly to the top, sides, or bottom of the table. Zhang found that performance in the identification task decreased in the animation conditions compared to baseline conditions in which no animation was present. Furthermore, the animation particularly hurt performance when it contained information similar to the targeted information that was irrelevant to the task.

Animated banners are typically used as attention getters for advertisements. However, there is at least some evidence suggesting that users do not recall animated banners more than static banners (Bayles, 2002). Furthermore, advertisements, in general, tend to be viewed negatively, especially pop-up ads (Fogg et al., 2003). Thus, designers should take caution when determining whether to include animation. Animation is not always bad, but its presence can hurt performance on other tasks.

***Page Load Times***    The proliferation of high-speed Internet (i.e., broadband) services such as digital subscriber line (DSL) and cable modems during the last decade has drastically reduced the number of households that connect to the Internet via dial-up modems (U.S. Department of Commerce, 2010). The U.S. Department of Commerce's survey of connection types showed that, in 2009, 63.5% (75.8 million) of U.S. households used broadband services (up from 4.4% in 2000), whereas only 4.7% (5.6 million) of U.S. households used dial-up (down from 37.0% in 2000). Though this shift has abated many of the page load time issues for websites accessed from home computers, similar issues are now appearing in the context of mobile devices as more and more users begin to access the Web on-the-go at reduced connection speeds (when compared with broadband). It is important to take the users' connection speed into account because the connection speed may determine some of the users' behaviors. For example, a user may have no qualms about downloading a large media file when he or she is connected to the Web through a cable connection but may hesitate to do so when connected with a mobile device.

Users dislike long Web page load times whether they are operating a traditional computer (e.g., Lightner et al., 1996) or a mobile device (Equation Research on behalf of Gomez, Inc., 2009). There are many reasons why users may react unfavorably to long page load times (e.g., Bouch et al., 2000), including (1) not knowing whether the user made an error, (2) not wanting to wait "forever" to complete a task, (3) thinking that the site is not secure or well designed, and (4) losing his or her train of thought or task set during the delay.

Jacko et al. (2000) conducted an experiment evaluating the effects of network delay on users' perceptions of the quality of Web documents. They manipulated the page load time (mean delay times were 575, 3500, and 6750 ms for the fast, medium, and slow conditions, respectively) of Web pages from a website with only text or one with text and graphics. The content of both websites were the same. Users judged the text and graphic documents to be of higher quality than the text-only documents at short delays, but text-only documents were judged to be of higher quality at long delays. Jacko et al. noted that the lower quality judgments for graphic/text pages with long delays may be due to users attributing the long delay to graphics involved in the document. Sears et al. (2000) also showed that users with slower connections are also less impressed with Web page graphics than those who tend to have access to faster connections. Ten years ago, Nielsen (2000) recommended that Web pages be formatted in a manner

that can load in 10 s or less. Then, in 2004, a study by Galletta et al. suggested that delays should be less than 8 s to promote positive attitudes from users and less than 4 s to encourage users to continue with the task or to revisit the site later. Most recently, a study conducted by Forrester Consulting on behalf of Akamai Technologies, Inc. (2009) found that almost half (47%) of the 1048 online shoppers they surveyed expect to wait no more than 2 s for a Web page to load when they are browsing or searching for a product, and 40% responded that they will actually leave a site if forced to wait 3 s for a page to load. Unfortunately, the average page load times for websites of top shopping, banking, and airline companies are about 4 seconds on a mobile device (Gomez, 2010). Furthermore, a study by Equation Research on behalf of Gomez, Inc. (2009) found that 33% of 1001 mobile device users expect Web pages to load on their mobile device as quickly as (or faster than) on their home computer (another 25% expect the Web page to load almost as quickly on their mobile device as on their home computer). However, in that same study by Equation Research on behalf of Gomez, Inc., only 20% of the users responded that they would wait 5 s (or less) for the page to load before giving up and exiting the page (30% of users reported they would wait for 6–10 s).

Bouch et al. (2000) found that users' tolerance for delays decreased as the time they spent on the task increased, but if the page loaded incrementally, users were more tolerant of longer delays. If it is not possible for a page to download in the recommended time, users should be notified of this in advance. One way to help minimize the download time of Web pages is to reduce graphics to thumbnails and allow users to "zoom" or access larger images separately (perhaps by using an image link).

## 3.3 Designing for Accessibility and Universal Access

One benefit of having a website is that it can be accessed from anywhere and at any time with a variety of computing devices. For a website to be of maximal use, it should be designed proactively to promote accessibility from the early design phases and throughout the development life cycle. Stephanidis and Akoumianakis (2011) consider access to be a contextual issue that is determined by three major parameters: target user, the access terminal or interaction platform, and the task context.

Although a particular website can be viewed by anyone who can arrive at its "address," it is likely that the site is designed to target all not users but rather a subset of users. For example, a website devoted to being a portal to refereed publications in cognitive neuroscience is unlikely to be used by elementary school children. Thus, this site does not have to take into account the cognitive capabilities of elementary school children, but rather, it should be designed to promote easy access of research materials for scientists and medical professionals from all over the world. The website should also be designed to be usable on different computing devices that the target users are likely to use for accessing the information, such as personal computers, laptops, and personal data assistants. Finally,

the design of the website should take into account the context in which the site will be used, such as to browse through the contents to see the latest research in the area or to look up a specific piece of information of interest. In the following sections, Web design issues for different classes of users will be discussed.

### 3.3.1 Cross-Cultural Designs

Cultural differences in the user population relating to time, language, communication style, and social context may affect Web use (Rau et al., 2011). For example, users can be grouped into two general classes in terms of their perception of time: monochronic and polychronic (see, e.g., Rose et al., 2003). Monochronic cultures view time in linear fashion and are very task oriented. Polychronic cultures view time in a more flexible manner in which several tasks can be worked on concurrently and the users switch back and forth between the various tasks. Rose et al. conducted a study with users from two countries whose cultures are primarily monochronic (United States and Finland) and two whose cultures are primarily polychronic (Egypt and Peru). They found that all users had a negative attitude toward delays, but it was less pronounced for the polychronic cultures than for the monochronic cultures.

Web designers should take into account not only cultural issues such as time perception but also the resources to which users are likely to have access. For example, Chung (2008) indicated that between 2000 and 2007 there was tremendous growth in online users from Latin America, the Middle East, and China. Yet, many users from these countries do not have effective means for accessing information on the Web because many search engines and Web portals are designed to primarily serve English-speaking users. Thus, there is a need for Web designers to take into account cross-cultural issues in developing websites such as the representation of meaning through icons, symbols, and colors, the use of graphics, and the differences in page layout when translating images and text from different languages [see Rau et al. (2011) and Chapter 6 for reviews on cross-cultural Web design]. Some of the guidelines summarized by Rau et al. are:

- Use unambiguous language.
- Allow extra space for text.
- Accommodate text reproduction methods.
- Do not embed text in icons.
- Use an appropriate method of sequence and order in lists.
- Take linguistic differences into account.
- Take the direction in which text is read into account.
- Be aware that variations exist within the same language.
- Provide natural layout orientation for information to be scanned.
- Provide layout orientation compatible with the language being presented for menu designs.

- Note that icons designed and tested well in one region may not be accepted by people in other regions.
- Provide a combination of text and picture when designing icons.
- Examine the textual component in the graphics on the Web carefully when it is intended for a global audience.

### 3.3.2   Designing for Older Adults

The population of older adults is large and increasing rapidly. It is estimated that by the year 2050 the number of adults 55 years of age or older will exceed 136 million (U.S. Census Bureau, 2008). Bitterman and Shalev (2004) indicated: "Senior citizens are connected to the Internet for the longest time at a single sitting—more than any other age group" (p. 25). Furthermore, Internet use trends indicate that people who used the Internet when they were younger will continue to use it as they become older (U.S. Department of Commerce, 2010). Thus, websites should be designed to take into account the capabilities of older adults.

Because declines in sensory, cognitive, and motor functioning with age can affect the users' ability to interact with computing devices, it is important to take these considerations into account when designing a website. Below are some design guidelines relating to perceptual and cognitive changes with age that Web designers should take into account [based on recommendations from Bitterman and Shalev (2004) and Fisk et al. (2004)].

Perceptual changes:

- Use larger letters and avoid decorative or cursive fonts (e.g., 12-point sans serif letters).
- Avoid style sheets that prevent users from increasing the font size.
- Use bright colors and avoid combinations of colors of short wavelengths (blue–violet–green).
- Maximize contrast (at least 50:1 contrast, e.g., black text on white background).
- Increase the resolution of elements on the screen.
- Minimize clutter.
- Avoid moving and scrolling text.
- Provide redundant information (e.g., graphic and text or visual and auditory).
- Avoid high-frequency sounds (above 4000 Hz).

Cognitive changes:

- Use a consistent structure for the site and layout of the Web page.
- Convey the system's status clearly.
- Provide clear feedback for errors.
- Minimize demands on working memory.
- Allow for recognition of information, rather than requiring recall.
- Group information.

- Provide a site map that illustrates where the user is.
- Emphasize important and relevant information.
- Provide a "help" section or "support" information.

### 3.3.3   Accessibility for Users with Disabilities

In the United States, approximately 8.5% of the population has at least one of the following types of disability: blind or severe visual impairment, deaf or severe hearing impairment, difficulty walking, difficulty typing, or difficulty leaving home (U.S. Department of Commerce, 2002). Websites should be designed to take this population into account. Designers should not regard having to make the site more accessible to users with disabilities as an extra burden because websites that are designed to improve accessibility for disabled populations often produce benefits to people without disabilities as well (Caldwell and Vanderheiden, 2011). For example, while proper headings are necessary for an accessible design, they also improve usability. Users with vision impairments who use assistive technologies called screen readers are able to jump directly to headings to find content more quickly and easily, and with the headings in place, users without vision impairments are also able to focus on the content they are looking for. Taking headings to the next accessible step, creating an appropriate hierarchical structure with headings will improve usability one step further as well. To create an appropriate hierarchical structure with headings, the level 1 heading (h1; there should be only one level 1 heading per Web page) should be the first heading on a Web page, only level 2 headings (h2) should be directly under the level 1 heading, only level 3 headings (h3) should be directly under level 2 headings, and so on. For example, a possible heading structure is (note: indentation is used for structural demonstration purposes only):

- h1
  - h2
  - h2
    - h3
  - h2
    - h3
    - h3

Providing a proper logical structure such as this is necessary for accessibility because it provides information to a screen reader user about where they are in the flow of information. However, it also assists users without visual impairments because when headings are marked up in this way the same level headings will have the same visual appearance (and different level headings will have a different appearance), and thus the headings will provide a quick outline for the content presented on the screen.

There are many resources to assist the Web designer in creating accessible Web pages. First, there are the Section 508 standards of the Workforce Rehabilitation Act (Access Board, 2000), which federal agencies (and

companies creating products to sell to the government) are required by law to follow in order to make websites accessible. An update of the Section 508 standards is due out in 2010 or 2011. There are also the Web Content Accessibility Guidelines (WCAG) created by the World Wide Web Consortium. There are two versions of the WCAG: 1.0 (Chisholm et al., 2001) and 2.0 (Caldwell et al., 2008). WCAG 2.0 (principle-based) guidelines are often found to be too vague and difficult to implement, so many developers continue to use the earlier version, WCAG 1.0 (technique-based guidelines) for guidance on creating accessible websites. WCAG 1.0 recommends the following to promote the development of Web content that will be accessible to people with disabilities:

1. Provide equivalent alternatives to auditory and visual content.
2. Do not rely on color alone.
3. Use markup and style sheets, and do so properly.
4. Clarify natural language use.
5. Create tables that transform gracefully.
6. Ensure that pages featuring new technologies transform gracefully.
7. Ensure user control of time-sensitive content changes.
8. Ensure direct accessibility of embedded user interfaces.
9. Design for device independence.
10. Use interim solutions.
11. Use W3C technologies and guidelines.
12. Provide context and orientation information.
13. Provide clear navigation mechanisms.
14. Ensure that documents are clear and simple.

Web pages designed following these guidelines (and/or the Section 508 standards) will be more accessible by users with diverse sensory capabilities than if no accessibility guidelines had been consulted but will not be guaranteed usable by people with disabilities. For example, an image used only to create space between two sections on the screen could have an equivalent auditory alternative of "spacer image" for a screen reader to read in order to conform to the first guideline in WCAG 1.0. However, this would make the user experience much more difficult for a person with a visual impairment who navigates the page using only a screen reader because he or she would be exposed to this unnecessary auditory information. The only way to know for sure that users with disabilities can actually succeed in completing the tasks that they have come to a website to complete is by user testing with users with disabilities.

## 3.4 Security and Privacy

The Web allows users to access information, exchange information, and perform transactions online. However, there are well-founded concerns about privacy and

security since personal data collected about users need to be protected. Some users try to avoid websites that ask for personal information because they fear misuse of this information. For example, a user may be hesitant to register his or her e-mail address with a site in order to view its contents because he or she does not want to deal with the possibility of receiving unsolicited emails from the site's organization or one of its affiliates. To date, the most prominent effort for online privacy protection is the W3C's Platform for Privacy Preferences (P3P) project (see http://www.w3.org/P3P/). The goal of the P3P project is to enable websites to encode their data collection and data use practices in a machine-readable XML format and to provide a simple and automated mechanism for users to specify their privacy preferences through a Preference Exchange Language called APPEL. Through the use of P3P and APPEL, a website's privacy policy can be checked against the user's privacy preferences to determine whether the site's data collection and data use practices are acceptable to the user. Although the P3P project is a significant step toward developing privacy protection mechanisms, it is still in development and has its limitations.

In addition to privacy concerns, issues relating to information security have received tremendous attention in recent years because much of our personal information flows through the Web as we receive online services or make online transactions. As a result, it is essential for websites to have reliable security systems that protect the sites against information theft, denial of service, and fraud (see, e.g., Schultz, 2011). The most common method used by websites to identify and authenticate users is the user name–password combination. However, despite its pervasive implementation, it is well known that the user name–password combination is a relatively weak security method because many users fail to adopt crack-resistant passwords (Proctor et al., 2002a). Users also tend to create passwords that are easy to remember (e.g., Riddle et al., 1989; Klein, 1990) or write them down. Furthermore, because different sites have different requirements for acceptable passwords, users have trouble remembering unique passwords for multiple accounts (Vu et al., 2007). One reason why the user name–password method is still popular despite its limitations is that it is relatively easy to implement and is accepted by users (as opposed to more intrusive methods, such as biometrics).

Websites should also be designed to protect against breaches in security such as hacker attacks (unauthorized access to the information stored by the website), denial-of-service attacks (which cause the network to slow down or website to stop working), Web defacements (unauthorized modification of the content of the site), and computer viruses (Schultz, 2011). Techniques to counter security breaches are beyond the scope of this chapter. However, given that the users' trust in the website can be obliterated by security breaches and the potential costs and legal ramifications associated with the breaches can be great, it is important to emphasize that care should be taken when designing the website to incorporate security mechanisms.

## 4  EVALUATING WEB USABILITY

Web usability refers to the ease with which a website can be used, its efficiency and effectiveness, and the satisfaction it provides to users (e.g., Brink et al., 2002). Web usability is extremely important because it is a major determinant for whether or not a particular website will be successful (Nielsen, 2000). Because Web usability is an area within the general domain of computer software usability (see Vu et al., 2011), many issues relevant to software usability discussed in Chapter 46 also apply to Web usability.

Although the topics of Web design and Web evaluation were covered separately in this chapter for ease of presentation, designing and evaluating Web usability often occur in iterative cycles (Mayhew, 2011. Web evaluation should be implemented early in the development process and throughout its life cycle. It is not adequate to conduct usability evaluations on a final product to catch the "bugs." Moreover, usability problems discovered on a final product may not always be fixable. Thus, it is important to emphasize that usability evaluations should be implemented in early, as well as late, phases of design, where usability problems can be identified and more easily fixed.

Web usability evaluation is dependent on the goal or purpose of a website. These goals and purposes were elicited from the organization or users at the start of the design process covered earlier in the chapter and should include consideration of:

1. *Target Users*. Information and descriptions of the target users should include demographics, Web and computer experience, core user tasks, task environment, and preferences. Characteristics of the target users can be obtained by examining user profiles (Fleming, 1998) or personas (Cooper, 1999). *User profiles* are brief summaries of real users' characteristics. *Personas* refer not to real people but to a representation of a type or category of users. Personas are typically used when designers do not have access to user profiles but have a general idea of the characteristics that actual users might have and can be based on the designers' knowledge of who the real users are likely to be.

2. *Core User Tasks*. Core user tasks are those tasks that are frequently performed by the target users. Core user tasks are highly dependent on the nature of the website. Below are examples of some likely core user tasks for each of the major types of websites:

   - *News/Information Dissemination*. Find out the late-breaking news; check the weather or stock market.
   - *Portal*. Find websites relating to Web design; find electronic resources on the topic of usability.
   - *Communication*. Chat with other users with a common interest in e-business; e-mail a friend.

   - *Search*. Find information on a topic such as cancer; find a professor's e-mail contact information in a university's online directory.
   - *E-Commerce*. Purchase Jamaican Blue Mountain coffee; purchase a computer online.
   - *Company/Product Information*. Find the location of a store; track delivery status of a product.
   - *Entertainment*. Watch a movie trailer; play a game online.

The core set of user tasks can be defined at different levels. For example, higher level tasks can include browsing, researching, communicating, searching, purchasing, and accessing entertainment. Each of the higher level tasks can be broken down into subtasks such as locating a product on a Web page, "placing" it into the "shopping cart," providing billing information, and providing shipping information. Once the goals of the website are defined and the core user tasks are established, one of several usability methods can be used to evaluate whether the website is successful in conveying the purpose of the organization and supporting the users in accomplishing their tasks.

### 4.1  Evaluation Methods

There are several general classes of usability tests, although some of the specific methods under each can cut across categories (see Tullis and Albert, 2008):

- Interviews, focus groups, and surveys/ questionnaires
- Naturalistic observation
- Participatory evaluation (ethnographic methods and diary studies)
- Web-based methods (automated sessions, Web logs, and opinion polls)
- Prototyping (paper prototypes and interactive prototypes)
- Usability inspections (heuristic evaluation, cognitive walkthrough, and alternative viewing tools)
- Usability lab testing (usability and performance testing)

The first four classes of usability tests were introduced earlier as methods to help elicit information about users and core user tasks when determining what content to include in the website. However, they are also used as techniques for evaluating usability later in the design process. For example, interviews, focus groups, and surveys/questionnaires can be used to determine the difficulties that users have while interacting with the website and their opinions, attitudes, satisfaction, and preferences for the different features, layout, or structure of the website. Similarly, naturalistic observation can be used to evaluate users' performance on different tasks and facial or bodily expressions while interacting

with a website. Participatory evaluations can be used to evaluate the website in the context of the users' social and task environment or by having users' log usability problems and concerns as they encounter them in daily use of the website.

As mentioned earlier, the Web itself is a tool for performing evaluations on a particular website. When a site is accessed, the Web server records information about the files sent to a browser, which can include the date, time, host domain (the Web address of the requesting browser), file name, referrer (the URL of the page that provided the link), and so on. Not only can Web logs reveal information about the users, such as how many users visit a website and from which domain they are visiting, but Web logs can also be used to evaluate the site by examining the frequency with which specific Web pages in the site are visited, the amount of time spent on a page or task, the success versus bail-out rate, and navigational paths that users take while interacting with the site. Web log data may also provide some clues for usability problems. For example, if a specific Web page is not visited frequently, designers can conduct further investigation to determine whether the lack of access to the page is due to where it is placed within the site or the content that it conveys.

Prototyping, usability inspections, and usability lab tests are used more often in later phases of design, after a conceptual prototype has been developed and can be evaluated. It is important to note, though, that any of these usability methods can be used throughout the design process. For example, a questionnaire can be administered to users at the start of the design phase to determine the types of tasks that users are likely to perform on the website, in the middle of the development life cycle to determine what users like or dislike about the current version of the website and what they would like to see in the final version of it, or near the completion of the site to obtain users' feedback and impressions of the overall functioning of the site.

Instrumented Web browsers can also be used to conduct automated sessions of remote usability tests. Participants recruited for these tests are provided with the instrumented version of the browser, for which they are asked to complete certain tasks by visiting one or more websites. Performance measures such as time on task, successes and failures, links followed, and files opened are recorded. Users can also indicate when they have completed a task (either successfully or unsuccessfully) by clicking on a "finish" button and then be prompted to continue to the next task. Automated sessions may be best for summative usability evaluations (Jacques and Savastano, 2001). In fact, West and Lehman (2006) found no major differences in findings (task success rates and user satisfaction ratings) from an automated usability test and one conducted by a usability engineer. Although observational data from the usability engineer provided more information to the design team about usability issues, the written comments provided by users from the automated sessions were sufficient to identify primary usability issues relating to task failures.

### 4.1.1 Prototyping

Prototyping is a particularly useful tool to evaluate the usability of a Web design, especially at earlier phases of development. Alternative designs for the site can quickly be "mocked up" and tested by usability experts or end users. Prototypes can be as basic as drawn images and features on a piece of paper (low fidelity) or more advanced, to mimic the "look and feel" of a real website (high fidelity). The main distinction between a prototype website and a real one is that the prototype is not fully functioning but, rather, is a representation of the site along with simulations of the functions and features of the site. For example, designers can use a high-fidelity prototype of a website to study the presentation of the search results page by having users click on a search button to take them to a predesigned results page. That is, the results page is not returned by the actual search but is linked to "fake" data.

Low-fidelity prototypes consist of paper mock-ups, storyboards, or paper prototypes. These prototypes are usually hand drawn, without the detail or polished look of a high-fidelity design. The goal of using low-fidelity prototypes is to convey the conceptual design rather than to test its features. As shown by Newman et al.'s (2003) study with expert Web designers, paper prototypes are still commonly used, even though it may not take much time to implement the same design in HTML to be presented on the Web. The Web environment does, however, make it easier to design a "skeleton" website with interactive features (Pearrow, 2000):

- *Paper Prototypes*. Paper prototypes are hand-drawn designs of different screens or static printouts of screen shots. They allow designers to focus on the global properties of the website and extreme flexibility for changing components of the design. Functional aspects of the design can be illustrated via buttons and links and additions to the design (e.g., to mimic a drop-down menu) can be made on Post-It notes.

- *Interactive Prototypes*. As aforementioned, it is easier to build interactive prototypes of a website using HTML. Pearrow (2000) made two distinctions for developing interactive prototypes: horizontal and vertical. The emphasis for a horizontal prototype is to enable all the top-level functions, whereas the emphasis for a vertical prototype is to enable the functions along a particular path (e.g., a task to be completed).

### 4.1.2 Usability Inspection Methods

Usability inspection methods are typically used to evaluate the usability of a system without testing end users (see, e.g., Cockton et al., 2008). Inspection methods cannot replace user testing (see, e.g., Vu et al., 2011) but can reveal many usability problems quickly, before end users have to be recruited and tested. They are also typically considered to be less expensive than many other methods used to evaluate usability because the expert needs to be able to access the website only during his or her evaluation. User-based testing,

on the other hand, often requires the cost associated with setting up a usability lab and payment for the usability expert as well as the end users participating in the test. Inspection methods are generally based on design guidelines or recommendations, best practices, and particular findings derived from research studies and theoretical frameworks. The two best known and most frequently used inspection methods are the heuristic evaluation and cognitive walkthrough. However, since the Web can be accessed from a variety of platforms, alternative viewing tools are often used to ensure the usability of the site when accessed by different computing devices.

***Heuristic Evaluation***    With a heuristic evaluation, usability experts examine the functions, features, layout, and content of a website and determine whether the site's format, structure, and functions are consistent with established guidelines or design recommendations (e.g., Nielsen, 1993). Some of these heuristic guidelines for Web design include (based on Pearrow, 2000):

- Chunk together related information.
- Use the inverted pyramid style of writing.
- Place important information "above the fold."
- Avoid gratuitous use of features.
- Make the pages scannable.
- Keep download and response times low.

Usually, three to five evaluators are needed to find the majority (at least two-thirds) of the usability problems (Nielsen and Molich, 1990). A single evaluator typically finds only about 35% of usability problems (Nielsen, 1993). Furthermore, the more familiar and experienced the evaluators are with human factors and usability engineering, the more effective they become at identifying usability problems. In addition to evaluating whether the website adheres to design principles and recommendations, evaluators can determine whether the site contains common Web design mistakes and remove them before they become usability problems. The top 10 mistakes in Web design from 1996 to 2007 posted by J. Nielsen are listed in Table 2.

***Cognitive   Walkthrough***    With cognitive walkthrough, usability evaluators "walk through" the steps that a user would execute when performing specific tasks on the website. The evaluator tries to perform the task from the user's perspective and identifies any problems that users are likely to encounter. The method focuses on how easy the website is to use and on how easy the functions in the site are to learn and use (e.g., Polson et al., 1992). For each step of the task, the evaluators are encouraged to ask themselves the following questions (e.g., Wharton et al., 1992):

- Will the user form the right goal for the task?
- Will the user notice that the correct action is available?
- Will the user associate the correct action with the correct control or feature?
- Will the user receive feedback about their progress in the task?

Before the evaluators perform the cognitive walkthrough, they should prepare a list of tasks to be performed and questions to be answered when performing each task to guide them through the process. Evaluators need to ensure that the types of tasks they will perform during the evaluation are representative of the tasks that the users typically perform and that a range of difficulty levels be included. The walkthrough itself can sometimes be a tedious and slow process, but there have been some suggested streamlined versions of the cognitive walkthrough that are intended to be more efficient (e.g., Spencer, 2000).

Blackmon et al. (2002, 2003) introduced a variant of the cognitive walkthrough designed especially for the Web. Their Cognitive Walkthrough for the Web (CWW) evaluation process simulates the users' step-by-step interactions with the website in a goal-directed task, such as searching for specific information in the site. CWW uses latent semantic analysis to identify usability problems associated with heading/link titles. More specifically, CWW can identify headings or links that are (1) likely to be confusable with other headings/links in the page or site, (2) unfamiliar to the target audience, and (3) likely to lead to a specific goal (i.e., the goal can be classified under competing headings). Blackmon et al. (2003) used CWW to identify usability problems associated with the headings/link titles of an experimental website designed to present encyclopedia articles. They showed that the performance on the site improved significantly after the site was repaired for problems identified by CWW.

In general, cognitive walkthroughs are particularly beneficial for helping the design team to think along the lines of users' goals and knowledge. Cognitive walkthroughs, though, are less successful than heuristic evaluations at identifying more serious usability problems (see Cockton et al., 2008).

### 4.1.3  Evaluations with Alternative Viewing Tools

Because there are many computing devices that allow users to access the Web from any place at any time,

**Table 2  Top 10 Web Design Mistakes, 1996–2007**

1.  Bad search
2.  PDF files for online reading
3.  Not changing the color of visited links
4.  Nonscannable text
5.  Fixed font size
6.  Page titles with low search engine visibility
7.  Anything that looks like an advertisement
8.  Violating design conventions
9.  Opening new browser windows
10. Not answering users' questions

*Source*: Based on Jakob Nielsen's Alertbox, available at http://www.useit.com. Readers should visit useit.com to read more details about the mistakes.

it is important that designers also consider how the website will be displayed on a variety of browsers (e.g., Internet Explorer vs. Firefox) and platforms (e.g., Web TV, PDAs, mobile phones). Alternative viewing tools are viewers, or software tools, that are intended to show designers how a website would look on different devices and platforms. In addition to the platform issue, Web designers should also keep several earlier versions of popular browsers because it may take up to two or three years before users "upgrade" from one browser version to another (Nielsen, 2000).

### 4.1.4 Usability Lab Tests

Usability lab testing is probably the best method for evaluating the website in terms of its effectiveness in promoting successful interactions with the users. Most usability experts would agree that the methods described earlier are useful tools when evaluating Web usability, but they cannot replace usability lab tests. As a result, many of the techniques described above are used in addition to usability lab testing at various phases of the design life cycle. The basic methodology and procedure on how to conduct a usability test have been described in Chapter 46 (see also Pearrow, 2000; Brink et al., 2002; Dumas and Fox, 2008) and are discussed only briefly in this chapter.

A usability lab test for websites involves observing and analyzing users' task performance (e.g., successful completion rates and failure rates, task completion times, and errors) while interacting with a website as well as their thought processes during the task (e.g., understandings, misunderstandings, and preferences). Ideally, usability lab tests should occur several times throughout the design phase so that iterative evaluations can be made.

During the test session, the evaluators should be separated from the participant by a one-way mirror, so that the participant can be observed but the evaluator does not "get in the way." Communication with the participant is usually done through an intercom system, and the evaluators should allow time for users to adjust to this communication medium. If the designer wants to evaluate the effectiveness of alternative Web designs or page layouts, the users' performance with the various versions of the website can be evaluated. Before bringing users into the lab, designers should determine the goal for the test (e.g., test the navigation paths or the efficiency with which the task can be performed), the population from which the sample users will be recruited, the specific tasks that users are to perform, the procedures that are to be followed, as well as how the data will be coded and analyzed:

1. *Sample of Representative Users*. The users that are recruited to participate in the usability test should be as representative as possible of the targeted user group. Each test participant is usually asked to perform several tasks and to provide detailed information about their interaction with the website. Because of the extensive nature of usability testing, relatively few users are selected and tested. Usually four or five users are needed

to find about 80% of the usability problems (Brink et al., 2002), but a larger sample size (e.g., 8–10 users) can increase the number of usability problems detected as well as providing a more representative sample of the target population.

2. *Sample of Representative Tasks*. The specific tasks that users are asked to perform should be based on a subset of the core user tasks that were identified earlier in the design process. The task should be representative, in terms of both the type of task (search or navigation) and level of difficulty. If the version of the website has not been placed on the Web, the designers should simulate response times for the system to match the connection speed that the end users are likely to encounter.

3. *Procedures to Be Followed*. Typically, a usability test starts with an introductory session in which participants are given an opportunity to familiarize themselves with the lab setup and ask any questions that they might have. Participants are usually given consent forms to sign which include information about the nature of the test, duration of the test, type of compensation, confidentiality of their data, and a statement indicating that their participation is voluntary. Some organizations also require participants to sign a nondisclosure agreement. During the test, the experimenter should try to keep the participants on task but should not have too much interaction with the participants so that the experimenter does not bias the outcome of the test. The experimenter should be empathetic when participants get frustrated during the test. Participants should not leave the test thinking that it was their fault that they had difficulties with the tasks. After the usability test is over, questionnaires or interviews can be administered to collect information about the participants' background and/or their opinions about the tasks.

Although the costs of performing usability tests are much higher than those associated with performing usability inspections, usability testing is better than usability inspection methods at finding general, severe, and recurring problems. It is generally agreed that usability lab testing should not be skipped just because the design was tested previously for usability with inspection methods.

### 4.1.5 Evaluating Accessibility for Users with Disabilities

By definition, accessibility is different from usability because it is focused on providing basic access to the information and functionality needed to accomplish user tasks rather than making that functionality more user friendly. But at its core accessibility is usability for users with disabilities, or at least it should be. This is because the motivation behind creating an accessible design should be "usable accessibility" (Henry, 2002), where users with disabilities not only are able to access information and functionality but also are able to enjoy

a quality user experience. Testing for this quality user experience for users with disabilities must come later though because first we must handle the basic (technical) access to information and functionality on a website.

There are many different tools to help a Web designer evaluate the technical accessibility of a website, but they generally fall into one of two categories (several fall into both), automated testing tools and manual testing toolbars:

- Automated testing tools
  - *Use*. These tools conduct an automated check of a website (or page) by going through the HTML and CSS files to determine if they conform to Section 508 standards, WCAG, or both (depending on selected options) and then typically present a list of accessibility successes, warnings, and failures for the website (or page).
  - *Example*. Deque Ramp (http://www.deque .com/products/ramp).
- Manual testing toolbars
  - *Use*. These toolbars are added on to browsers and contain multiple tools that can be selected to aid in the accessibility evaluation of a Web page (e.g., a tool to highlight all images on the page that do not have alt text). They obviate the need for evaluators to dig through lines of HTML in order to determine whether Web pages have been marked up properly.
  - *Example*. The Web Developer Extension for Mozilla-based Browsers (http://chrispederick .com/work/web-developer/).

Unfortunately, automated testing tools are not able to provide accurate accessibility information about a website's conformance to many standards/guidelines because many of them require human interpretation. For example, one of the WCAG 1.0 guidelines states that a text equivalent should be provided for every nontext element. There is no way for an automated testing tool to determine whether the alternative text used for an image is a text equivalent for that image (i.e., fulfills the same function as the original image). Furthermore, much of the information that automated testing tools do provide needs to be validated with manual testing. Thus, automated testing tools are generally used to find accessibility problem areas within websites with large numbers of pages and to guide testing with manual testing toolbars. However, it is never a good idea to completely skip the manual evaluation of a Web page because the automated testing tool did not report any accessibility problems. It is appropriate, though, to evaluate the accessibility of one type of page and apply the results to other similar pages (e.g., pages that use the same template).

After technical accessibility has been examined (and repaired where necessary), the evaluation can move on to the determination of the usable accessibility of the website. It is important that technical accessibility barriers be repaired before the evaluation of usable accessibility takes place because technical accessibility

allows users to interact with the interface. For example, technical accessibility in the form of allowing a screen reader to work with a website for a user with visual impairments is the equivalent of providing a monitor for a user without visual impairments to work with the website. The actual testing for usable accessibility closely resembles usability testing and many of the same methods for evaluating usability can be used (e.g., interviews, participatory evaluation, heuristic evaluations, walkthroughs, user testing; see, e.g., Henry, 2007). Although creating the most accessible websites for users with disabilities requires their inclusion in the design process, many of the interaction issues they face can be teased out by experts who know how (and with what technology) users with disabilities navigate websites and who can use screening techniques to simulate barriers similar to those faced by users with disabilities. While it may at first seem a daunting prospect to user test both accessibility and usability of a website, it should be remembered that users with disabilities come to websites to complete the same tasks as users without disabilities and so can help to evaluate accessibility and usability simultaneously.

## 4.2  Summary

This section reviewed usability evaluation methods for Web design. Some of the methods were geared toward understanding the user, whereas others were focused on finding design problems. It is important to note that all of these methods have different strengths and weaknesses. Thus, designers need to decide which method would be most appropriate to their goals, which can differ depending on the nature of the website and stage of the design process. From a human factors point of view, the design process should be an iterative one, where improvements are made based on the findings from multiple usability evaluations. We endorse a multi-method approach for evaluating Web usability because different methods should yield converging findings for many relevant design issues but also provide unique insights into other important factors that may influence user trust and use of a website.

In industry, thorough user testing and multiple iterations may be prevented by time and monetary constraints. To overcome this barrier, Medlock et al. (2005) proposed the use of a Rapid Iterative Testing and Evaluation method (RITE method). The RITE method emphasizes rapid changes to the design as soon as a usability problem is identified and a solution is available. With RITE, changes can be made after a single participant identifies a problem rather than after a complete user test with multiple participants. The benefit of incorporating quick changes is that the next participant can evaluate the "improved" design, reducing the iterative design process time. It should be noted that the RITE method relies on traditional usability evaluation methods summarized in this section and is a tool for designers to use when they are under time constraints. This method should not replace traditional methods that are more thorough in nature, as those methods tend to provide the most complete usability findings.

## 5 CONCLUSIONS

Websites should be designed and evaluated for usability from their conception and throughout the development cycle. The impact of designing for Web usability can be seen by examining case studies in which the return of investment is immense. Below are just two examples of usability success stories (see also Bertus and Bertus, 2005; Richeson et al., 2011).

- Dell Computer's investment to improve the usability of its e-commerce website in the fall of 1999 led to a dramatic increase in sales, going from $1 million per day in September 1998 to $34 million per day in March 2000 (Black, 2002).

- The United States Computer Emergency Readiness Team (US-CERT) is a government agency charged with "providing response support and defense against cyber attacks for the Federal Civil Executive Branch (.gov) and information sharing and collaboration with state and local government, industry and international partners" (see http://www.us-cert.gov/aboutus.html). Because the two target audiences of US-CERT consist of technical computer professionals and nontechnical users (e.g., home and business users), they wanted to make sure that their website was usable for both groups. After conducting usability tests and implementing changes to the site that addressed user concerns, they found that both technical and nontechnical user success rates improved over 20%. Moreover, satisfaction with the site improved 16% for technical users and 93% for nontechnical users (US-CERT, 2005).

As illustrated by these examples, it is wise to take usability into account when designing websites. Web resources can change on an hourly, daily, weekly, monthly, or yearly basis. Thus, it is important that the website be maintained so that it provides accurate content and continues to be highly usable. However, maintaining a good website is a challenge for designers because new technologies continue to emerge, making it difficult to keep up with the evolving Web.

## 1 INTRODUCTION

A vision of ambient intelligence (AmI) is offered in the report of the Information Society Technologies Advisory Group of the European Commission (ISTAG, 2003, p.1): "The concept of Ambient Intelligence provides a vision of the Information Society where the emphasis is on greater user-friendliness, more efficient services support, user-empowerment, and support for human interactions. People are surrounded by intelligent intuitive interfaces that are embedded in all kinds of objects and an environment that is capable of recognising and responding to the presence of different individuals in a seamless, unobtrusive and often invisible way."

As an emerging field of research and development, AmI is rapidly gaining wide attention by an increasing number of researchers and developers worldwide. The notion of AmI is becoming a de facto key dimension of the emerging information society spanning across every human–computer interaction (HCI) research and development domain since next-generation digital products and services are explicitly designed in view of an overall intelligent computational environment. The latter reflects a

fundamentally interdisciplinary research approach necessitating knowledge fusion and technology transfer.

Computer networks, sensor/actuator technologies, user interface software, pervasive computing, artificial intelligence, adaptive systems, robotics, and agent systems are currently seen as the primary domains with a strong impact on AmI research (Nakashima et al., 2010). Computational vision and sensor networks acquire information from the environment regarding events and activities which take place. This information is then elaborated by high-level reasoning modules for behaviour monitoring and for determining the intelligent reaction of applications to what happens in the environment.

While a wide variety of different technologies are involved, the goal of AmI is fundamentally dual: on the one hand to hide the presence of its technological infrastructure from the end users as much as possible and on the other hand to smoothly integrate in everyday objects, thus making it "disappear." The design requirements of an AmI system are: (i) *unobtrusiveness*—devices are distributed in the environment, embedded into different physical objects, becoming invisible to humans unless visibility is needed; (ii) *personalization*—its

behavior can be configured to address individual user requirements; and (iii) *adaptation*—it is capable of automatically modifying its behavior relying on the recognition of user and context characteristics, including individual preferences, without requiring conscious mediation [International Organization for Standardization (ISO), 1999]. To this end, AmI systems support interactivity based on the continuous interpretation and processing of tasks, activities, and contexts (Aghajan et al., 2009).

The AmI environments are anticipated to have a profound impact on the everyday life of citizens in the information society and to potentially permeate a wide variety of human activities. They will affect the type, content, and functionality of the emerging products and services as well as the way people will interact with them (e.g., Emiliani and Stephanidis, 2005; Coroama et al., 2004; Edwards and Grinter, 2001). In the near future, it is expected that the resulting technologies will redefine the way people today understand and use computers. On the other hand, the anticipated omnipresence of technology also raises doubts and fears. For example, continuous monitoring of human presence and activities through sensors may be difficult to accept and raises concerns of privacy and security. Additionally, the question arises of what consequences may be caused by the potential failure of a technological environment which is so deeply intertwined with all sorts of human activities and how people can be protected from negative consequences (Bohn et al., 2005). In this context, as the border between really useful supportive technology and the so-called technological nightmare becomes much thinner, it has been argued that it is of critical importance for AmI environments to develop and evolve from the very beginning with a strongly human-oriented focus towards ensuring that the emerging potential is fully realized and potential pitfalls are avoided. As stated in (Roe, 2007, p. 157), "As all technological innovations, Ambient Intelligence is not good or bad per se, but its impact on people will depend on how it is deployed and used, the time and scale of deployment and the care devoted to involve people in its development."

Therefore, human factors acquire fundamental importance in AmI environments. In this context, *human factors* as defined by Czaja and Nair (2006, p. 32) is "the study of human beings and their interaction with products, environments and equipment in performing tasks and activities. The focus of human factors in on the application of knowledge about human capabilities, limitations, and other characteristics in the design of human-machine systems . . . .The general objectives of human factors are to maximize human and system efficiency and health, safety, comfort and quality of life."

People, their social situation, ranging from individuals to groups, and their corresponding environments and activities (office buildings, homes, public spaces, etc.) become the focus of design considerations and inform the design and interactive behavior of artifacts, applications and services, and ensembles thereof. Besides, human factors knowledge is also instrumental in defining the intelligence of the environment, that is, creating environments capable of "understanding" and fulfilling human

needs and unobtrusively supporting human activities. In order to exhibit more humanlike understanding of human needs and activities and provide contextually appropriate feedback, AmI environments need to acquire sensor information about humans and their functioning as well as to extract adequate knowledge for analysis of such information about human functioning (Aarts and de Ruyter, 2009; Bosse et al., 2010). In other words, human-centered AmI environments can only be achieved through a deep understanding of human activities, interaction, and communication (Nijholt et al., 2009).

On the basis of the above considerations, this chapter discusses the centrality and role of human factors in the emergence and development of AmI environments. In particular, Section 1 analyzes the user-centered design process in the light of the requirements posed by AmI, focusing on emerging problems and potential solutions toward applying and revising existing methods and techniques or developing new ones. Section 2 focuses on some user experience factors which are considered as critical in AmI, including natural interaction, accessibility, cognitive demands, emotions, health, safety and privacy, social aspects, cultural aspects, and aesthetics. For each of them, a brief overview of the main issues involved is provided. Section 3 illustrates three case studies involving the user-centered design of AmI artifacts, discussing for each of them the main adopted design process and the relevant user experience qualities. Finally, Section 4 summarizes the emerging research challenges and puts forward the need for a more systematic approach to the above issues.

## 2 HUMAN-CENTERED DESIGN PROCESS IN AMI ENVIRONMENTS

User centered-design (UCD) has been defined as an approach to designing ease of use into the total user experience with products and systems (Vredenburg et al., 2001) and constitutes a cornerstone of human factors engineering. It involves two fundamental elements: multidisciplinary teamwork and a set of specialized methods for acquiring user input and converting it into design.

The need for UCD has been identified quite early in the HCI field, and numerous articles and books have been written on the subject (Gould, 1988; Hewett and Meadow, 1986; Norman and Draper, 1986). ISO 13407 (1999) provides guidance on human-centered design activities throughout the life cycle of interactive computer-based systems. User-centered design is not simply conducting usability studies or talking to users; it emphasizes the active involvement of users and requires studies to understand users as well as to drive and evaluate the design and the final system. As technology rapidly advances, computer use spreads to almost every domain of everyday life, and new interaction paradigms emerge, UCD remains through the years a fundamental process for the design of every interactive system. In this light, ISO 13407 has been revised to ISO 9241-210 (ISO, 2010) to reflect recent changes and advances which highlight six main principles of UCD: The design is based upon an explicit understanding of users, tasks, and

environments; users are involved throughout design and development; the design is driven and refined by user-centered evaluation; the process is iterative; the design addresses the whole user experience; and the design team includes multidisciplinary skills and perspectives.

UCD includes four iterative design activities, all involving direct user participation, as shown in Figure 1:

1. Understand and specify the context of use, the nature of the users, their goals and tasks, and the environment in which the product will be used

2. Specify the user and organizational requirements in terms of effectiveness, efficiency, and satisfaction and the allocation of function between users and the system

3. Produce designs and prototypes of plausible solutions

4. Carry out user-based assessment

In the context of AmI, the importance of UCD increases even further, but its complexity also increases and the need emerges for rethinking some aspects of the process and of the related methods. In AmI, "focusing on the human" goes beyond previous approaches and truly refers to a new paradigm in developing and using technology. In such a new paradigm, ease of use, unobtrusive design, privacy management, and personalization constitute the main building blocks of the definition of a human-centric interface. AmI environments are by definition capable of adapting to their inhabitants, as they embed two fundamental features, monitoring and reasoning, which make them dynamically reactive to what happens within them.

The next sections discuss each of the UCD activities from the point of view of AmI in an attempt to anticipate the main challenges which will need to be addressed and outline potential directions of investigation.

## 2.1 Context of Use

The context of use in user interface design is usually considered as including the characteristics and roles of users, their goals and tasks, as well as the characteristics of the physical, social, and technological environment where a system is used.

In AmI, the context of use becomes much more complex and articulated as the number and potential impact of relevant factors increase dramatically with respect to conventional computing devices, particularly

regarding the (co-)presence of people, computing devices, and other elements in the surrounding environment. In other words, interaction is no longer a one-to-one relationship between a human, a specific task, and a specific device in a static context. Rather, it becomes a many-to-many relationship between diverse users and a multitude of devices in a dynamically changing environment, where none of the typical context-of-use factors can be assumed as stable over the interaction. It is believed that the key to identifying suitable design approaches in the context of AmI relies precisely in the interplay between the user, the physical and social environment, the available technologies, and the tasks of users. All these factors are highly dynamic and interrelated and vary over time.

Additionally, in AmI, the context of use needs to be not only appropriately captured but also modeled and embedded in the technological infrastructure in such a way as to facilitate the sensing and monitoring of the related parameters.

### 2.1.1 Defining Context of Use in AmI

In defining the AmI context of use, care must be taken to accommodate the complexity deriving from omnipresence, "disappearance," and intelligence of technology.

For example, the very concept of "user" needs to be revisited (Stephanidis, 2001). Different levels of awareness and participation to the communication and computing processes may occur in the AmI environment, according to the characteristics and requirements of different individuals, but also according to the characteristics of the spatial/temporal/technological contexts of human activity. Humans are no longer simply "operators" or "users" but may play different roles in the overall process.

Additionally, a user's abilities may change over short time intervals according to various conditions partly determined by external conditions (e.g., other elements of the environment). Also, as users move in the environment, the current context of use as well as the current interaction technologies may dynamically change (e.g., a different room with different characteristics and technologies). Many users with different needs and requirements may be present at the same time in an environment, and interact concurrently, and this fact may introduce potential conflicts. For example, in smart homes, all inhabitants who are present at the same time are users, but possibly each one is conducting different activities which may interfere with someone else's activities. As a result, *role awareness*, in addition to *user awareness*, becomes

**Figure 1**   Activities involved in UCD (from ISO, 1999).

prominent for adaptation in AmI systems. Additionally, the context may adaptively change due to decisions made by AmI applications and not only according to the current user location (e.g., according to different times of the day of different days). Also, devices can be plugged in or removed from the environment at any time. The dynamic availability of services is also likely to lead to user tasks changing on the fly.

As a consequence, the context of use in AmI should be captured in a dynamic rather than static way, posing various challenges for the methods to be used, the types of information to be gathered, and the representations to be adopted. Indicatively, Table 1 illustrates the context-of-use factors typically included in UCD, whereas Table 2 presents a modified version taking into account factors which are relevant in AmI.

Many of the factors in Table 2 are dynamic, that is, they may depend on other context factors (e.g., available devices may depend on location of the user). As a consequence, the definition of the context of

use in AmI is also strictly related to the issue of monitoring, as it is critical in identifying the elements to be monitored, as well as the conditions and parameters according to which monitoring should take place. In other words, context-of-use factors are not only what the designers should know but also what the system should be aware of. This need is commonly referred to as context awareness, defined as "The environment can determine the context in which certain activities take place, where context relates meaningful information about persons and the environment, such as positioning and identification" (Aarts and de Ruyter, 2009, p. 8).

### 2.1.2 Methods and Techniques for Capturing the Context of Use

Methods commonly adopted in UCD to capture the context of use include stakeholders' identification, surveys, paper-based questionnaires, field study/user observation, diary keeping, and task analysis (Maguire, 2001).

**Table 1  Context-of-Use Factors**

| User Group | Tasks | Technical Environment | Physical Environment | Organizational Environment |
|---|---|---|---|---|
| System skills and experience | Task list Goal | Hardware Software | Auditory environment | Work practices Assistance |
| Task knowledge | Output | Network | Thermal environment | Interruptions |
| Training qualifications | Steps | Reference materials | Visual environment | Management and |
| Language skills | Frequency | Other equipment | Vibration | communications structure |
| Age and gender | Importance | | Space and furniture | Computer use policy |
| Physical and cognitive capabilities | Duration Dependencies | | User posture | Organizational aims |
| Attitudes and motivations | | | Health hazards Protective clothing and equipment | Industrial relations Job characteristics |

*Source*: From Maguire, 2001, p. 595.

**Table 2  Context-of-Use Factors in AmI**

| User Groups | Human Activities | Technological Environments | Physical Environments | Social Environments |
|---|---|---|---|---|
| Individual vs. group | Goals | Available hardware devices, including input/output | Time parameters (day, time, etc) | Activity practices |
| Language skills | Activities | Network | Auditory environment | Roles |
| Age and gender | Output | Software platforms | Thermal environment | Interruptions |
| Physical and cognitive capabilities | Typical location | Middleware | Visual environment | Communication structure |
| Attitudes and motivations | Tasks and steps | Already existing applications and services | Vibration | People copresence |
| Cultural background | Frequency | Sensors and other equipment | Space, furniture | Privacy threats |
| Knowledge of the environment applications, services, and interactive features | Importance Duration Dependencies and intertwining with other activities | Available data from sensors Available reasoning resources | User position and posture Health hazards | |
| Domain knowledge | Required assistance | | | |
| Interaction preferences | Delegation | | | |
| Emotions and psychological conditions | Collaboration | | | |

In principle, all the above methods and techniques can be useful in the context of AmI. However, their application may vary. For example, observation-based methods may evolve due to the monitoring and reasoning facilities offered by the environment itself, which offer the opportunity to gather larger amounts of data regarding various aspects of human activities in an environment over longer time periods. However, the application of such an approach requires the availability of experimental infrastructures or already existing functional environments as well as the presence of real users behaving and acting naturally in the environment. To address this issue, facilities and laboratories have been set up where different AmI technologies are being developed, integrated, and tested in a real-life context, usually simulating a home environment (e.g., Georgia Tech's Aware Home,[*] MIT's House_n,[†] Philips' HomeLab,[‡] Fraunhofer-Gesellschaft's inHaus,[§] and Microsoft Home[¶]).

On the other hand, more traditional methods such as surveys, questionnaires, and diaries can still be very relevant when no facilities are yet available for experimentation.

The identification and modeling of user activities and tasks constitute a different challenge. Typical task analysis techniques have been claimed to be poorly suited to AmI (Verpoorten et al., 2007), as they do not capture the interrelationships of tasks with other contextual factors. For example, traditional task analysis techniques, due to their origin (business environments and application), are oriented toward highly structured tasks with specific goals and steps. However, in AmI environments, everyday human activities do not always have a specific goal and are characterized by a much looser structure, which may not easily decompose into discrete steps. Various extensions of traditional task models have been proposed in this respect. For example, Vredenburg et al. (2001) discuss an approach to generate activity patterns from task structures. Luyten et al. (2005) propose a task-centered approach to design for ambient intelligent environments. The approach is based on visualization and simulation and is targeted to capture, during design, the strong dependency of task execution on the situation or context of use as well as the consequences of a context change on the execution of task specification.

## 2.2  User Requirements

A prerequisite for the successful development of AmI environments is that user requirements are appropriately captured and analyzed. In particular, it is necessary to anticipate future computing needs in everyday life and acquire an in-depth understanding of the factors which will determine the usefulness of diverse interactive artifacts in context. These requirements are likely to be more subjective, complex, and interrelated than in previous generations of technology.

As a starting point toward analyzing user requirements in AmI, studies have been conducted through the use of scenario techniques. Both positive (ISTAG, 2003) and "worst case" (Wright et al., 2010) scenarios have been proposed.

While scenarios provide a useful starting point, they cannot be considered as sufficient to fully capture future human needs and expectations in AmI environments. On the other hand, for the user community it is not easy to express needs and preferences regarding a technological environment which is hard to imagine. In order to contribute to the development, users should be made aware of the technological possibilities and potential approaches to build up the new environment.

It is therefore necessary to bring users in direct contact with AmI technologies and the possibilities they offer. To this purpose, research infrastructure and simulation environments such as those discussed in the previous section can play a fundamental role.

Studies on human requirements in AmI environments have also started appearing, mainly targeted to the home environment. Röcker et al. (2005) reported a multicultural study combining scenario-based techniques, focus groups, and open-ended discussions to identify requirements for the home environment. A set of prioritized requirements was derived, including, besides general issues, support for housekeeping and safety, assistance for personal environment organization and home organization, and support for care and communication with others.

Hellenschmidt and Wichert (2005) reported an experiment targeted to analyze different kinds of ambient assistance in living room environments. In this experiment, 143 subjects interacted with a home entertaining system presenting integrated functions like TV, radio, audio and video playing, telephone, and light controls. Based on the results, seven kinds of assistance were identified with varying levels of user involvement and awareness (from situations where the user is fully informed about all changes in the environment to situations where the environment changes without any direct action of the user).

Zhang et al. (2009) described an experiment aimed at matching user interface intelligence in smart home environments with the type of task to be carried out and the age of the users. Following Rasmussen et al. (1994), tasks are classified as skill-based tasks, rule-based tasks, and knowledge-based tasks.[‖] Interfaces are also distinguished according to three levels of intelligence (low, medium, and high). The results of the study, involving two user groups of young and older people, respectively, show that the level of intelligence of the

---

[‖] In skill-based tasks, performance is governed by patterns of preprogrammed behaviors in human memory, without conscious analysis and deliberation. In rule-based tasks, performance is governed by conditional rules. Finally, at the highest level of knowledge-based tasks, performance is governed by a thorough analysis of the situation and a systematic comparison of alternative means for action.

user interface, as well as the age of the users, significantly affects performance for different types of tasks. Overall, the need arises for highly usable user interfaces allowing direct and accessible user control, avoiding the need to use a variety of different applications to control different devices, and providing an intuitive overview of the overall current state of the intelligent environment.

Schmidt et al. (2007) reported a study involving a combination of contextual inquiries, cultural probes, technology probes, educating the user, participatory design sessions, and creating prototypes from persona-inspired designs. The presentation of physical prototypes has been contextualized in the possible scenarios of everyday life activities (e.g., "when you wake up," "when you brush your teeth"). This proved to be particularly useful for generating design ideas and for understanding the user profile. Indeed, people find it easier to relate to the task-orientated nature of the scenarios, rather than to the abstract and often function-orientated nature of a system specification. The combination of the two, scenarios of everyday life and tangible previews of future technology, proved to be a powerful method to stimulate their creativity. Using the technology probes, people appeared to be less worried about technologies invading their home, thus reducing concerns and fears. Interviews were also used at a later stage, based on ideas generated in the previous phases.

## 2.3 Producing Designs

The design of AmI environments introduces new challenges, primarily due to the embedded interactivity "hidden" in a variety of interconnected, multifunctional computing artifacts (Emiliani and Stephanidis, 2005). This is due to the multifunctional nature of artifacts that must be smoothly integrated in everyday objects. It is therefore crucial to systematically examine how typical interactive functions combine with the rest of functions offered by such artifacts and the way the design of all functions can be optimally accommodated. In particular, typical HCI design processes will likely need to be revisited in terms of their overall scope. For example, while accessibility and usability of every devices in isolation is necessary, it is still not sufficient to guarantee usability in an overall distributed environment where the combined presence of artifacts could possibly introduce new usability issues. This also implies a closer study of the similarities and differences of the physical world and the digital world, as these worlds will no longer be clearly separated but, on the contrary, will be strictly interrelated and fused. Interaction in AmI environments may take place through a mixture of physical and digital elements. Therefore, a convergence emerges between interaction design and industrial design which will need to be addressed through novel methods and techniques (Butz, 2010).

In the context outlined above, a series of new research challenges emerge. At the level of interaction design, new design principles will be required, stemming from the fusion and extension of design principles of everyday objects with principles of user experience design.

Prototyping and related tool support also constitute an issue for AmI environments. Currently available support for user interface prototyping is mainly based on user interface builders incorporated in most integrated development environments. However, such tools do not fully address the need of prototyping in AmI. For example, they are usually bound to specific devices, interaction platforms, and widget toolkits and are not suited to designing a pervasive user experience across devices. A potential step forward to address this issue is the provision of adaptable interaction toolkits, comprising device-aware widgets which know how to display themselves and how to compose an interface layout on different devices (see Chapter 54 of this handbook, "Design for All: Computer Assisted Design of User Interface Adaptation"). Additionally, toolkits to develop dynamically distributed user-interfaces for mobile users, capable of exploiting for interaction purposes ambient computing resources available at the current location, such as the Voyager toolkit (Savidis and Stephanidis, 2005), are very important for reducing the user interface implementation complexity.

Simulation of AmI environments also allows an instrument to bring future users closer to the new technological environment without requiring extensive development. As stated elsewhere (Bandini et al., 2009), traditional design and modeling instruments can provide a suitable support for designing the static properties of AmI environments, for example, through the construction of three-dimensional (3D) mock-ups, but they are not suitable for defining their dynamic behavior and responsiveness. Simulators, on the other hand, allow envisioning both the static features of the ambient intelligence system as well as its dynamic response to the behavior of humans and other relevant entities situated in it.

Another important change in AmI environment is likely to affect who the designers should be and which design knowledge they should possess. Given the omnipresence of technology, the ideal solution would be for users themselves to be able to take decisions about the interactive features of the environment in which they live. Towards this objective, the environment should be able to provide to users very easy means to personalize interaction. The technological environment should empower end users to tailor the environments to their needs, providing methods and tools for editing, interpreting, linking, executing, and rendering of application functions in a user-friendly and intuitive way (Lieberman, 2001).

An example of an approach in this direction is design and play (Kartakis and Stephanidis, 2010), which allows the quick configuration of user interfaces for smart homes ready to be used. Such an approach can be further simplified and automated based on the consideration that the smart home can detect the presence of interactive artifacts and exploit knowledge about their characteristics. In such an environment, designers are likely to undertake new roles, as their main task will be to encode user experience knowledge in the environment rather than directly produce user interface prototypes. Additionally, designers will need to

be aware of the fact that the interaction behavior of the environment will not be statically determined by design but will be more dynamic and will evolve based on initial design and on data gathered through monitoring.

## 2.4   Evaluation

The evaluation of AmI technologies and environments will also need to go beyond traditional usability evaluation in a number of dimensions, concerning both the qualities of the environment to be assessed and assessment methods.

### 2.4.1   Qualities of AmI Environments

Performance-based approaches to usability are not adequate for AmI environments, as they were developed for single-user, desktop applications and are usually applied in laboratory evaluations. Additionally, it is difficult to specify tasks that capture the complexity of everyday activities, and a more subjective view of the user experience is necessary. Qualities which may need to be taken into account in evaluating AmI technologies and environments include highly subjective cognitive and emotional factors (Theofanos and Scholtz, 2004). Therefore, evaluation should target the overall user experience and the emotional response to technology (Hassenzahl and Tractinsky, 2006) rather than traditional usability. However, the concept of user experience needs to be further articulated in order to derive measurable qualities. For example, Gaggioli (2005) presents an attention-based framework for user experience assessment in AmI. Other factors which may need to be assessed include emotional reactions to technology (Herbon et al., 2006), engagement, and fun (Mandryk et al., 2006) as well as trust and user's perception of security and privacy in the environment (Lo Presti et al., 2005).

Adams and Russell (2007) reported a study that is addressing emotional responses to two intelligent ATM prototypes. The two prototypes were similar, but one of them was purposefully designed to be more stressful, showing a lower level of intelligence in the interaction. The results confirmed that the stressfulness of the prototype caused real problems to users going well beyond traditional usability and produced a strong emotional reaction of frustration.

Qualities which characterize AmI environments from a user experience point of view are discussed in more detail in Section 3.

### 2.4.2   Evaluation Methods and Techniques

Ambient intelligence technologies and systems challenge traditional usability evaluation methods because the context of use can be difficult to re-create in a laboratory setting. This suggests that the evaluation of user's experience with AmI technologies should take place in real-world contexts. However, evaluation in real settings also presents difficulties, as there are limited possibilities of continuously monitoring users and their activities (Intille et al., 2006). For example, the experience sampling method, which aims at capturing the user experience in the field, takes advantage of the wide diffusion of mobile devices to request feedback from people during their activities. This approach allows capturing on-time feedback, avoiding to the users the need for recalling situations and related experience at a later stage. Using this approach it is also possible to contextualize questions based on the time of day, the user location, and other parameters (Vastenburg and Romero Herrera, 2010).

Appropriate facilities are required for combining user experience in context with the availability of the necessary technical infrastructure for studying the users' behavior over extended periods of time. It is expected that future testing and evaluation methods and activities will rely to a large extent upon the simulation of the interactive behavior of the technological environment as well as upon continuous monitoring data. For example, human emotions in the environment can be analyzed through face and speech recognition techniques but also physiological monitoring (Herbon et al., 2006).

As in the case of design, evaluation also tends to acquire a more continuous nature in AmI environments. In the long run, the embedded intelligence allows the environment to assess and improve itself, blurring the distinction between evaluation and interaction. Experience research (Aarts and de Ruyter, 2009) aims at developing methods and techniques that allow the validated feedback of users in the process of generating experiences. In experience research, three main dimensions of user experience evaluation are distinguished: (i) eliciting and validating end-user insights in the societal context, (ii) execution of user-centered design cycles in controlled laboratory environments, and (iii) testing of novel concepts and solutions in real-life settings.

## 3   USER EXPERIENCE IN AMBIENT INTELLIGENCE ENVIRONMENTS

This section discusses some of most important aspects of user experience in AmI environments, with the aim of identifying emerging approaches to defining, modelling, and assessing such factors in AmI environments.

### 3.1   Natural Interaction

The pervasiveness of interaction in AmI environments requires the elaboration of new interaction concepts that extend beyond the current user interface concepts such as the desktop metaphor and menu-driven interfaces (Aarts and de Ruyter, 2009). AmI will therefore bring about new interaction techniques as well as novel uses and multimodal combinations of existing advanced techniques, such as, for example, gaze-based interaction (Gepner et al., 2007), gestures (Ferscha et al., 2007), and natural language (Zimmermann et al., 2004). Progress in computer vision approaches largely contributes to the provision of natural interaction in AmI environments, making available, among other things, techniques for facial expression, gaze and gesture recognition, face and body tracking, and activity recognition.

Additionally, interaction will be embedded in everyday objects and smart artifacts. This concept refers to interfaces that use physical artifacts as objects for

representation and interaction, seamlessly integrating the physical and digital worlds.

Such objects serve as specialized input devices that support physical manipulation, and their shape, color, orientation, and size may play a role in the interaction.

The interaction resulting from tangible user interfaces is not mediated and it supports direct engagement of the user with the environment. Consequently, it is considered more intuitive and natural than the current keyboard and mouse-based interaction paradigm (Aarts and de Ruyter, 2009).

Interaction in AmI environments inherently relies on multimodal input, implying that it combines various user input modes, such as speech, pen, touch, manual gestures, gaze and head and body movements, as well as more than one output modes, primarily in the form of visual and auditory feedback. In this context, *adaptive multimodality* is prominent to support natural input in a dynamically changing context of use, adaptively offering to users the most appropriate and effective input forms at the current interaction context. An implementation framework for adaptive multimodal input for cross-media board games is discussed in Savidis and Lilis (2008). Finally, multimodal input is acknowledged for increasing interaction accuracy by reducing uncertainty of information through redundancy (Lopez-Cozar and Callejas, 2010).

## 3.2 Accessibility

Accessibility in the context of AmI is usually intended as inclusive mainstream product design, although a contextual definition is not yet available. However, a gradual transition from assistive technologies to mainstream accessible products is foreseeable (Antona et al., 2007). Given the variety and plurality of devices in AmI environments, different levels of accessibility may be distinguished. A first level concerns accessibility of individual devices. Personal devices will need to be accessible to their owners, but probably basic accessibility should be provided also for other users with potentially different needs. A second level is the accessibility of the environment as a whole, which may be provided through environmental devices and other interactive artifacts. In this case, accessibility can be intended as equivalent access to content and functions for users with diverse characteristics, not necessarily through the same devices, but through a set of dynamic interaction options integrated in the environment.

It is likely that some of the built-in features of AmI environments, such as multimodality, will facilitate the provision of solutions that will be accessible by design (Carbonell, 2006; Richter and Hellenschmidt, 2004). For example, blind users will benefit from the wider availability of voice input and output. Different modalities can be used concurrently, so as to increase the quantity of information made available or present the same information in different contexts or, redundantly, to address different interaction channels, both to reinforce a particular piece of information or to cater for the different abilities of users. A novel aspect is that in AmI environments the accessibility of the physical and the virtual world needs to be combined. For example, for blind, visually impaired, and motor-impaired users, requirements related to interaction need to be combined with requirements related to physical navigation in the interactive environment. Along the same lines, the complexity of the environment and the disappearing of technologies can become insurmountable obstacles for cognitively impaired users if not properly addressed. Age-related factors are also very important, particularly in the light of the fact that a large part of AmI applications will be targeted to supporting independent living and that current understanding of the needs and requirements of users of different age in such a complex environment is limited.

## 3.3 Cognitive Demands

Ambient Intelligence should not introduce increased complexity for its users. As technology "disappears" to humans both physically and mentally, devices are perceived no longer as computers but as smart interactive artifacts of the surrounding environment (Streitz, 2007). The nature of interaction in AmI environments is the result of evolution from human–computer interaction to human–environment interaction (Streitz, 2007) and human–computer confluence (Ferscha et al., 2007). These concepts emphasize the fusion of technologies and environments and the increased involvement of interaction with digital artifacts in all aspects of human life.

Putting strong emphasis on adaptation and usability, AmI environments need not be interaction intensive, despite the fact that humans are surrounded by a wide range of computing devices of different functionality and scale. Therefore, interaction shifts from an explicit paradigm, in which the users' attention is on computing, toward an implicit paradigm, in which interfaces themselves drive human attention only when required or preferred (Schmidt, 2005). Interaction in the emerging environment will be based no longer on a series of discrete steps but on a continuous exchange of information (Faconti and Massink, 2001). Continuous interaction differs from discrete interaction since it takes place over a relatively longer period of time, in which the exchange of information between the user and the system occurs at a relatively high rate in real time. A first implication is that the system must be capable of dealing in real time with the distribution of input and output in the environment. This implies an understanding of the factors which influence the distribution and allocation of input and output resources in different situations for different individuals.

Due to the intrinsic characteristics of the new technological environment, it is likely that interaction will pose different perceptual and cognitive demands on humans compared to currently available technology (Gaggioli, 2005). It is therefore important to investigate fundamental and essential functions of the brain, including perception, thinking, emotion, learning, memory, attention, heuristic search, planning, reasoning, discovery, and creativity (Aarts and de Ruyter, 2009). The main challenge in this respect is to identify and avoid forms of interaction which may lead to negative

consequences such as confusion, cognitive overload, frustration, and so on.

Adams and Russell (2007) presented a cognitive user model targeted at providing a simple framework for the investigation of cognitive factors in AmI. It identifies nine components of human cognition relevant to the use of AmI technologies, namely input and perception, output and responses, feedback, working memory, emotions, mental models, executive functions, complex response skills, and long-term memory.

## 3.4  Emotions

AmI environments should take the user's emotions into account, that is, they should be emotion aware (Zhou et al., 2007) and, when appropriate, realize affective behavior. This implies that the environment should be able to interpret human emotions, generate responses which embed an emotional dimension, and also be able to influence users' emotions. Emotion awareness can help the environment to fine tune its behavior to offer to the users a better user experience, as understanding emotions is essential to the creation and re-creation of experiences (Westerink et al., 2008). Affect computation may constitute the basis for more advanced adaptive behavior, essentially leading to *affective adaptation*. The latter allows for broader adaptation scenarios in AmI environments, where interaction is continuous and users are involved in numerous interaction sessions with varying roles. An implementation of affective adaptation for games, where even affect computation is realized as an adaptive function, is discussed in Savidis and Karouzaki (2009).

An emotion is a physiological response to a situation. Emotions are commonly related to a set of elements, including anger, fear, happiness, sadness, love, surprise, disgust, and shame. Other emotions may be composed from these basic elements. Emotions are usually simply divided into positive and negative, although more articulated scales can be devised. Various approaches have been proposed to enable AmI environments to sense and measure people's emotions. Facial expression and speech characteristics are both reliable indicators of emotional states. Progress in wireless sensors also allows to unobtrusively monitor physiological parameters which show important correlations to various types of emotions, such as heart rate, electrodermal activity, facial muscle activity, and voice (Herbon et al., 2006).

Work has also been conducted in the area of creating means for expressing emotions in AmI technologies, mainly through lifelike avatars. Ortiz et al. (2007) reported a study which confirmed the capability of older users to recognize avatars' emotion expression as well as the positive effect of emotional avatars on the users' experience.

Emotional intelligence is the human ability to be aware of one's own and other people's emotions and react appropriately. An emotion-aware AmI environment should exhibit similar abilities and provide services which respond to emotions (Zhou et al., 2007).

Examples of the emotional behaviors that AmI environments attempt to stimulate in their inhabitants are affective presence, which aims at stimulating participation and creative inspiration (Boehner et al., 2005), laugher (Melder et al., 2006), playfulness into experiencing and understanding information (Eyles and Eglin, 2007), sense of care (Kröse et al., 2003), and wellness (Coughlin et al., 2009). Various means are exploited to generate or control emotions in AmI environments, from avatars and robots capable of emotional expressions to art, music, lighting, and other environment features.

## 3.5  Health, Safety, and Privacy

In a situation in which technology may act on the physical environment and deal with critical situations without the direct intervention of humans, it is also likely that new hazards will emerge for people's health and safety. Possible malfunctions or wrong interpretations of monitored data can lead to unforeseeable consequences, especially for disabled users who will be more dependent on technology than others. Therefore, appropriate strategies for avoiding risks must be elaborated and validated, with emphasis on users' awareness of the involved issues. A related challenge is the consideration of interoperability among different technologies and devices, as the correct functioning of the intelligent environment as a whole needs to be ensured.

Another relevant requirement is privacy, which concerns the effective protection of personal data that are collected through the continuous monitoring of people in AmI environments. Security and avoidance of human errors which may undermine the privacy of data emerge as fundamental requirements for Ami environments (Kraemer and Carayon, 2007). New challenges arise concerning how a person will be able to know what information is recorded, when, by whom, and for which use (Friedewald et al., 2007). Acceptability levels of data availability in the environment may vary depending on many factors and may ultimately be a matter of trade-off between the need for privacy and the options offered by the available information about the users.

In this context, users' acceptance of continuous monitoring becomes a relevant issue. Such acceptance is likely to depend on the perceived functional benefit of AmI environments and on the availability of mechanisms that enable participants to make their own choices in a way that is understandable, transparent, and independent of their comprehension level (Aarts and de Ruyter, 2009). This amounts to users developing trust in the intelligent environment. Wright et al. (2010) provide an in depth discussion of privacy issues in AmI environments, suggesting a series of countermeasures to ensure that AmI technologies develop in such a way to avoid privacy pitfalls and generate trust. These include technological solutions as well as socioeconomic solutions. Technological solutions include minimal data collection, transmission and storage, data and software security, privacy protection in networking, as well as authentication and access control. Regarding the latter, biometric recognition systems appear to be particularly promising in seamlessly enhancing users' protection in AmI environments. Nontechnological measures to address privacy issues include guidelines, standards, codes of practice, legislation, and public awareness.

Although AmI is only moving its first steps, it already very clearly appears that its human-centered and inclusive development raises a variety of ethical and social issues which necessitate appropriate policy, standardization, and legislative intervention (Bohn et al., 2005; Kemppainen et al., 2007). Relevant legislative areas are, for example, personal data protection, consumer protection, accessibility, and telecommunications regulation. In particular, privacy and security are overwhelming discussion topics in relation to AmI.

## 3.6 Social Aspects

In AmI environments, computing is expected to become far more dependent on social factors than it has in the past. Cooperation will be an important aspect, and communication and access to information will be concurrently used to solve common problems in a cooperative manner; moreover, cooperation may be among human users themselves or among user representatives (agents and avatars), to whom variable degrees of trust can be assigned. Access to information and communications will no longer be the task of an individual but will be extended to communities of users who have at their disposal common (sometimes virtual) spaces in which they can interact. Finally, the dynamic reconfiguration of context will be highly dependent on social phenomena (users moving in the environment, meeting, communicating to each other, collaborating, etc). User adaptation may become more difficult when multiple users interact in the same environment (Søraker and Brey, 2007). A typical example is the automatic selection of TV programs based on user habit. The presence of more than one user is likely to make this process more complex, and "group habits" need to be defined. Therefore, users in AmI environments can no longer be studied only at an individual level, and accounts of social behaviour become equally important.

Social connectedness is another essential element of the user experience in AmI environments and concerns the extent to which the environment behaves "socially" toward its inhabitants (Aarts and de Ruyter, 2009). Three main factors can be identified: (i) adoption of communication protocols that are compliant with societal conventions and follow social rules (socialization); (ii) awareness of user's emotions and adaptation of behavior accordingly (empathy, affective adaptation); and (iii) consistent and transparent behavior in interaction with people, which is recognized by the users as conscientious (consciousness).

Another important aspect of AmI environments is social presence, which reflects the degree to which the environment facilitates and supports human social interaction (Biocca et al., 2003). AmI needs to convey both the physical and virtual presence of people interacting and communicating through the environment. People's presence can be detected through sensors and can be represented, for example, through avatars but also through more subtle cues.

## 3.7 Cultural Issues

While AmI develops at a global level, it may be anticipated that cultural factors will become particularly relevant in identifying and reasoning about users' goals and tasks, which may be highly influenced by different cultural backgrounds (Søraker and Brey, 2007).

One of the main characteristics of AmI is natural interaction. However, what is seen as natural behavior and how certain forms of behavior relate to underlying desires depends to some degree on our cultural background. Behavioral indicators such as the range and importance of gesticulation, facial expressions, and body language can differ radically from one culture to another. In this respect cultural issues play a very relevant role in the AmI environment context, and the design of AmI environments needs to be informed by a deep understanding of the different cultures addressed.

Additionally, cultural values and practices may influence the acceptance of AmI technologies and of the environment as a whole. Bick et al. (2009) reported a study investigating the impact of assertiveness, future orientation, gender egalitarianism, uncertainty avoidance, power distance, institutional collectivism, in-group collectivism, performance orientation, and humane orientation on the acceptance of AmI technologies in hospital settings. The obtained results led to the conclusion that national cultural influence factors have a significant effect on the perceived usefulness of ambient intelligence. In particular, the dimensions of humane orientation, uncertainty avoidance, power distance, institutional collectivism, and in-group collectivism appear to play a significant role such that higher scores in these dimensions lead to greater acceptance of ambient technologies.

## 3.8 Aesthetics

Aesthetics is a subject receiving increasing attention in the design of AmI environments, as it is an essential aspect of everyday usage. Another reason is that the design of AmI technologies, as already observed in Section 2.3, needs to combine interaction design with other design traditions engaged in the design of everyday things, thus bringing into play a very different set of perspectives, values, and approaches (Redström, 2007). Aesthetics concerns the form and appearance of artifacts, addressing questions concerning structure and composition, use of material, overall consistency, and so on. Though the area of aesthetics in the design of AmI environments is still very far from presenting a coherent framework, there are attempts to develop related notions, building on industrial design tradition. Overall, the investigation of aesthetic aspects of interactive environments appears to transcend typical human factors studies based on user-oriented statistics and to involve issues such as (Redström, 2007):

- Engagement
- Temporal structures (e.g., interaction patterns and expressions of use that evolve over time)
- Alternative forms of use that challenge expectations on use and user
- Relations to context, for example, cultural references, user identity, traditions, other design domains
- Alternative interface and material combinations

## 4   CASE STUDIES

This section presents three case studies illustrating some aspects of the development of AmI artifacts in the context of the ICS-FORTH AmI Programme. These examples address different application domains and contexts of use, namely the domain of culture in the museum environment, the domain of education and learning in the classroom environment, and the domain of family activities in the home environment. They are small- to medium-size design cases which inevitably address only a limited part of the large number of issues which arise in a human-oriented approach to AmI, regarding both the design life cycle and the user experience aspects taken into account. However, they are illustrative of the implications of putting focus on users and on their contexts of use when designing AmI environments as well as the importance of qualities such as natural interaction, positive user emotions, playfulness, and aesthetic considerations in envisioning AmI artifacts.

### 4.1   iRoom

iRoom is a multimedia system targeted at archaeological and historical museums which supports the exploration of large-scale artifacts in actual size (e.g., a wall painting, a mosaic, a metope) through noninstrumented, location-based, multiuser interaction (Zabulis et al., 2010).

As its name implies, the system is installed in a room ($6 \times 6 \times 2.5$ m³) in which a computer vision subsystem tracks the location of its occupants. This subsystem is comprised of eight calibrated FireWire cameras ($66° \times 51°$) mounted at the corners and at the in-between midwall points, viewing the room peripherally in steps of $45°$. On one of the room walls a dual-projector back-projection screen ($4.88 \times 1.83$ m²) is installed. Behind the screen lies a control room that contains two $1024 \times 768$ short-throw projectors, two stereo speakers, and three workstations. Additionally, in the room there is an information kiosk and a stand with mobile phones. Mobile phones run a custom application that can receive information about their holder's position and render information accordingly.

iRoom (see Figure 2) can present large-scale images of artifacts with which one or more visitors can concurrently interact simply by walking around.

Visitors enter the room from an entrance opposite the wall painting. The vision system assigns a unique ID number to each person entering the room. In the room entrance there is a "barrier" created by four queue posts that guides visitors to move leftward or rightward along a short corridor in order to walk further into the room. As two help signs illustrate, visitors entering the room from the right-hand side of the corridor are considered to be English speaking, while those from the left-hand side, Greek speaking. When at least one person is detected in the room, a soft piece of music starts to play.

The whole room is semantically split into five zones of interest, delimited by different themes presented on the wall painting. These zones cut the room in five vertical slices (with respect to the projection). Furthermore, the room is also split into four horizontal zones that run parallel to the wall painting which are delimited by their distance from it. Thus, a $5 \times 4$ grid is created comprising 20 interaction slots. When a visitor is located over a slot, the respective wall painting part changes, depending on the slot's distance from the wall. For example, when a visitor is in front of a wall piece but standing at the first zone, an outline of the piece is presented along with a descriptive title. If the visitor moves to the zone that is closest to the wall, specific details of the piece are highlighted and related information is provided. All information is presented in the user's selected language. Since users get a unique ID, the system keeps track of the information they have seen as well as the time they have spent on each slot. This allows assigning more than one piece of information to one slot, which may be presented to the visitor when revisiting it. When multiple visitors concurrently use the system, interaction works as follows. If more than one visitor is standing on the same vertical zone of slots, the person who "controls" the respective wall piece (i.e., information is presented according to his or her

**Figure 2**   The iRoom system.

language preferences and position) is the one standing closest to the wall. If this person leaves, the next in line gets control, and so on.

Beyond location sensing, iRoom also supports two other types of interaction: (a) a kiosk and (b) mobile phones. The kiosk offers an overview of the wall painting, an introductory text, and two buttons for changing the user's language. When a visitor stands in front of the kiosk, all information is automatically presented in the visitor's originally set language. Furthermore, the wall piece in front of which the visitor has spent most of the time is highlighted. Mobile phones are used as multimedia guides, presenting images and text (that can also be read aloud) related to the visitor's position. In order to assign a mobile phone to a specific visitor, the visitor has to stand at a spot in the room denoted by a white X and press the phone's selection button.

### 4.1.1 Human Factors in iRoom

iRoom was designed in the context of a wider project targeted to enhance the museum visit experience through interactive edutainment. A formative evaluation of iRoom has been conducted using ethnographic field methods (Blomberg et al., 1993). To this purpose, the exhibit was installed in a dedicated space resembling an exhibition area of a museum. The use of video recording was avoided, since previous experience has shown that users tend to be more reluctant in freely exploring and experimenting with a system when they know they are being recorded. In the case of the dedicated exhibition space, participants were invited on an ad hoc basis, among people of all ages and cultural/educational background visiting (e.g., politicians, scientists, school classes) or working in FORTH facilities (including their families).

Up to now, more than 100 persons have participated. Typically, evaluation sessions involved a facilitator accompanying the visitors, acting as a "guide," and another distant observer discreetly present in the exhibition space. Since there were numerous evaluation sessions, alternative approaches were used. For example, when, at earlier stages, the interactive behavior of iRoom was tested, the facilitator would first provide a short demonstration to the participants and then invite them to try. Alternatively, when ease of use and understandability were assessed, the facilitator would prompt participants to freely explore the artifact without instructions. During and after the sessions, the facilitator held free-form discussions with the participants, eliciting their opinion and experience and identifying usability problems as well as likes and dislikes. The facilitator kept a small notepad for taking notes. After the visitors eft, the two observers would discuss the session, taking additional notes, often reenacting parts of it, in order to clarify or further explore some findings.

Overall, the opinions of all participants about the exhibit ranged from positive to enthusiastic. People of all ages agreed that they would like to find similar systems in museums they visit. Usually, when visitors were first introduced to the exhibit there was a short exclamation and amusement phase, during which they seemed fascinated by the technology and tried to explore its capabilities but, interestingly, after that most of them spent considerable time exploring the exhibit's content. Over different installations it was observed that the large size and luminous intensity contribute to the enhancement of visitor appreciation of the system.

Language selection came to be considered a considerably challenging task for interactive exhibits, rarely addressed by previous efforts. For example, a kiosk was initially used as a means of language selection. During evaluation it was observed that it created both problems of visitor flow (people had to stand in line) and erratic behavior (multiple visitors standing too close during language selection). The current scheme of implicit selection was an improvement in terms of both usability and robustness.

Other identified problems include intended versus unintended actions in location-based interaction and interaction fuzziness. When a visitor crossed the iRoom (e.g., to move closer to a friend), an avalanche of wall changes were triggered. This fact was especially irritating when the visitor was moving in front of other users, momentarily "stealing" their control over a slot. As a solution, a minimum dwell time was adopted in order for a user to gain control over a slot. Another "grey area" was the room's entrance. Since very often people were just peeking in or wanted to watch what was going on before engaging, the only functionality assigned to the zone close to the door was language selection and start of music play (to provide some reactive behavior to the first user stepping in). Also, visitors standing at the boundaries of slots in iRoom would sometimes be in a state of accidentally (or even worse constantly) switching between them. To remedy this problem, the slot's area where the user is has been enlarged.

### 4.2 AmIDesk

AmIDesk (Antona et al., 2010) is an augmented school desk designed in the context of a research project targeted to investigate the potential of AmI technologies in enhancing the learning experience in the classroom through integrating ambient interaction and digital augmentation of physical paper. It consists of an additional piece of furniture designed to fit typical school desks. Such an "add-on" provides a custom plexiglass 27-in.-diagonal wide screen whose inclination can range from $30^\circ$ (with respect to desk surface) to completely horizontal. It embeds almost invisibly all the devices required for the operation of the AmI applications and has a width of 40 cm, thus requiring relatively limited additional space with respect to the standard desk.

The AmIDesk includes:

- An Intel Core 2 Quad Core PC running MS Windows 7
- Two DLP miniprojectors located behind the screen
- One mirror for reducing the projection distance
- Two cameras located behind the screen
- Infrared projectors located behind the screen

- One camera located on top of the screen and capturing images of the conventional desks
- One smart pen and its transmitting device.

To better exploit the custom screen dimensions, a horizontal window manager was developed which includes two application and two menu areas. The screen supports multitouch interaction using the software reported in Michel et al. (2009) (see Figure 3). The smart pen input is captured through the Pegasus SDK.[*] The front vision software, currently under refinement, supports the identification of pages and other features of printed material as well as the recognition of simple gestures. Its combination with the desk's multitouch display allows augmenting physical learning materials with additional context-dependent information.

AmIDesk integrates a set of software applications for enhancing the learning experience of English as a second language. These include a login screen, a welcome screen, an individual personal area summarizing the current delivery status of all assignments, a dashboard where students can temporarily save material, assigned exercises in electronic form with the supported hints and help, a dictionary–thesaurus application, a personal dictionary application, a note-taking application, an application for viewing course-related multimedia, and language-learning games (e.g., hangman). The dictionary–thesaurus presents a short definition of the word, its pronunciation, a button allowing the student to hear the pronunciation, some synonyms, and a few examples of use in a sentence. In addition, the thesaurus offers options for extended descriptions, grammar information, a complete list of synonyms and antonyms, and several examples.

Although AmIDesk is designed for individual use, collaboration is foreseen for some tasks. For example,

**Figure 3**    The AmIDesk touch screen.

the students can exchange materials and the teacher can send materials (e.g., assignments) to the personal areas of all students through simple gestures. The smart environment automatically restricts actions that can be carried out by the students according to the current context. For example, when a reading task is active, the students cannot use some functionality in their system (e.g., multimedia, saving, printing), and when an exercise task or a test is being carried out, students are not allowed to send material to other student's personal areas. The system will also produce statistics regarding the hints that have been requested, per student and for the whole class, so the teacher will be able to monitor the student's progress. The system also monitors the success rate of each exercise and provides statistics. The teacher can then combine this with the hint statistics to review results and adjust the difficulty (remove/alter exercise) in order to improve the learning curve. The system can also measure the time needed by each student to complete a specific task.

### 4.2.1   Human Factors in AmIDesk

The approach followed in the design of AmIDesk was user centered, involving a small group of young learners from the very first steps of the design and targeting to provide intuitive and seamless tools to improve the learning and classroom experience.

The classroom constitutes a challenging context of use for the design of AmI technologies. In practice, there are severe space and layout limits to the introduction of AmI equipment which should be unobtrusive, hidden, or embedded in traditional classroom equipment and furniture. It is very important that such equipment can be installed smoothly and easily moved around in the environment and that space requirements are as limited as possible. This implies several constraints on how the AmI classroom environment can be developed. Additionally, legislation concerning school furniture must be taken into account. In the case of AmIDesk, for example, EU normative regarding standards dimensions of school desks was considered in order to establish the dimensions of the add-on artifact.

The requirements for AmIDesk were originally elaborated through scenarios, with the overall goal of ensuring that the resulting design goes at the heart of the learning process. To this purpose, learning of English as a foreign language was selected as a testing domain, and current practices were examined to identify useful support which can be offered through AmI technologies, focusing on preparation for the first and advanced certificates (thus addressing an adolescent student population). Based on such an analysis, extensive usage scenarios were compiled. The scenarios mainly address activities which take place in the classroom; however, an important consideration is that the software to be developed should be general enough to also support learning at home or elsewhere, independently from the classroom infrastructure and the augmented desk itself. In particular, the scenarios address the seamless context-dependent provision of useful additional information during language-learning activities. Interaction with the provided facilities is based on gestures, either

through the desk screen or directly on paper resources. For example, the learner can indicate a word on the page to view additional information about it or the answer to a fill-the-gap exercise to receive feedback or hints. Text entry during learning activities is based mainly on handwriting through a smart pen. However, an on-screen keyboard is also currently under design to support small text entry tasks on the touch screen. The desk should also be able to identify each user through a personal object (e.g., a school diary, pen, etc). The developed scenarios led to the identification of a set of software applications to complement the desk.

Following the development of the AmIDesk prototype, a formative evaluation experiment was conducted involving five young learners of English as a foreign language (one male and four females aged 11–16, all studying for a first or advanced certificate in English, and all familiar with PCs and mobile phones but not with AmI environments). The experiment was targeted to collect users' opinion regarding:

- The desk itself
- The overall idea of the interactive student desk in the AmI class and how it can assist learning
- The usefulness of each application regarding the English course and in particular the thesaurus, the multimedia application, the personal area for assignments and homework delivery, the myVocabulary area, and the hints and confirmations during exercises
- The UI layout and aspects of the supported gesture interaction

The experiment took place individually for each learner. After a very brief introduction, the learners were driven through a simplified scenario illustrating the main aspects of the desk and the related applications.

During the execution of the experiment, the children were asked questions about various aspects of the scenario, and notes were taken with all their comments. After the completion of the scenario, they were asked to fill out a questionnaire composed of 17 questions. Of the questions, formulated in an informal style to appeal to young learners, 15 used a Likert scale from 1 (sure!) to 5 (no way!). The remaining 2 questions concerned listing aspects of the scenario that the children particularly liked or disliked. Overall, the results were very positive, as all the children involved in the experiment were very interested about the desk and its applications, and some were enthusiastic about having such an artifact available in their classroom.

The preferred features of the desk were the personal area and the dictionary followed by the educational games, the dashboard, the hints and confirmations, touch interaction, pointing at things and viewing info, and the electronic submission of assignments. The disliked features were mainly the desk size and color (the green color had been used for facilitating vision processing) and, with respect to the user-interface (UI) mockups, again the colors and the fonts.

The young learners appreciated the educational support which the desk aims to provide as well as the potential for better organization of work between the classroom and the home environment and collaboration with teachers and other learners. Some of the children also proposed to include a grammar application similar to the thesaurus application, displaying grammar rules, verb tables, and so on, related to the task at hand. On the other hand, the young learners appeared to view the desk as a "trendy gadget" and were very sensitive to aesthetic issues, asking for the possibility of personalizing the desk color, selecting fonts, colors, background images, and avatar images. Regarding interaction, they appreciated the gesture-based applications, but they also asked for more traditional interaction means such as the keyboard.

The results of this investigation are currently being explored in the development of a larger set of applications as well as of a toolkit of pervasive widgets supporting interaction in the classroom environment.

### 4.3 booTable

booTable is an interactive "smart" coffee table prototype, accompanied by a couple of stools, constructed by recycled paper and designed to look as a modern piece of furniture (Grammenos et al., 2010) (see Figure 4). It builds upon the paradigm of surface computing but endeavors to overcome the identified limitations of current design practices. All technological parts (except the inevitable power cord) are carefully concealed in its body through the creation of appropriate design features. booTable fuses alternative, highly versatile input technologies and provides dual visual output, complementing the projection surface with a secondary display channel.

Multitouch input is supported through physical signal measuring. The adopted sensors include four touch buttons, a circular touch, and a vibration sensor. They are placed immediately below the surface in a completely invisible way. A Wiimote above the table's surface is

**Figure 4**  The booTable beta prototype.

also used to track IR-tipped pens and IR-fingertips. Identification of various objects is achieved using a radio-frequency identification (RFID) reader.

booTable is accompanied by two matching stools that also embed sensing technologies and by a set of tabl-e-cloths. Tabl-e-cloths realize an innovative concept. They are RFID-tagged printed canvas sheets that act both as a tangible means for launching software applications and as the basic layer for creating mixed-reality interfaces. booTable stools also embed a wireless sensor for detecting user presence.

booTable comes with a large variety of family-oriented applications, including a book and DVD information retriever, a photo slide show and album, a family notes application, a creative painting application, a chess game, an invaders game, a dual screen storyteller, a mobile phone hub, various e-clocks, and smart light control.

### 4.3.1   Human Factors in booTable

booTable underwent an iterative design process through the realization of two different prototypes with quite different characteristics. The initial design requirements were based on the one hand on the limitations identified in current tabletop interactive systems and on the other hand on the context of use of family activities. Identified requirements include:

- Table functionality: The artifact would be a regular coffee table of the type usually found in the living or sitting room. The surface would be appropriate to support beverages, magazines, books, game boards, and small items such as keys, mobile phones, and remote controls.

- It should have distinctive, attractive, and ideally innovative design. It should be something that people would like to put in their living rooms as is, even if bare from its interactive behavior.

- It should look like a piece of furniture and not an electronic device or gadget. All technological components and their traces should be hidden. When the system is off or inactive, it should still be useful and presentable.

- It should fuse multiple input and output technologies.

- It should be able to somehow change its appearance in order to be personalized and fit in multiple spaces.

- It should target all types of families, with any number of members (even just one), of different ages.

- It should strive for high usability and ease of use by the broadest possible spectrum of user population without requiring previous computer expertise.

- The tabletop should support a large diversity of everyday tasks, including leisure activities.

- The construction cost should be as low as possible.

- It should be as flexible as possible, so that design ideas that did not work out could easily be "removed" and new ones could be tried out without having to reconstruct the prototype from scratch.

Based on the above requirements, a set of usage scenarios was elaborated, and a first wooden prototype of booTable was built. After developing the required software, an informal assessment of the concept and its implementation was conducted during the time course of one week with the voluntary participation of 27 individuals of both genders with ages varying from 15 to 62 years old. Fourteen of them were technology savvy while the rest were random visitors, friends, and so on. The assessment process was short and very flexible. It basically consisted of a brief introduction to the concept, vision and goals of the project, a demonstration of the developed applications during which participants were prompted to interact with the system, and finally a discussion aimed at eliciting impressions from the overall experience, positive and negative aspects of the implementation, ideas for additional applications, and the estimated usefulness and desirability of such a future product. User verbalizations were hand noted by one of the members of the development team.

Overall, the participants' reactions and first impressions were very positive. All of them showed a vivid interest in the concept and stated that they enjoyed interacting with the table. Especially the non- technology-savant ones were rather surprised by the fact that furniture may come equipped with interactive functionality. Most of them regarded it as "useful," "fun," and "impressive" and stated that, at a price similar to a flat-screen TV or a PC, they would probably consider purchasing it. Users were also prompted to help identify as many drawbacks of the prototype as possible. As a result, a number of issues, from simple concerns (e.g., the table was probably too high for a coffee table) to serious usability problems (e.g., RFID tagging and cataloguing books), were identified. In addition, several other problems, mainly related to the selected construction materials and hardware, were raised by the development team. In summary, the conducted evaluation led to abandoning wood as a construction material, as the artifact was too heavy and bulky and needed to be placed against a wall. Additional issues concerned the quality of graphics, the performance of some of the sensors, the low refresh rate of the secondary display (an electronic picture frame), the cumbersome use of RFID tags for retrieving books and DVD information, and the need for more detailed context information for the proper functioning of the smart light application. Based on the above, a beta version of booTable was developed, entirely realized in recycled paper, and the necessary hardware modifications and enhancements were implemented. These included the replacement of the PC to provide better graphics, the replacement of the photo frame with a 7-in. touch screen, a rearrangement of the sensors underneath the table surface, and the installation of a bar code scanner. Various software modules were also modified, and new ones were added.

Upon its completion, the beta prototype of booTable was showcased to a large audience at the exhibition of a major HCI conference. The overall impression regarding both the look and "feel" was very encouraging, while the fact that it was made by recycled paper created a lot of positive reactions. Since many of the people that experienced it were HCI practitioners, many fruitful discussions were held which included interesting ideas about potential improvements and new applications.

## 5 EMERGING CHALLENGES

The issue of human factors in AmI environments is particularity complex, and the current state of the art is still far from offering consolidated practices regarding how to design AmI environments in a human-oriented fashion and how to address the user experience in a more rigorous and scientifically sound way. In this context, a number of new research challenges emerge, including:

- Investigation of human characteristics, abilities, and requirements in the context of AmI
- Suitable accounts and models of the context of use; implies investigating how to model, embed, and reason about user experience qualities in order for AmI environments to exhibit intelligent behavior
- Definition of a user experience framework for AmI environments, taking into account interaction naturalness, accessibility, cognitive demands, emotions, health, safety and privacy, social and cultural aspects, and aesthetics, and elaboration of related assessment criteria and metrics
- Multidisciplinary approaches to defining acceptable levels of safety and privacy risks in AmI environments and establishing related standards, regulations, and technical solutions
- Elaboration of design methods suitable for very complex interactive environments
- Reappraisal of industrial design methods and techniques for integrating interactive and other functional characteristics of artifacts and environments

Given the complexity of AmI technologies and their high level of interdependence with the use context, it is believed that substantial progress toward facing the above issues will be brought about as AmI environments further develop. This is particularly important when taking into account the large amount of usage data that AmI environments will make available, through monitoring, for further analysis and improvement.

This endeavor will be highly multidisciplinary, involving collaboration across multiple domains and building upon several disciplines, including HCI, social sciences, requirements engineering, software quality, human factors and usability engineering, and software engineering. Therefore, it is critical to bring together research teams and diverse user groups so as to start a constructive dialogue and establish a common

vocabulary. The direct and active participation of user representatives in shaping ambient intelligence technologies and applications to reflect and anticipate their needs is also considered a critical factor. Therefore, appropriate research infrastructures are needed to act as test beds and incubators of future technologies.

Towards this end, the Institute of Computer Science (ICS) of FORTH is in the process of creating a large-scale, state-of-the-art AmI facility intended, among other things, to support the establishment and conduct of a line of research targeted to HCI in AmI environments and technologies. This research facility will initially address the application domains of housing, education, work, health, entertainment, commerce, culture, and agriculture. The facility will also encourage international collaboration through hosting visiting scientists from around the world.

It is believed that such a research facility will have a significant role in ensuring that AmI emerges and develops in a way that is acceptable and can be adopted in the long run by all members of the information society as well as facilitating and driving a smooth transition of AmI technologies from research into real-life situations.

## 6 SUMMARY AND CONCLUSIONS

This chapter has discussed the centrality and role of human factors in the emergence and development of AmI environments, focusing on:

- The user-centered design process and how it is affected by the complexity of AmI environments
- Basic user experience qualities which need to inform the design of AmI environments but also be captured and modeled so as to enhance interaction, responsiveness, and intelligent behavior of the environment

To illustrate the above, Section 1 discussed the UCD process in light of the requirements posed by AmI, focusing on emerging problems and potential solutions for applying and revising existing methods and techniques or developing new ones. Overall, the UCD process as practiced today appears to be a more than valid starting point for investigating how to put users at the center of AmI development. Various well-known methods and techniques have been shown to be useful in this respect. However, UCD in AmI needs to face the challenges and exploit the opportunities posed by the extended context of use and its inextricable fusion with the interactive environment. A very important aspect in this respect is the availability of monitoring data over extended period of times, which can be exploited when adapting interaction and environmental behavior on the fly but also in continuously reshaping design as well as proposing new methods and techniques for the various UCD activities.

An additional element to take into account is the fusion of technology with the human living space, which brings about the requirements of combining

interaction design with industrial and architectural design. Clearly, as it happened decades ago with the emergence of HCI, an opportunity exists here for the foundation of a new design discipline deeply rooted in human factors but characterized by its own processes, methods, rules, and practices.

Section 2 focused user experience factors considered critical in AmI, including natural interaction, accessibility, cognitive demands, emotions, health, safety and privacy, social aspects, cultural aspects, and aesthetics. For each of them, a brief overview of the main issues involved has been provided, focusing on existing or emerging approaches. Obviously, the list is not complete, and existing approaches far from offer a comprehensive framework.

Section 3 presented three case studies of the UCD of AmI artifacts developed in the ICS-FORTH AmI Programme, namely an interactive wall for the display of museum artifacts, an augmented school desk, and a smart coffee table. Obviously, the scope of these case studies is limited. However, each illustrated in practical terms some aspects of the adopted design process and of the user experience qualities relevant to the specific projects.

Finally, Section 4 put forward the need for a more systematic approach to the above issues. To this end, the availability of appropriate research infrastructures and multidisciplinary collaborations is critical.

## 1 INTRODUCTION

In its short history, human–computer interaction (HCI) has been characterized by a trend toward elaborating, designing, and establishing more human-oriented, natural, and intelligent forms of interaction, progressively addressing the needs and requirements of a wider, less experienced, and more naive user basis (Stephanidis et al., 1998). This path is intrinsically linked with (i) the progressive emergence of new, more general and systematic framework for studying and designing interaction and (ii) technological evolution supporting the establishment of richer alternative interaction techniques and user interface styles.

The concept of interactivity between humans and computers, contextually defined in this chapter as *the extent to which the characteristics of an interactive system affect the communication behavior of both the user(s) and the system itself*, plays a crucial role in this respect. Interactivity is not a new concept, as it has been investigated in the literature with respect to both human communication and various types of interactive systems. In this chapter, the evolution of interactivity as it has manifested itself in HCI is considered.

Although it is difficult to identify the forces that shape the evolution of interactivity, two main mechanisms can be considered, on the one hand technological advancements and breakthroughs offering new possibilities, and on the other hand the social impact of these technologies, starting from specializsed user communities and gradually expanding to the society at large. Such impact could take many forms, ranging from the commercial success and user adoption of graphical operating systems to the shaping of the new information society in the age of the Internet.

To shed light on interactiviy in the context of HCI, understand its evolution, and outline emerging challenges, this chapter firstly briefly reviews existing accounts of interactivity, focusing on identifying dimensions of the concept which can be meaningfully used for analyzing and explaining its various instantiations in HCI.

Second, the chapter looks at different theoretical frameworks of design and evaluation that influenced the evolution of interactivity.

Third, it looks into the evolution of interaction, starting from the 1950s until today, by concentrating on technological and research advancements that have led to the current interaction models and styles, as well as at application domains that fostered significant steps in the evolutionary path of interactivity. A brief outline of the most important interaction paradigms is presented, outlining the interactivity dimensions addressed in each of them.

Finally, it attempts to present the latest developments and emerging trends in HCI and address several issues that concern them.

## 2 CONCEPT OF INTERACTIVITY

### 2.1 Interactivity in Human Communication

The concept of interactivity originates in the context of human communication and has been addressed in various related disciplines, such as philosophy of language, linguistics, semiotics, and communication psychology. While a review of such accounts is beyond the scope of this chapter, some basic aspects of interactivity in human communication naturally lend themselves to provide terms of comparison in analyzing interactivity in HCI.

In the famous work on communication theory by Shannon and Weaver (1949), communication has been defined as a process whereby information is enclosed in a package and is channeled and imparted by a sender to a receiver via some medium. The receiver then decodes the message and provides feedback to the sender. All forms of communication require a sender, a message, and an intended recipient. However, the receiver does not need to be present or aware of the sender's intent to communicate at the time of communication in order for the act of communication to occur. Communication also requires that all parties share a common code or language for message exchange.

Interactive communication is commonly defined as a process involving at least two participants, where the content of a particular message is determined in part by the content of the prior messages from all participants, that is, by the communication context (Chapanis, 1988). Interactive communication can take place through a symbolic system, notably natural language in spoken or written form, and complementary through gestures, facial expressions, and actions. Natural language is a unique symbolic system. Some of the most important distinguishing characteristics of human language are (Hockett, 1960):

- *Vocal–Auditory Channel*. Standard human language occurs as vocal communication (i.e., producing sounds with the mouth), which is perceived by hearing it. Exceptions are writing and sign language, which are examples of communication in the visual and manual channels, respectively.

- *Rapid Fading* (*Transitoriness*). The human language signal does not persist over time. Speech waveforms fade rapidly and cannot be heard after they fade. Writing and audio-recordings can be used to record human language, so that it can be re-created at a later time.

- *Interchangeability*. The speaker can both receive and broadcast the same signal. This is distinctive from some forms of animal communications.

- *Total Feedback*. Speakers can hear themselves speak and can monitor their language performance. This differs from some other simple communication systems, such as traffic signals, which are not normally capable of monitoring their own functions.

- *Semanticity*. This is a fundamental aspect of all communication systems, implying that specific signals can be matched with specific meanings. Speakers of a language recognize the meaning to which a signal is associated.

- *Arbitrariness*. There is no necessary connection between the form of the signal and its meaning.

- *Discreteness*. The basic units of speech (such as sounds) can be categorized as belonging to distinct categories. There is no gradual, continuous shading from one sound to another in the linguistics system, although there may be a continuum in the real physical world.

- *Displacement*. The speaker can talk about things which are not present, either spatially or temporally. For example, human language allows speakers to talk about the past and the future as well as the present. Speakers can also talk about things that are physically distant (e.g., other countries, the moon) or even refer to things and events that do not actually exist.

- *Productivity*. Human languages allow speakers to create novel, never-before-heard utterances that others can understand. Human beings are unrestricted in what they can talk about, and no area of experience is accepted as necessarily incommunicable. This includes language and communication themselves. Thus human language allows metalinguistic discourse.

- *Learning*. Human language is not something inborn. Although humans are probably born with an ability to do language, they must learn, or acquire, their native language from other speakers. This is different from many animal communication systems where the animal is born knowing their entire system, for example, bees.

Another inherent characteristic of natural language, which distinguishes it from formal languages, such as programming languages and command languages, is underspecification of meaning, which may take two forms, namely ambiguity and vagueness. Ambiguity refers to the fact that natural language words and utterances may be interpreted in different ways depending on context. Vagueness refers to the fact that natural language may refer to events and entities at an

abstract level, omitting details that are not relevant in a specific context. Underspecification is often mentioned as a "defect" of natural language, which constitutes an obstacle to precise communication. On the other hand, it can be seen as an economy mechanism which allows human communication to be specific enough for a particular purpose with the minimum necessary effort (Wasow et al., 2005).

Apart from the characteristics of language, human spoken dialogue can be analyzed along a number of dimensions which appear to be relevant also in the wider context of HCI. These include (Petukhova and Bunt, 2009):

- *Dialogue Purpose and Domain of Discourse.* Dialogues are usually motivated by goals, tasks, or activities which are noncommunicative in nature, for example, to obtain certain information, to solve a problem, and to act in a game.
- *Contact, Presence, and Attention,* A basic requirement of communication is that the parties are in contact and stay so. For some types of dialogue this aspect is of a particular importance, namely when there is no or limited visual contact between the participants. For example, telephone conversations are dependent on the quality of the communication channel. But also, when dialogue participants have direct visual contact, they tend to permanently check the attention of their interlocutors and their readiness to continue the conversation. To this purpose, they utilize both their bodies and facial expressions (e.g., gaze) and a variety of vocal phenomena to show attention as well as the type of reaction they expect from others.
- *Grounding and Feedback.* Successful dialogue is based on shared knowledge and beliefs (Clark, 1996). To establish such a common communication basis, speakers and addressees during dialogue attempt to confirm that each of them has understood what is uttered. This process is called grounding. Grounding includes feedback (Traum, 1999), that is, the speaker during dialogue provides information on his or her own processing of the partner's previous utterance(s).
- *Taking Turns.* Turn management, another essential aspect of any interactive conversation, is defined as the distribution of the right to occupy the sender's role in dialogue. Turn taking is usually understood as obeying normative rules, depending on the speaker's needs or motivations and beliefs, and on the rights and obligations in a conversational situation.
- *Social Obligations and Politeness.* Participating in a dialogue is a social activity, where one is supposed to do certain things and not others and to act in accordance with the norms and conventions regulating social behavior. Each participant in dialogue not only has functional but also ethical tasks and obligations and performs social obligation acts to fulfill these. Such obligations

include politeness rules, such as not imposing anything to the communication partner, offering alternative options, and encouraging positive feelings (Lakoff, 1973).
- *Dialogue Structure.* Dialogue participants may at several dialogue stages indicate their view of the state of the dialogue and make the hearer acquainted with his plans for the continuation of the conversation. The speaker can give indications that he or she is going to close the discussion of certain topic(s) or wants to concentrate the hearer's attention on a new topic. Dialogue structuring is based on the speaker's view of the present linguistic context, on his or her plan for continuing the dialogue, and on the assumed need to structure the discourse for a partner.
- *Handling Errors.* Speakers continuously monitor the utterance that is currently being produced or prepared to produce (Clark and Krych, 2004), and when problems or mistakes are discovered, they stop the flow of the speech and signal to the addressee that there is trouble and that a repair follows (error signaling). Human conversations contain large numbers of phenomena such as disfluencies, interruptions, confirmations, anaphora, and ellipses (Glass, 1999).
- *Timing.* Another aspect of communication which is concerned with disfluent speech production is time management, where the speaker suspends the dialogue for one of several reasons and resumes it after minor (stalling) or prolonged (pause) delay. Delays take place at all major levels of planning—from retrieving a word to deciding what to talk about next (Clark and Fox Tree, 2002).
- *Adaptation.* One of the most robust findings of studies of human–human dialogue is that people adapt their interactions to match their conversational partners' needs and behaviors (Pennebaker and King, 1999). People adapt the content, the syntactic structures of their utterances, as well as their lexical choices to match their partners'. They also adapt their speaking rate, amplitude, and clarity of pronunciation (Walker at al., 2007). Adaptation is also a crucial aspect of intercultural communication, that is, people adjust their communication styles toward or away from each other during cross-cultural interactions (Cai and Rodriguez, 1996).

Besides speech dialogue, other aspects of human communication are also important, For example, recent phenomenological views on language and communication emphasize action associated with speech (Tripathi, 2005). These actions into which language is woven are inseparable from communicative meaning. Thus, language has an extra dimension associated with social conventions and actions, such as gestures, pointing, and body language. Human beings have the ability to utilize their entire bodies for the purpose of communication (rather than simply voice or writing), thus implying

multimodality. The tone of the voice, body language, and gaze all constitute communicative meaning, either consciously or subconsciously (Bunt and Beun, 1998).

Human communication is also supported through semiotic systems other than natural language, namely iconic languages. Icons are semiotic signs which directly resemble the objects they refer to. In contrast to natural language, iconic languages are not arbitray. Because of their communicative power, which transcends different languages and cultures, icons are used in a variety of real-life situations to inform people about particular conditions or give instructions. Typical examples appear in public information spaces, trains, airplanes, cars, and printed books (Barker, 2000). The human ability to communicate through action and iconic languages is at the center of the notion of direct manipulation (see Section 4.3).

Finally, emotion plays a central role in human communication, especially when disagreement between participants emerges. Emotional reactions represent an important type of feedback on the effects of utterances on dialogue participants. In dialogue, emotional reactions can be signaled by response speed, reiteration of claims, lexical choice, response avoidance, sentence length, and so on. Likely emotional reactions are defensiveness, indignation, frustration, anger, regret, guilt, and enthusiasm (Anderson and Guerrero, 1998).

## 2.2 Interactivity in HCI

Many definitions of interactivity have been provided in the HCI literature, especially with reference to Web services, computer-supported communication, computer-supported work, electronic advertising, e-learning, interactive TV, electronic games, and virtual reality.

User–machine interaction was the focus of early definitions of interactivity, in which the emphasis was on human interaction with computers. To be interactive, a computer system must be responsive to users' actions. In this context, interactivity has generally been measured in terms of input or output devices, for instance, the number of "point-and-click" opportunities on a computer screen (Shneiderman, 1998). Norman (1990) suggested that the interactive process is a repeated loop of decision sequences of a user's action and the environment's reaction.

However, though user–machine interaction is an important aspect of interactivity, it is not adequate to fully capture the concept, especially since the emergence of more advanced technology such as the Internet. As a result, researchers have started investigating interaction in a technological context more broadly, also considering other types of interaction, such as user–user interaction and user–message interaction.

User–user interaction is usually discussed from an interpersonal communication perspective. In this respect, the more communication in a computer-mediated environment resembles human interpersonal communication, the more interactive such an environment is considered (Ha and James, 1998). However, a medium such as the Internet offers many possibilities to break the boundaries of traditional interpersonal communication. Through the Internet, people no longer

need to be at the same place or communicate at the same time. Research has shown that computer-mediated communication and face-to-face communication are not functional alternatives (Flaherty et al., 1998), as each has distinctive characteristics and addresses different needs.

From a user–message interaction perspective, interactivity is defined as the ability of the user to control and modify messages (Steuer, 1992). Whereas people have little control over messages in traditional media, the Internet gives users much more freedom in controlling the messages they receive and allows messages to be customized according to the users' own needs. Based on the above, Liu and Shrum (2002) define interactivity as the degree to which two or more communication parties can act on each other, on the communication medium, and on the messages and the degree to which such influences are synchronized.

Other definitions have focused on two distinct aspects of interactivity: reciprocal communication and control (Liu, 2003). Reciprocity implies that interaction should allow two-way flow of information, and the information being exchanged in a sequence should closely relate to each other (Rafaeli and Sudweeks, 1997). Additionally, the exchange of information should happen in real time. The control dimension implies that participants should be able to exert control on both sent and received information (Jensen, 1999) as well as over the communication medium. Both control and reciprocal communication are important aspects of interactivity. Control helps ensure a reciprocal exchange that satisfies the needs of all communicating parties, while reciprocal communication provides an effective channel for exerting control. Melding the two aspects, Liu and Shrum (2002) proposed three dimensions of interactivity: active control, which describes a user's ability to voluntarily participate in and instrumentally influence a communication; two-way communication, which captures the bidirectional flow of information; and synchronicity, which corresponds to the speed of the interaction. Based on the above, Liu (2003) defines a framework for measuring interactivity on websites.

Interactivity has been discussed also in relation to new media and educational technologies. Rice (1984) defined "new media" as consisting of communication technologies that allow or facilitate interactivity among users or between users and information. Heeter (1989) describes six dimensions of interactivity in new media: (i) complexity of available choice, meaning the amount and variety of user choices; (ii) the effort that any user of a media system must exert to access information; (iii) responsiveness: interactivity is a continuous variable measuring how "actively responsive a medium is to users"; (iv) information use monitoring, that is, how well information selection can be monitored across a population of users; (v) ease of adding information, meaning the degree to which users can add information for access by the audience; and (vi) interpersonal communication facilitation, which comes in at least two forms: asynchronous (allowing users to respond to messages at their convenience) and synchronous (allowing for concurrent participation).

Downes and McMillan (2000), following an interview-based study, propose a conceptual definition of interactivity identifying six main dimensions: direction of communication, time flexibility, sense of place, level of control, responsiveness, and perceived purpose of communication.

In the domain of e-learning, Chou (2003) investigates a technical framework for interactivity following an empirical methodology. The framework includes the following dimensions: (i) choice, that is, the amount and multimedia type of information users (learners and instructors) have access to as well as other types of user options; (ii) nonsequential access, that is, users can access information in a nonlinear way; (iii) responsiveness to learner, tha is, the system responds to a user's request without delay; (iv) monitoring information use, that is, the system can collect data on the users themselves, their selections, their use of information, and so on, and the users can monitor personal information which is collected; (v) personal-choice helper, that is, information is available to help learners choose instructional content; (vi) adaptability, that is, the interaction process and the exchange of information are adapted to individuals; (vii) playfulness, that is, information stimulates users' curiosity and fun; (viii) facilitation of interpersonal communication, that is, users can communicate asynchronously and/or synchronously; and (ix) ease of adding, that is, users can add information and content to the system.

Based on the instructional quality of the interaction, Schwier and Misanchuk (1993) identified three levels of interaction, namely reactive, proactive, and mutual interactions. A reactive interaction is a response to a given question. Proactive interaction involves learner's construction and generation activities during the learning process. In a mutual interactive environment, the learner and system are mutually adaptive in reactions with each other. The relationships among the three levels of interaction are hierarchical in terms of quality of interaction. Therefore, the quality of a mutual-level interaction is higher than that of a proactive-level interaction, and the quality of a proactive-level interaction is higher than that of a reactive-level interaction. Consequently, the higher levels of interaction provide a greater opportunity for mental engagements and learner involvements than the lower ones.

In the context of virtual reality, Steuer (1992) defines interactivity in telepresence as a concept which "refers to the degree to which users of a medium can influence the form or content of the mediated environment" (p. 80) and can be further understood in terms of degrees of speed, range, and mapping. Speed relates to how responsive the system is to the user's actions. Range refers to how many possibilities for manipulation there are in the mediated environment, including intensity (loudness, brightness, etc.), spatial organization (where objects appear, etc.), and temporal ordering. Mapping in this context refers to how closely actions taken on the mediated environment are mapped to corresponding "natural" actions in the human physical environment, thus contributing to a sense of telepresence.

New media are usually intended to include electronic games. In such a context, interactivity is considered a very important design dimension. Friedl (2002) distinguishes three levels of interactivity in games: player to player, player to game, and player to computer. By understanding these different types of interactivity, game designers can identify the factors that affect each and use appropriate techniques and methods in their own game designs. These factors also provide a basis for continuous evaluation during the development process and can be used to classify and analyze online game designs.

The above variations on the theme of interactivity lead to two observations. First the concept of interactivity in HCI, while somehow commonly understood, is still subject to research in order to achieve consensus on its constituting dimensions across perspectives and application domains. Second, many of the aspects of interactivity which have been taken into account in existing work in the HCI field are closely interrelated with aspects of human communication as briefly outlined in Section 2.1.

The next section will present an analysis of popular design frameworks as they have evolved in the HCI field over the years, attempting to highlight how emphasis on different design concerns impact the interactivity of the design outcomes.

## 3   THEORETICAL FRAMEWORKS

This section looks into the theoretical frameworks that influenced interaction design and consequently the development process, the degree of human-centeredness of the proposed interaction paradigms, and eventually the evolution of how users use and perceive interactive technology. In the overall evolutionary history of interactivity, these theoretical frameworks can be thought of as driving forces that influence and guide interactive technology development, with the underlying assumption that the more human-centered the design process, the more interactivity assumes a fundamental role.

### 3.1   Human Factors and Ergonomics

Frederick Taylor's (1911) *The Principles of Scientific Management* was arguably the first publication aimed at improving the work practice using the new technologies of the time in the industry. The prime motivation was improving efficiency, and although this was more of a management-oriented work than actual human factors, it served as the starting point for looking scientifically at the work process and the people who executed the necessary tasks.

Efficiency and cutting down time and costs was the primary motivation, but during World War II there was a shift of priorities. It was important to improve the safety and efficiency of aircraft cockpits and weapons systems to cut down on human loss. Here is where the actual foundations of human factors and ergonomics lie. In the work done to improve aircraft equipment and controls, the focus was on the human side, and instead of trying to suit people to the work task and

$$T = a + b \log_2\left(1 + \frac{D}{W}\right)$$

**Figure 1** Fitts's Law, where $T$ is the average time taken to complete the movement; $a$ represents the start/stop time of the device (intercept) and $b$ stands for the inherent speed of the device (slope). These constants can be determined experimentally by fitting a straight line to measured data. The distance $D$ is from the starting point to the center of the target and $W$ is the width of the target measured along the axis of motion, where $W$ can also be thought of as the allowed error tolerance in the final position, since the final point of the motion must fall within $\pm W/2$ of the target's center.*

equipment, the opposite was now the case; the U.S. army employed psychologists who studied the behavior of pilots and made measurements to determine human capabilities and limitations. An obvious example that was derived from this research domain was the work of Fitts, made famous by his law (see Figure 1), which was part of a study aimed at finding optimal designs and solutions for cockpit controls that would be easier to use by pilots. From the point of view of interactivity, early work in human factors and ergonomics can be seen as a first attempt to match the system's characteristics to the human user and design systems which are better suited to human abilities.

After World War II, in 1957, the aviation psychologists formed the Human Factors Society (HFS, later named the Human Factors and Ergonomics Society) in the United States. This new discipline thrived in the following years (Grudin, 2008).

### 3.2 Model Human Processor/GOMS

The most influential work that emerged from the marriage between cognitive psychology and human factors, as well as computer science, was the model human processor (MHP; see Figure 2), first presented in detail in the seminal book *The Psychology of Human-Computer Interaction* by Card et al. (1983). It is interesting to note the background of the authors. Card, with a background in psychology, was working in Human Factors at Xerox, and Newell, already a well-respected researcher in artificial intelligence, took an interest in studying human behavior (McCarthy, 1988).

The model is based on looking at the interaction between the human and the computer fundamentally as an information-processing task, that is, treating the two parties of the interaction, the human and the computer, as two information-processing systems, each with its own properties, performance capabilities, and limitations. The human user is the party that has specific goals and attempts to accomplish them by feeding commands to the computer system. Output from the computer is processed and reviewed, and the cycle continues until the user goal is accomplished. In the MHP, the human information-processing system is treated in terms

analogous to those of the computer system; the human cognitive architecture consists of 3 processors (perceptual, cognitive, and motor), the memory (working and long term), 19 parameters, and 10 principles of operation.

The presentation of visual information on the computer display is perceived by the perceptual processor (basically the eyes and ears). The cognitive processor processes information chunks from memory that was put there by the perceptual processor. The motor processor acts after those chunks have been processed and evaluated and a decision toward accomplishing a goal has been taken. An action may be performed by the motor processor. All these events can be isolated and ultimately analyzed to find the optimal and most efficient solutions.

The authors did not imply that human users do actually operate fundamentally as computers do; in fact they explicitly stressed that this is not the case. However, the model provided tangible and quantifiable measures of performance for some of the tasks and consequently allowed measuring (in some cases at least) how different presentations and parameters of the interaction affect the efficiency and usability of the communication between the two systems and how the user may benefit in accomplishing his or her goals.

In the same book, the GOMS (goals, operators, methods, and selection rules) analysis framework was also presented. A GOMS analysis of a task describes the hierarchical procedural knowledge a person must have to successfully complete that task. Based on that and the sequence of operators that must be executed, it is possible to make quantitative predictions about the execution time for a particular task. Other analyses, such as predictions of error, functionality coverage, and learning time, are also sometimes possible. Since the original formulation presented in Card et al. (1983), a number of different forms of GOMS analysis have been developed, each with slightly different strengths and weaknesses (John and Kieras, 1996; Byrne, 2008)

The above approaches have led to further analysis of humans as information-processing systems. The fundamental assumption and identification of the human user as a system that can be divided into further subsystems that can be analyzed have produced a significant volume of work (mainly from the human factors side of the community), which in large part has been applied successfully in HCI. For example, under the human information-processing system approach, extensive work has been conducted on issues of human attention, distraction, memory performance, problem solving, response times, and more, all of which are related to interactivity phenomena. While the hard science behind this work is irrefutable, there are however differing opinions on the success of the application of such models among HCI specialists, specifically regarding the overall interaction experience from the perspective of the user and the general context of use. A complementary approach to the human information-processing model that partially addresses this issue is the ecological approach (Wickens and Carswell, 2006), which takes into account the environment and views the information flow, not in distinct stages, but as an integrated flow.

---

* All figures in this chapter are in the public domain and have been retrieved through Google.
**Figure 2**    Model human processor.

Three years after the publication of *The Psychology of Human-Computer Interaction* (Card et al., 1983), another approach came into focus from the cognitive science discipline which tried to address the lack of accounting for the personal experience of the user in the above models, named user-centered design, which is addressed in the next section.

## 3.3 User-Centered Design

User-centered design is among the most influential design philosophies in the HCI community and had a major impact in the design and development of information systems. Traditionally, the software development process was seen as a series of distinct stages of activity that reminisce a waterfall, in which each activity naturally leads into the next. This is generally known as the waterfall model (Royce, 1970).

Inherited from the traditional engineering industry, the waterfall model divided the process into neat and manageable sections, ideal for setting and monitoring deadlines, as well as producing a rich amount of tangible deliverables. However, its monolithic nature is not really suited for the development of software, especially when usability issues are taken seriously. User-centered design became the alternative that emerged from the HCI community, shifting the focus from a technology-driven approach to the user being the center of each development phase. In addition, it responded to the unrealistic distinction between each stage of development by calling for the blending of each development phase and the need for iteration in the various stages of the process life cycle, with each iteration loop ending with an evaluation of the outcome based on user feedback.

As a result of this approach, every stage in the life cycle is characterized by the strong involvement of users, in the beginning as the main source of requirements specification, later as the main providers of feedback, to the final evaluation of the product with user testing. Each stage of the development cycle has been a subject of research and the past years have seen the introduction of many different techniques to enhance the quality of the outcome. For example, in the requirements specification stage, analysts employ the use of field observation, focus groups, personas, diary keeping, and more. In the design stage, rapid prototyping and evaluation techniques with user testing or expert evaluation techniques are adopted.

In 1986 Norman and Draper were the editors of a collection of papers under the title *User Centred System Design* (UCSD), which they described as "the design of computers, but from the user's point of view." In his chapter in the book, entitled "Cognitive Engineering," Norman presented his model of HCI, based on cognitive science. This model decomposes human action into seven distinct stages, starting from establishing a goal to evaluating the outcome from the computer in relation to this goal. The precise number of stages in the model can vary; the author nevertheless claimed that any theory of action involved a continuum of stages in the action/execution side and similarly in the perception/evaluation side of the full interaction cycle.

In the same chapter he also mentions mental models, a concept that he also discussed, among others, in the book *Mental Models* (Gentner and Stevens, 1983): "people form internal, mental models of themselves and of the things and people with which they are interacting. These models provide predictive and explanatory power for understanding the interaction" (p. 7). Mental models were another cognitive psychology construct that was primarily used to explain how people perceived the world around them and how these affect cognition and reasoning in interaction.

## 3.4 UX, POET, and Emotional Design

The term *user experience* (UX) was made popular by Norman, Miller, and Henderson when they were working for Apple in the 1990s. In 1995, they published a paper which dealt with the cross-organizational process that Apple used in interface research and development. The overall process was called user experience. The defining feature of the UX process was to view the user's interaction, not just in terms of hands-on experience with the company's product, but, more broadly, encompassing all interaction with the company itself, including marketing, retail, support, and services. In practice, this meant the bridging of various departments within the company, keeping them inside the loop of development and emphasizing intercommunication and collaboration.

In the beginning the term did not have a well-defined meaning and was subject to diverse interpretations. For example, as it coincided with the explosion of the Web and the dot.com bubble (see Section 4.5), companies used the term as "user-centered design for the web" (Morville, 2010). In time and with adequate clarifications given by its influential originators, user experience has been established as a well-understood concept. ISO 9241-210 gives this definition: "a person's perceptions and responses that result from the use or anticipated use of a product, system or service (International Organization for Standardization, 2010)." The definition's notes explain that user experience includes the users' emotions, beliefs, preferences, perceptions, physical and psychological responses, behaviors, and accomplishments that occur before, during, and after use. Three factors are listed that influence UX: system, user, and the context of use.

The Nielsen-Norman Group's definition is given from a company's perspective:

> "User experience" encompasses all aspects of the end-user's interaction with the company, its services, and its products. The first requirement for an exemplary user experience is to meet the exact needs of the customer, without fuss or bother. Next comes simplicity and elegance that produce products that are a joy to own, a joy to use. True user experience goes far beyond giving customers what they say they want, or providing checklist features. In order to achieve high-quality user experience in a company's offerings there must be a seamless merging of the services of multiple disciplines, including engineering, marketing, graphical and industrial design, and interface design.[*]

---

[*] http://www.nngroup.com/about/userexperience.html

UX views HCI in its broader context. When an organization creates technology, it embodies in a product its idea for a solution to an end-user problem, with the goal that this will ultimately help the organization itself. HCI is how the end user interacts with the product, but this symbiotic relationship between the end users and the organization lies at the core of how that interaction is structured. Understanding the user experience, therefore, is the process of understanding the end-user needs and the organization needs with the goal of maximizing the benefit to both.

In his *The Psychology of Everyday Things* (POET), a book highly influential among the design community, expanding on the ideas presented in UCSD, Norman (1990) emphasized usability and making products easier to use. Design aesthetics were not really considered, in fact there were remarks about designers winning awards for products that lacked usability. However, aesthetics and beauty are always major factors while considering a product. The book is highly influential as noted, but it did receive criticism regarding this. Norman included the gist of this criticism in his 2002 essay called "Emotion and Design: Attractive Things Work Better":

> If we were to follow Norman's prescription, our designs would all be usable, but they would also be ugly.

Seeing that this critique was in fact valid, Norman looked into how emotion and affect influence the user experience, acceptance, and ultimately preferences. The 2002 essay became the preface for his 2004 book *Emotional Design*, which again proved to be influential in the design community. In the book, the author presented three aspects of design that deal with human response towards it, based on psychology's ABC model of attitudes. The ABC model stands for affect, behavior, and cognition. Translated to design aspects these became visceral, behavioral, and reflective. The behavioral aspect can be thought of as "traditional" HCI territory; effectiveness of use, how well the design fulfills its purpose. The other two aspects were the so-to-speak missing pieces for a more holistic approach to design, namely emotion and rationalization. The visceral aspect deals with the design's appearance and beauty and how those affect users. It is part of human nature, a system to make rapid judgments of what is good or bad, safe or dangerous, and of course if something is beautiful and desirable. The reflective aspect is the rationalization and intellectualization of a product. A product can be totally unusable but still be desirable, to the point that users will forgive its shortcomings in usability. A telling example was the teapot for the masochist (see Figure 3), famous from the cover of POET. Not particularly beautiful (visceral), certainly not useful but scores highly on the reflective aspect; it can become an object of discussion, it tells a story, and it is unique and therefore desirable. What was more interesting, however, was that all these three aspects are influencing each other and a designer may actually take advantage of this.

The point of these aspects regarding design is that it was not enough to focus on usability alone. A user

**Figure 3**   The masochist's teapot.

will begin evaluating a product (including interfaces) and form an opinion about it from the moment he or she looks at it. The response of the user on the visceral and reflective levels will influence the experience of usage. The design must therefore be appealing aesthetically, which will make the user invest more time in interaction with it to learn how to use it. The same applies for the reflective aspect. If the user perceives that the design appeals to his or her self-image, it will enhance the visceral appeal or more surprisingly the behavioral appeal (see Figure 4).

Don Norman's work was not the first to underline these aspects of design, although it certainly helped bring them into the spotlight. Research into emotions and affect and their influence on cognition was being done years before. The essay, for example, cites the experiments conducted by Kurosu and Kashimura (1995) and then duplicated by Tractinsky (1997), which proved that indeed aesthetics and affect play a role in the usability of interfaces.

### 3.5   Universal Access and Design for All

The emergence of the Web and of the so-called information society in the 1990s brought about radical changes in the way people work and interact with each other and with information. In this context, the "typical" computer user can no longer be identified. In the past, the typical computer user was often considered as a professional, capable and willing to
**Figure 4**   Juicy Salif — an example of emotional design.

use technology in the work environment in order to increase productivity and performance. In the new environment, interactive artifacts are used by diverse user groups, including people with different cultural, educational, training, and employment background, novice and experienced computer users, the very young and the elderly, and people with different types of disabilities.

Accordingly, while in the past computer-mediated human activities were mainly oriented toward the business application domain, in the context of the information society existing applications undergo fundamental changes, and new ones appear. The latter include access to online information, e-communication, digital libraries, e-business, online health services, e-learning, online communities, online public and administrative services, e-democracy, telework and telepresence, and online entertainment.

Finally, technological proliferation increases the range of systems or devices facilitating access to information resources. These devices include personal computers, but also standard telephones, cellular telephones with built-in displays, television sets, information kiosks, and various types of information appliances. Depending on the context of use, users may employ any of the above to review or browse, manipulate, and configure information artifacts at any time.

The above radical changes brought about the need to revise HCI frameworks and approaches to cater for a much larger and diversified user base and context of use,

leading to the concepts of universal access and design for all (see also Chapter 54).

In Stephanidis et al. (1998) universal acccess is defined as follows: "Universal access in the Information Society signifies the right of all citizens to obtain equitable access to, and maintain effective interaction with, a community-wide pool of information resources and artifacts" (p. 6). Accessibility has been a term traditionally associated with elderly individuals, individuals with disabilities, and more in general individuals with functional limitations (Stephanidis et al., 1999). However, because of the current influx of new technologies into the market, the population of users who may have particular interaction requirements is growing. As a result, accessibility has taken on a more comprehensive connotation. This connotation implies that all individuals with varying levels of abilities, skills, requirements, and preferences be able to access information technologies (Stephanidis et al., 1999). Universal access also implies more than just adding features to existing technologies. Rather, the concept of universal access emphasizes that accessibility be incorporated directly into the design (Stephanidis et al., 1998).

The term *design for all* denotes an effort to unfold and reveal the challenges of accessibility and usability as well as to provide insights and instrument appropriate solutions in the HCI field (Stephanidis et al., 1998). The fundamental vision is to offer an approach for developing computational environments that cater for the broadest possible range of human abilities, skills, requirements, and preferences.

Design for all in the information society is the conscious and systematic effort to proactively apply principles and methods and employ appropriate tools in order to develop information technology and telecommunication (IT&T) products and services which are accessible and usable by all citizens, thus avoiding the need for a posteriori adaptations or specialized design. Design for all in HCI recognizes, respects, values, and attempts to accommodate the broadest possible range of human abilities, requirements, and preferences, eliminates the need for "special features" and fosters individualization and end-user acceptability.

Design for all fosters a proactive strategy, postulating that accessibility and quality of interaction need to be embedded into a product at design time. This entails a purposeful effort to build access features into a product as early as possible (e.g., from its conception to design and release). In the context of HCI, a proactive paradigm is advocated for the development of systems accommodating the broadest possible end-user population. In other words, design approaches are required that seek to minimize the need for a posteriori adaptations and deliver products that can be adapted for use by the widest possible end-user population (adaptable user interfaces).

This implies the provision of alternative interface manifestations depending on the abilities, requirements, and preferences of the target user groups. The main objective in such a context is to ensure that each end user is provided with the most appropriate interactive experience at run time. Producing and enumerating

distinct interface designs through the conduct of multiple design processes would be an impractical solution, since the overall cost for managing in parallel such a large number of independent design processes, and for separately implementing each interface version, would be unacceptable (Stephanidis, 2001).

The scope of design for diversity is broad and complex, since it involves issues pertaining to context-oriented design, diverse user requirements, as well as adaptable and adaptive interactive behaviors. This complexity arises from the numerous dimensions that are involved and the multiplicity of aspects in each dimension. In this context, designers should be prepared to cope with large design spaces to accommodate design constraints posed by diversity in the target user population and the emerging contexts of use in the information society. Moreover, user adaptation must be carefully planned, designed, and accommodated into the life cycle of an interactive system, from the early exploratory phases of design through to evaluation, implementation, and deployment. Additionally, design for diversity is anticipated to be an incremental process in which designers need to invest effort in anticipating new as well as changing requirements, accommodating them explicitly in design through continuous updates.

In terms of interactivity, universal access and design for all introduce two important dimensions previously overlooked in HCI: the individual diversity of users as well as the need to adapt interaction behavior to such diversity. This implies that there is no best interaction style, but different interaction styles may be appropriate in different circumstances depending on the involved users and the context. For example, universal access fosters the view that both visual and nonvisual (e.g., speech-based) rendering of an interface dialogue can be provided (either alternatively or multimodally) to cater for the interaction requirements of sighted and blind users.

## 4  EVOLUTION OF INTERACTION

The evolutionary history of interaction began with the introduction of computer technologies in the 1940s and 1950s. The primary force behind this evolution was technological research. Over time, when new technologies became mature enough to allow for different approaches to interactivity, the theoretical frameworks briefly outlined in the previous section came into play, along with business and user adoption of the various interactive products. This section looks into the most widespread paradigms of interactivity. This includes describing the evolutionary history of the interactive technologies involved but also, where appropriate, the evolution of specific application domains, such as the World Wide Web, where the key aspect of interactivity is not the technology involved (in this case network servers and clients, the infrastructure, and the various protocols) but the context of use and the new information space that is available to humans.

The above-mentioned evolution is punctuated by the debate among approaches based on the conversation metaphor, which tries to emulate human dialogue, and the model world metaphor, which emphasizes the user's direct action mediated through a visual language (Hutchins et al., 1986). The conversational metaphor privileges textual language, whereas the model world paradigm relies more on iconic languages (although text may also be present).

The conversation paradigm lies at the basis of interaction paradigms such as command-based interfaces and speech interfaces, whereas the model world metaphor informs direct manipulation interaction and all its subsequent evolutions. Whereas the conversation paradigm addresses interactivity by progressively developing methods and tools to better understand the communication context, the model world paradigm adopts a radically different approach, whereby the context is reconstructed visually to ground communication.

In more recent years, these two paradigms appear to merge in multimodal interfaces, virtual environments, and ambient intelligence (AmI) environments.

### 4.1  Early Stages

HCI started in the 1940s with the construction of the first computers. At that time, interaction was very cumbersome and limited to trained scientists. ENIAC (see Figure 5), arguably the first general purpose electronic computer, was a massive machine that occupied a large room and needed weeks to program via punch cards. Such were the machines for about a decade. While the main focus was to keep the machines working correctly, that is, functionality, there was also an effort to make the interaction easier for the operators by formatting printouts and reducing the programming tasks by creating machines that could store programs, usually on tape (Grudin, 2008). In the strictest sense, the interaction was limited to basic operation of the machine. The process of programming and using the output was a separate work done away from the computer itself. In 1955 transistors replaced tubes in computer hardware, but the basic mode of interaction was basically the same. Until the mid-1960s this was the norm; the only people who had hands-on access were operators and data entry personnel who dealt with switches, knobs, and dials. It was not until the invention of the microchip and later the microprocessor that the way people interact with computers would change radically, making HCI a discipline that is relevant and essential to the design of computers.

This has been called the first wave of computing (Weiser and Brown, 1997), characterized by many people making use of a single computer. Computers were large mainframe machines that people booked time on to run their programs and get back their results, without actually dealing with the machine itself.

The second wave of computing is the current one, the era of the personal computer (PC), when advancement in technology made it possible to have small PCs for individual discrete use. During this period, there was an explosion in the evolution of interaction, starting from the command-based interfaces, to graphical user interfaces (GUIs) and direct manipulation, to Web-based and mobile interaction.
**Figure 5**  The ENIAC computer.

The third wave has been given many names, such as ubiquitous computing, the invisible computer, AmI, and calm technology, each name pointing to the presence of computers in the environment, in the background, where one person now has access and use of many computers distributed in the surrounding environment.

### 4.2  Command-Based Interaction

Command-based interaction was typical of command line interfaces. These were the de facto interfaces that people used in the 1970s and a significant part of the 1980s. Command line interfaces are based on the conversation model and provide a means of passing instructions to the computer by typing them in with the keyboard in the form of commands, which could be whole words or abbreviations. An example is the Windows Command Prompt, where the user can type in DOS-type commands.

Their advantages are that they provide direct access to system functionality and can be very efficiently used by expert users. They can also be very flexible with the use of parameters that allow the user to perform complex tasks with one command.

Their first incarnation was in the form of teletypes, where the operator would type in commands and receive one-line output from the computer, such as feedback or status messages, on scrolling paper. These were then replaced by glass teletypes or video display units, available to very few at the beginning until the CRT (cathode ray tube) monitors that became more widespread (see Figure 6).

On the other hand, command line interface users complained about the slower speed and lack of flexibility in entering multiple commands. But the most serious problem with command-based interaction is the slow learning curve, as the user must learn the various, often arbitrary commands. Indeed, one task of HCI at the time

was the design of command names in order to make them more easily memorable. So, even if expert users tend to prefer working with command line interfaces, most people viewed this type of interaction baffling and the sight of a blinking cursor on a screen did not give any clues to the proper use of the system. Command-based interfaces, although they attempt to establish a simple form of dialogue, present very limited interactivity, as there is no conversational context, and exchanges of command feedback are independent from each other.

Until the 1980s, computers were reserved for use in work by trained staff performing often tedious data entry tasks and for the computer enthusiasts. It would not be until the commercial success of the Mac in 1985, and more prominently of the Windows 3.0 environment in 1990, that command line interfaces would gradually disappear or start being integrated into GUIs. In fact, many applications currently still offer a dual mode of interaction by incorporating a command line interface complementary to the GUI.

### 4.3  Direct Manipulation

Direct manipulation (Schneiderman, 1983) was the next major step in the way people interacted with computers. Related research started in the 1960s and brought out novelties such as the mouse or the GUI (Engelbart, 1963; Engelbart and English, 1968; Sutherland, 1963), was further developed into prototypes in the 1970s until finally Xerox's Palo Alto Research Center completed the Alto and then the Star system. It would take a few more improvements and additions by Apple in the Lisa computer and more importantly in the Macintosh, which became a commercial success to bring the Desktop Metaphor and Direct manipulation to the mainstream. This shift was solidified with the global success of Microsoft's Windows, starting in 1990 (Windows 3.0) and exploding by the time Windows 95 was released.

**Figure 6**  Command line interfaces.

This new means of interaction offered easiness of use, more intuitive interfaces, and a richer experience. It marked the beginning of the second wave of computing, where PCs were available to the wider audience for discrete use, and with the addition of the more friendly interaction that GUIs and direct manipulation interaction offered, suddenly computer use was becoming the norm instead of a sophisticated work tool that needed extensive training to operate (see Figure 7).

In direct manipulation interaction users perform actions directly on visible objects with the use of a pointing device, most usually a mouse. Objects include window controls, menus, icons, buttons, and other elements in the so-called WIMP (windows, icons, mouse, pointer) interfaces (such as those mentioned above), but there are other types of direct manipulation interfaces, such as 3D interfaces [in virtual reality (VR) environments] or haptic interfaces.

The advantages were obvious compared to command line interfaces. The new interfaces were easier to learn and remember; the user received immediate visual feedback and more accurate representations of what he was working on, that is, WYSIWYG (what you see is what you get), and it was easier to reverse actions (undo), which meant that the new interfaces were also less error prone. Finally, these visual-rich interfaces exploited more fully the human use of visual–spatial cues.

On the other hand, the new paradigm was a much more challenging job for the designer; instead of formatting screens of text, the designer should consider color choices, layout choices, GUI control choices, and a lot more. Even many years after the establishment of the WIMP style of interfaces and extensive HCI research on the subject, it is not an easy job.

Direct manipulation interfaces can be distinguished in two main categories, namely WIMP and post-WIMP.

WIMP are the classic interfaces that have been the standard GUIs for most computers in the past 25 years. The name comes from the elements that characterize the interface, that is, the windows and icons on the screen manipulated with the mouse pointer. As described above, this style of interaction originated in the late 1970s, when the GUI was combined with the mouse in the Alto machine and then the Star. The

**Figure 7**  Graphical user interfaces.

Macintosh would make the match a commercial success, introducing the now familiar Desktop Metaphor to the public, where the screen is metaphorically viewed as the top of a desk and various objects that lie on it may be manipulated by the mouse pointer.

While WIMP-style interfaces still dominate as the interaction style, there are several other examples of direct manipulation interfaces that either expand on the classic WIMP interfaces or are entirely different. An example of the former would be the recent multitouch interfaces developed by Apple,[*] where the use of a touchpad (on the macbook) or the screen itself (as in the iPad) allows the user to manipulate objects via different gestures and movements.

---

[*] http://www.apple.com/magictrackpad/

An example of the latter is Google Earth's* Zooming User Interface (ZUI), where the interaction is focused in the zooming in and out of a 3D photorealistic representation of Earth and clicking points of interest.

These two examples also serve to underline another important distinction between direct manipulation interfaces which concerns the hardware available. It is more common to visualize a typical personal computer with a keyboard and a mouse for input and a monitor for the outpu,t but the example of Apple's latest hardware points to new input techniques because of the novel hardware. There are more similar examples, for example, surface computing hardware, which are typically large surfaces that act as touch screens, where the user directly manipulates objects by touching them. Another example would be VR environments, where the hardware could include a VR helmet and a data glove or data wand to manipulate virtual objects (see Section 4.8).

Although they radically differ from the conversational paradigm of interaction, direct manipulation interfaces introduce several elements of interactivity. First, they establish a visual context, which plays the role of grounding the human–computer communication process. Second, they provide more structured dialogues and more articulate feedback with respect to command-based interfaces. An important aspect of direct manipulation is its reliance on metaphors. In this respect, visual languages used in direct manipulation interfaces fundamentally differ from natural language. However, it is exactly this metaphoric value which allows the direct manipulation paradigm to ground communication and enrich dialogue, by offering a real-world context in which users' actions can be rooted.

### 4.4 Conversational Interfaces

During the late 1970s and 1980s, when significant advances in the fields of artificial intelligence, natural language processing (NLP) appeared to be maturing, a trend toward the explicit provision of humanlike communication in user interfaces emerged. In the context of HCI, NLP applications range from various speech recognition systems to natural language interfaces to database, expert, and operating systems (Manaris, 1998).

As the use of computers expanded throughout society, affecting various aspects of human life, it became clear that the number and heterogeneity of computer users was were dramatically increasing and that that many of these users were not computer experts. The provision of interaction means exploiting natural language was conceived as a potential path towards increasing the user friendliness of interactive computer systems and their eventual acceptability to users.

NLP offers mechanisms for incorporating natural language knowledge and modalities into user interfaces. As NLP tools started becoming more powerful in terms of functionality and communicative capabilities, their contribution to HCI also became more significant.

The history of NLP can be very briefly summarized into three main phases. The first phase started in the mid-1940s and lasted until the early 1960s. It is characterized by an emphasis on algorithms relying mostly on dictionary-lookup techniques used in conjunction with empirical and stochastic methods. During this phase, some NLP application areas began to emerge. An example is speech recognition, employing speaker-dependent, template-based architectures.

The second phase in NLP spanned approximately from the early 1960s until the late 1980s. It was characterized by (a) a strong emphasis on language theory, including the lexicon, syntax, semantics, and pragmatics; (b) the construction of "toy" systems that demonstrated particular principles; and (c) the development of an NLP industry which commercialized many of the achieved results. In terms of applications, this phase is mainly characterized by question-answering systems and database interfaces (1960s) as well as interfaces to other interactive systems. During this phase, it became apparent that symbolic approaches to NLP problems were not adequate when attempting to widen linguistic coverage or apply the developed systems to a different domain. This realization motivated the development of nonsymbolic approaches, mainly based on statistics, connectionism, or the analysis of language corpora.

In the late 1980s, NLP entered an empirical and more "user-centered" phase. Major advances and tangible results from the last 50 years of NLP research were reinvestigated and applied to a wider spectrum of "real-life" tasks, including, for example, spelling checkers, grammar checkers, and limited-domain, speaker-independent, continuous-speech recognizers for various computer and telephony applications.

During this phase, HCI entered the mainstream of computer science. This was a result of the major advances in graphical user interfaces during the 1980s and early 1990s (see Section 4.3), the proliferation of computers, and the emergence of the World Wide Web (see Section 4.5). Accordingly, the evolution of NLP reflected the continued growth of research and development efforts directed toward performance support, user-centered design, and usability testing. Emphasis was mainly placed on systems integrating speech recognition and traditional NLP models as well as hybrid systems—systems combining results from symbolic, stochastic, and connectionist NLP approaches.

A conversational agent is the human—computer dialogue system that interacts with the user turn by turn using natural language. Efforts were initiated by Alan Turing (1950) in his famous paper "Computing Machinery and Intelligence." He suggested that within 50 years a computer would pass a comparison test if it is a human or a machine. Historically the first conversational agent was the ELIZA system (Weizenbaum, 1966). ELIZA featured the dialogue between a human user and a computer program representing a psychotherapist. ELIZA is based on simple stimulus–response architecture (i.e., patterns and related responses).

LUNAR (Woods et al., 1972), developed in late the 1960s, was the first natural language interface to a database (NLIDB). The LUNAR database contained chemical analyses of moon rocks and had a significant influence on subsequent computational approaches to natural language. Subsequently several NLIDB appeared

exploiting different approaches to handling natural language. By the mid-1980s, natural language interfaces to databases became a very popular research area, and numerous research prototypes were implemented.

These initial attempts identified a series of practical difficulties in the development of NLIDB, including extensibility of lexica and grammars and portability of systems across different application domains. Other criticisms came from the HCI community, since natural language was considered too ambiguous to provide effective communication in user interfaces. On the other hand, when restricted to some sublanguage to limit ambiguity, natural language loses its distinctive feature of allowing free expression and becomes more similar to a command or formal language which needs to be learned to be used (Hill, 1983).

Additionally, natural language interfaces were criticized for leading users to anthropomorphize the computer, or at least to attribute more intelligence than is warranted to it. This leads to unrealistic users' expectations regarding the capabilities of the system, and in turn such expectations lead to disappointment when the system fails to perform accordingly (Shneiderman, 1998). Various experiments were conducted to find out how users can adapt to system's restrictions in vocabulary and syntax, and the results appeared to confirm that humans are keener to learn a command language than to restrict their use of natural language to conform to the system's limited abilities (Slator et al., 1986; Ogden and Bernick, 1997).

In subsequent years, natural language interfaces have been applied to operating systems (Manaris, 1994) and information retrieval (Jacob and Rau, 1988). The focus in more recent approaches has been more on using speech as well as on achieving more natural forms of dialogue communication. Systems that use speech interfaces range from call routing to navigation systems to VoiceXML-type applications which enable speech interfaces on the Web (Jokinen, 2009). The common technology is based on recognizing keywords in the user utterance and then linking these to appropriate user goals and further to system actions. Speech-based conversational interfaces, besides recognizing speech input, also provide speech output (Zue and Glass, 2000).

Besides the capability to understand and generate linguistic expressions, some systems include cooperation and planning of complex actions on the basis of observations of the communicative context, that is, communicative competence (Jokinen, 2009). A well-known example of plan-based system is TRAINS (Allen et al., 1995), a train route planner, where a human manager and the system must cooperate to develop and execute plans.

The notion of natural interaction in this context refers to the spoken dialogue system's ability to support functionality that the user finds intuitive and easy. The challenge that speech and language technology faces in this context is not only in producing tools and systems that enable interaction in the first place but also to design and build systems that allow interaction in a natural way, that is, to provide models and concepts that enable experimentation with complex natural language interactive systems and to test hypotheses for flexible HCI.

In addition to improved interaction strategies, natural language interfaces are also required to be extended in their knowledge management and reasoning capabilities, so as to support inferences concerning the user's intentions and beliefs behind the observed utterances. The goal of building natural interactive systems thus comes close to studying intelligent interaction in general. Toward this end, research efforts have attempted to achieve context understanding (Jokinen, 2009) as well as to exploit the notion of grounding (see Section 2.1) which is inherent in human communication (Traum, 1999).

Further evolution of research toward natural dialogue–based communication has led on the one hand to developing the concept of multimodality (see Section 4.7) and on the other hand to embodying conversational systems in anthropomorphic representations (Cassell, 2001). Such anthropomorphism, implemented in the form of animated avatars, is targeted to make explicit the system's intelligent behavior and allows representing the system's knowledge to humans in multiple ways on multiple modalities (e.g., speech and hand gestures).

## 4.5 Web-Based Interaction

The Internet materialized in late 1969, when ARPANET was deployed, connecting four academic institutions in the United States. Soon, with the implementation of several network protocols, islands of networked computers appeared, leading to the introduction of services that had been developed in previous years, such as hypertext, email, and eventually the World Wide Web (Hafner, 1998). At the beginning the latter suffered from the same problems of command line interfaces compared to GUIs. It was not until 1994, when Mosaic was released, the first graphical web browser, very similar to the browsers we use today, that Internet use exploded beyond academia and government. Three years earlier the Internet had been made available for unrestricted commericial use, but it would take the graphical Web browser to provide the missing piece to exploit the full implications that the Internet presented.

From an interaction perspective, in its first years the Web consisted of Web pages that contained primarily text, images, and links to other Web pages. The Web pages themselves were not highly interactive; apart from clicking on links and navigating through Web pages, the primary interaction style was the familiar form-filling paradigm (Grudin, 2008), including elements such as entering text, selection from menus, checkboxes and option buttons, and submitting the forms via command buttons. Content was primarily static, but a major difference in the context of use was the discretionary nature of interaction. This had already begun with the introduction of home computers in the early 1980s, where users could choose to use a computer instead of the alternative "traditional" method (e.g., consider the typewriter–word processor options), but soon, as computers became the standard tool in the workplace, their use was not a matter of discretion anymore. The Web brought discretionary use back into focus and the vast number of competitive content choices and the notorious impatience with slow speeds meant that

user discretion and preference became a major research theme in HCI.

Perhaps the most striking change brought about by the introduction of the Web into the wide audience was precisely its penetration into everyday households. The computer was technology used by people with specific tasks and discrete needs, whether it was a work tool or an entertainment device. With the Internet and the Web, the computer became an interactive communication window to the world, as revolutionary a change as the television, only with much more potential and with much richer interaction.

This journey into the household began with the introduction of affordable microcomputers. The Macintosh and Windows provided the appropriate interface to make the technology more accessible to the novice user, and finally the Internet and the Web made it indispensable to the citizen of the information age. The new avenue of e-commerce made possible by the Web also meant that virtually all business environments had to employ computers, if anything for communication and coordination purposes. From a sociological perspective, the Web also gave rise to social computing, the creation of virtual communities in the form of forums and newsgroups, and more recently social networking sites such as Facebook or LinkedIn. Because of the Web, people simply spend much more time interacting with computers; for example, it was reported in 2005 that 75% of Americans use the Internet and spend an average of 3 h a day online (Stone, 2005).

If interactivity between computers and humans was a secondary issue before, its research dependent on technology developments, the Web definitely brought it to the forefront of hot topics, a fact evident by the sudden flourish of activity in the HCI discipline.

Naturally, a major proportion of this activity revolved around Web design practices and evaluation techniques. The Web brought many new interaction design issues to the table. This was a natural consequence for two reasons. First, because the Web was a new technology, it suffered from a lack of concrete design guidelines and practices. Second, creating a Web page was considerably easier compared to programming an application, so content was created by many people outside the computing community. A lot of people started publishing Web pages, many of which suffered from serious, amateur design issues, such as excessive use of colors and images, unreadable content, and inconsistency.

Matters were complicated by the inconsistencies across Web browsers, the platform-independent nature of the Web, the lack of control from the part of the designer in the way pages render on the user's end (e.g., browser window size, font settings, laptops vs. desktop PCs) (Nielsen, 1997), the lack of common standards, and the introduction of new Web technologies that were developed to provide richer interaction. The latter, as all new technologies, suffered from misuse and abuse of featurism over usability.

Some of these problems were addressed by the formation of the the World Wide Web Consortium (W3C), founded in 1994. The task of the consortium was to develop international standards for the World Wide Web, including its primary language, Hypertext Markup Language (HTML) or the Cascading Style Sheets (CSS) language,[*] which seeks to separate content from presentation. Another important activity of the W3C was the development of accessibility guidelines, aiming to reduce as much as possible the exclusion of users with disabilities from accessing the Web.[†]

Less formally but perhaps more influentially, Jakob Nielsen's work on Web design through his articles on correct practices and criticizing bad practices (such as his famous article on the top 10 Web design mistake), along with a number of books on usability for the Web, played (and still play) a major role in reducing design mistakes which were so frequent in the early Web, such as poor layout, bad choice of colors, abuse of distracting and annoying animations, poor content management, inappropriate writing style and typography, excessive size of Web pages, and consequent slow loading times and more.

HTML was problematic for the creation of good Web pages. It was simply inadequate from an interaction perspective, offering very little beyond simple form controls. In response to this, CGI-scripts, mostly written in Perl, "the duct-tape of the Internet," according to Hassan Schroeder Sun's first webmaster,[‡] were employed at the beginning to add more programming power to developers. By the end of the century, languages had been introduced specifically for the Web, such as Java, PHP, ASP, or Flash. This finally allowed developers to create applications for the Web that could match, at least to a certain extent, the interactive richness of standard software applications.

HTML was also inappropriate as a layout tool, having been implemented as a hypertext language, aiming to link content, not present it. In response to this problem, Web developers relied excessively on elements such as tables or graphics hacks to realize their designs, leading to accessibility issues. The development of CSS by the W3C answered that problem to an extent.

Regardless of specific interaction issues of the Web, the main challenge users faced on the Web was locating the specific content they were looking for. The Web is a vast space of information and it was soon apparent that one of the most important issues was searching. The names of the first popular browsers were a clear indication of this problem. Navigator and Explorer both hinted at an ocean of information that the user could surf through. Search engines therefore became a critical application and usually the starting point of the Web interaction experience.

### 4.5.1 The .com Bubble and Web 2.0

One of the most important events in the history of the Web was the so-called .com bubble and burst (Cassidy, 2003). It is important not only as a socioeconomic phenomenon but also as a case study to gain

---

[*] http://www.w3.org/standards/webdesign/htmlcss

[†] http://www.w3.org/standards/webdesign/accessibility

[‡] http://www.oreillynet.com/pub/a/oreilly/perl/news/importance_0498.html

lessons about the nature of the Web and what actually worked or not. Not to be underestimated also is the significant exposure the new technology received through mainstream media, which also played a part in the growth of the Internet and computer usage.

The period covered between the beginning of the bubble until the burst is generally considered to be between 1995 and 2001. In that time, Internet use exploded in numbers and a lot of companies tried to exploit this new exciting medium. Everyone was certain that the Web was changing society and that a new huge potential market was made available but there was definite uncertainty on how exactly to exploit this market. Many companies were founded without a specific business model and consequently went bust without ever making any actual profit, erroneously thinking that traffic would somehow generate revenue through advertising or that the elimination of the traditional brick-and-mortar model would translate to profit. The hype in the stock market and the soaring of stock values of these so-called .coms sustained this illusionary impression until roughly the end of the decade/century/millennium, but at the end the bubble burst and only those who had understood the nature of the Web survived, indeed thrived.

One explanation for the success of these companies, such as Google, eBay, and Amazon, was that they matched and took advantage of the specifications of the so-called Web 2.0. This concept, first articulated in 2001 after the .com burst, sought to explain the common factor between the aforementioned companies and propose a new approach for understanding the Web. The underlying principle was that the Web should be seen as a platform, as opposed to a medium for which standard desktop applications should be developed. The example cited by the originators of the concept is Netscape versus Google (O'Reilly, 2005). Netscape began by trying to replace the desktop with the "webtop" (their browser) and planned to populate that webtop with information updates and applets pushed to the webtop by information providers who would purchase Netscape servers. In reality, value was transferred up the stack to services delivered over the Web platform. Google on the other hand was such a service, and customers were paying directly or indirectly for its use. There were no issues of new software releases or operating system (OS)/hardware-specific editions. Netscape relied on the classic software paradigm, Google on the concept of the service running between the two computers (the Google server and the user's computer), in the Web space. The real challenge was managing the data and turning it into useful information for the end user. Similarly, Amazon did not offer a particularly different catalogue of products than its competitors, but it invested heavily in the management of all sort of data, so it could make it into useful information for its customers that would lead them to a purchase.

This focus on the data and its processing into useful information also pointed to another significant factor, namely users add value. Google and Amazon do not actually produce any of the data that they serve to their customers. Google simply collects data from the Web

and indexes it. Amazon keeps track of user behavior. eBay offers a platform for users to conduct transactions. Wikipedia does not generate its content, it only offers a means to manage it. It is the users that provide the actual content and this ultimately means that if an application can provide a useful service with a critical mass of users, then it can be successful. The underlying principle is in essence a paraphrase of the well-known Open Source mantra "given enough eyeballs, all bugs are shallow" (Raymond, 2000); given enough users, the content is valuable. Typical examples of this principle, apart from those mentioned above, are blogs, wikis, media-sharing sites (such as YouTube), social networking sites (such as Facebook or Myspace), and so on.

Collective user-generated information also proved to be the best solution regarding the Web's primary challenge, that of searching. Google became the de facto search engine by exploiting user sponsorship of websites by considering links as sponsorships of approval, with great success. The same principle also applies to Amazon, as it exploited its users' selections as an indication of what is the most probable content they were looking for, in the form of suggestions for related content. A key feature of a successful Web service is to provide the easiest route to desirable content, and managing collective user data has proved to be a very efficient way to achieve this.

In terms of interactivity, it can be argued that not much has changed in the way users physically interact with the computer or in what type of interaction controls are used. The input and output devices remain the same and only the link is a Web-specific interaction element in the interface. However, there is undoubtedly a major transformation in the context(s) of use as well as the environment space that the user moves through, resulting in an overall different user experience that has a profound effect on the way humans perceive computers. The Web 2.0 paradigm of harnessing collective intelligence and user-generated content is one example of how computer services have changed significantly in the course of a decade. The concurrent developments in communication technologies, specifically wireless and mobile communications, and the widespread availability of high-end mobile devices have provided a set of emerging tools which are starting to be used in augmented-reality and AmI applications.

## 4.6 Mobile Interaction

Mobile interaction is a relatively new field of research in the HCI community, but it has become one of the most interesting, since the current generation of mobile devices has reached a technological maturity that allows much more sophisticated interaction than when they first appeared. Furthermore, the inherent property of mobility and their personal nature, coupled with the advanced processing power and multimedia capabilities, makes them a good candidate for playing a major part in the way people generally interact with computers in the future (see Section 4.8). Before examining the characteristics of mobile interaction and the design challenges that stem from the device properties, this section looks into the historical context of mobile

devices, focusing on mobile telephony and personal digital assistants (PDAs), the combination of which (the smartphone), will be the primary focus of the chapter.

In 1979 Sony released the Walkman. It was an instant success because it managed to take one activity, listening to music, which was confined to the home, and take it anywhere. Its obvious advantage and appeal were that it was small and easy to carry around and offered the same service, more or less, with another much larger cassete player. Interestingly, before the product was launched, critics thought it would be a commercial failure because it did not offer a recording function. It turned out of course that most people did not need that specific function but were very happy with being able to listen to music anywhere. The Walkman also marked a trend toward miniaturization and portability.[*]

PDAs are basically hand-held minicomputers. The term was first used by Apple in 1992 to describe the Apple Newton,[†] the company's first attempt at creating a mobile device which also featured a touch screen. Before the Newton, the line was blurred between small hand-held electronic organizers (such as the very minimal Psion Electronic Organizer and the quite sophisticated Sharp's Wizard series) and portable PCs, which were closer to the size of what we now refer to as notebooks. The latter trace their roots back to 1972, when Alan Kay proposed the design of Dynabook (Kay, 1972), which however was never built into a working prototype. The Dynabook is considered the ancestor of the laptop or the tablet PC and was a huge influence on the Palo Alto by Xerox, which Kay had joined in 1970.

PDAs were quite popular in the 1990s, but the market was fragmented and the devices never really caught on as more than electronic organizers in the market, offering calendar support, note taking, and so on, despite efforts from major players such as Microsoft to support the medium by releasing a PDA-specific OS, CE Windows. However, PDAs were used extensively in business and health care.

Mobile telephony had a similar evolution (see Figure 8). Telephony started as a fixed-location service, then moved into the car (although mostly in the United States), until the mobile phone in the mid-1990s. Mobile telephony took off in the mid-1990s and the first-generation cellphones were large and rather cumbersome devices, with a minimal screen. The primary use of mobile phones at the time was limited to calling and answering as well as text messaging. The standard interface was the keypad plus some buttons, without any standard configuration across the various devices. Technological advancements led to devices with much better processing power and screens to the point that these devices were matching the capabilities of PDAs. Roughly by the early 2000s, mobile phones offered color screens, better GUIs, and smoother interaction than first-generation phones. Usability matured in getting the right design for the handsets as well as establishing design guidelines for the specific challenges posed by the nature of the devices, in regards to interface styles, text entry, and so on.

---

[†] http://en.wikipedia.org/wiki/Apple_Newton

**Figure 8**  Evolution of mobile phones.

Appropriately designing the hardware controls was not a trivial task either. Nokia took four years to reduce the number of buttons (besides the standard numeric keypad) from eight to four, from 1994 to 1998. It took extensive research and user feedback to realize that the mobile phone user at the time primarily did two fundamental tasks: dialing from the phone book and answering the phone. Therefore, the elegant and successful solution they came with, having simplicity in mind, was to use one big prominent button (the Navi-Key) directly below the screen. The button was used to answer and hang the phone as well as confirming a selection (Jenson, 2002).

New-generation mobile phones are also referred to as smartphones, since the next logical step was to combine the functionality of the mobile phone with that of the PDA (see Figure 9). The first official smartphone is arguably the Simon, a device designed by IBM in 1992 and released in 1993 by BellSouth. It featured a stylus-operated touch screen and combined a mobile phone with many PDA capabilities, including email. Its initial price was too high to penetrate the market. In 1996 Nokia released the Communicator, a mobile phone literally combined with a PDA device, as the first prototypes were a Nokia phone hinged together with a HP PDA. The 9000 Communicator, as it was called,

**Figure 9** From PDAs to smartphones.

effectively marked the beginning of the smartphones. It was a very cumbersome device, and it did not affect the PDA market much, but eventually smartphones rendered stand-alone PDAs almost obsolete. The term smartphone itself was probably used for the first time in 1997 when Ericsson released the GS88 phone.

Mobile interaction is radically different from PC interaction. The reasons for this can be grouped into two categories, device characteristics and context of use. The most obvious device characteristic is of course its size. This includes the size of the screen, as well as the size of the controls, usually the keypad and navigation buttons of the mobile phone. The fact that there is no standard screen size or hardware controls further complicates matters. Furthermore, the input/output interface consists of the screen and the keypad, that is, no mouse or keyboard is available. These two characteristics are the main factors influencing interface design in mobile devices.

Because of the lack of a pointing device, although modern mobile devices are capable of rendering quality graphical user interfaces, albeit in a small scale, the majority of the devices do not offer direct manipulation. Instead, the major interaction paradigm is scroll and select, where the interface is presented most commonly in the form of a list-based layout. This layout also takes advantage of the fact that most mobile screens are portrait oriented (height bigger than width). Several variations or features of list-based layouts can be found according to the task at hand. For example, a common implementation is fish-eye lists, where the item selected expands to reveal more information. Such a solution works well for long lists, such as contacts or email messages. Another helpful solution to long lists is circular scrolling, where the list loops after reaching

its end. This is helpful because users of mobile phones cannot use the scrollbar as they would on a normal PC with a mouse.

The second challenge in mobile interaction design is data entry, specifically text entry. Text entry with a keypad is a notoriously tedious process and users avoid it as much as they can. Solutions to this problem were the use of autocomplete functions, predictive text, either dictionary based or pure predictive algorithms (which seem to perform better overall) (MacKenzie et al., 2001), and other novel solutions, such as gesture recognition, shapewriting (both solutions for touch screen– equipped devices), and voice recognition.

It should be noted however that, although these paradigms and styles regarding mobile interaction concern approximately 79% of devices (Entner, 2010), the new-generation smartphones featuring touch screens overcome some of those problems by allowing direct manipulation interaction. They are still affected by the obvious size differences, and many of the guidelines certainly apply, but the difference in the overall user experience is very notable. This is important because the market share of these devices is growing very rapidly, and it is not a wild speculation to assume that this trend will continue in the following years (Entner, 2010), especially since all major players, including Google, Microsoft, Sony Ericsson, and Nokia, as well as Apple of course, the first that made a huge market impact with the iPhone, are focusing on the development of such devices.

In essence, smartphones appear to be creating a paradigm shift in mobile interaction that can be compared to the paradigm shift of command line interfaces to the direct manipulation of GUIs. The old

paradigm is scroll and select using hardware buttons, and the new one is direct manipulation interfaces through touch screens.

The context of using a mobile device is inherently different from the use of a static personal computer. Mobile phones are primarily communication devices but also, since the merging of PDA capabilities, cameras and media players, as well as the introduction of mobile Web technologies such as 3G, they have become part of a larger ecosystem of networked devices and an important personal appliance for the user. Simply put, today the owner of a modern smartphone does a lot more than simply call or text another person. The smartphone is also used as a music player, a Web browser (which involves many of the issues we discussed in the Web interaction section), a global positioning system (GPS), a gaming device, and more, usually on the go.

Evaluating mobile device usage is particularly challenging because it is not possible to conduct studies in the laboratory as the context of use is entirely different. Mobile users are by definition usually on the move and, more importantly, interaction occurs infrequently and in bursts. Observing the interaction in real circumstances however is equally difficult (if not more), since there are too numerous environments and circumstances to take into account and there is no way to predict when the user will actually use a device. Furthermore, interaction is mostly private, so the act of observation would contaminate the results as there is no way to determine if the user has altered his or her behavior (Jones and Marsden, 2006).

Regarding the context of use of mobile Web interaction, it merits a closer examination because modern smartphones have rapidly changed its use.

### 4.6.1 Evolution of Mobile Web Interaction

Access to the Internet through a mobile phone has been available since 1996, when Nokia released the 9000 Communicator model. However, the technical limitations of mobile devices made browsing the Internet almost impossible, as Web pages did not render gracefully on the small screen or at all, making them unreadable. As an attempt to address this problem, the Wireless Application Protocol (WAP) was developed in 1998 as an open international standard, based on which WAP browsers could provide the basic services of a desktop computer browser but in a simplified form to overcome device limitations. Slow speeds, pricing, and the notably poorer experience compared to the familiar desktop browsing were the reasons why the WAP-based mobile Web did not really catch on, with the notable exception of Japan. In the latter, a rival system to WAP was developed and released in 1999 by NTT DoCoMo, the i-mode, which became a huge commercial success. Soon afterward, its two major rivals in the mobile market in Japan offered WAP-based services, with considerable success as well. Mobile Web use in Japan has been far more widespread than the rest of the world until very recently. There are several reasons for this, primarily favorable flat-rate plans, extremely high 3G handset penetration and excellent network quality and signal coverage, and the carriers' approach of "open garden" as opposed to Western carriers who try to keep consumers on their portals (Billich, 2010).

3G mobile Web speeds are considerably better, but still the experience is not even remotely similar to the desktop counterpart. The main reason is that, instead of trying to fit everything in the tiny space of a mobile device screen, designers began to customize and reduce the functionalities offered through the mobile sites to make the experience more appropriate with the context of use of mobile users. This also followed the specifications by the W3C Mobile Web Initiative,[*] which addressed the issue of balancing the homogenous nature of the Web and the specific circumstances of the mobile context of use.

Regarding the latter, Google identified three primary contexts of use for mobile consumers of its services:

- *The Casual Surfer or "Bored Now" User*. Users who find themselves with spare time (such as waiting in lines, while traveling by train, sitting in cafés, etc). These users resemble the casual Web surfers. Since mobile phones cannot match the robust user input of a desktop PC, applications for these users should be tailored.

- *The Repeat Visitor or "Repetitive Now" User*. Users who seek the same information on a regular basis, such as stock market prices, weather reports, and sports scores. Catering to their needs would be ensuring that repetitive steps or search queries can be eliminated by "remembering" each user's preferences, in the same manner that cookies work in desktop browsers.

- *The "Urgent, Now!" Visitor*. Users who seek specific information fast, such as directions to the airport or the nearest ATM. The key issue in this case being location, mobile services catering to such situations should emphasize location awareness.

## 4.7 Multimodal Interfaces

The multimodal systems process combined natural input modes, such as speech, pen, touch, hand gestures, eye gaze, and head and body movements, in a coordinated manner with multimedia system output (Oviatt, 1999). Multimodal systems represent a paradigm shift from conventional WIMP interfaces toward providing users with greater expressive power and naturalness. The goals are twofold: to achieve an interaction closer to natural human–human communication and to increase the robustness of the interaction by using redundant or complementary information in different modalities (Reeves et al., 2004).

One of the first multimodal systems was Bolt's Put That There System (Bolt, 1980), where the users interacted with the world through its projection on the wall using speech and pointing gestures. Subsequent attempts in the domain of multimodal interaction rely on advances in speech and natural language processing,

---

[*] http://www.w3.org/Mobile/

computer vision, and gesture analysis. Major progress has occurred in both the hardware and software for component technologies like speech, pen, and vision, as well as in the development architectural components and design frameworks (Oviatt and Cohen, 2000). Additionally, applications have been built that range from map-based and virtual reality systems for simulation and training, to field medic systems for mobile use in noisy environments, to Web-based transactions and standard text-editing applications. An overview of architectures and applications for multimodal interfaces is provided elsewhere (Oviatt et al., 2000)

Multimodal systems integrate complementary modalities to yield a highly synergistic blend in which the strengths of each mode are capitalized upon and used to overcome weaknesses in the other. Whereas traditional interfaces support sequential and unambiguous input from devices such as keyboard and conventional pointing devices (e.g., mouse, trackpad), multimodal interfaces relax these constraints. For example, they can support asynchronous, ambiguous, and inexact input by applying more sophisticated analysis of input. They can also detect and correct errors utilizing models of the media, user, discourse, and task (Maybury, 1999).

Systems that process multimodal input also aim to give users better tools for controlling embedded visualization and multimedia output capabilities, as opposed to the limited possibilities offered by keyboard and mouse input, in particular when dealing with complex environments (Oviatt, 1999).

In the context of multimodal interfaces, as the center of HCI shifts toward natural multimodal behavior, human communication patterns are used to control computers in a more transparent interface experience than ever before. Such interface designs become more conversational in style, rather than limited to command and control, because many of the modes being processed are language-oriented (speech, manual gestures, pen input) or involve communication broadly defined (gaze patterns, body movement) (Oviatt and Cohen, 2000).

Achieving natural patterns of multimodal input is however not as straightforward as it would appear. A dominant issue in this respect concerns the integration and synchronization requirements for combining different modalities into a system. Oviatt (1999), in the seminal paper "Ten Myths of Multimodal Interaction," on the basis of empirical evidence as well as experience, analyzes common pitfalls which may negatively impact multimodal interaction design. Examples of such assumptions are that users will always interact multimodally if they have the possibility to do so, that speak and point is the dominant modality integration pattern, that speech is the primary input mode in multimodal systems, and multimodal languages do not differ from unimodal languages. Regarding this last point, which presents particular interest from the point of view of interactivity, Oviatt claims that multimodal languages are briefer, syntactically simpler, and less disfluent than natural unimodal speech, as multimodality allows to eliminate linguistic complexity resulting from the need to express verbally elements to which the user can

refer deictically (through gestures) using a different modality. A related issue concerns redundancy between modalities.

Whereas it is commonly claimed that the content conveyed through different modalities in multimodal communication contains a high degree of redundancy, it appears that users tend to use different modalities in a complementary rather than redundant way.

To optimize human performance in multimodal systems, principles regarding how to integrate multiple modalities or how to support multiple user inputs (e.g., voice and gesture) have been elaborated on based on cognitive science literature on intersensory perception and intermodal coordination (Reeves et al., 2004).

Perceptual user interfaces (PUIs), introduced by Turk and Robertson (2000), are multimodal user interfaces which combine active input, such as speech, pen-based gestures, or other manual input with a passive input mode that requires no explicit user command, such as vision-based tracking that unobtrusively monitors user behavior and senses a user's presence, gaze, and/or body position. Through perceptual interfaces, multimodality permeates into intelligent interaction environments where interaction is to a large extent implicit and continuous (see Section 4.10).

## 4.8  Virtual and Augmented Reality

Virtual and augmented reality (VR and AR, respectively) are two areas that share many aspects. Their difference lies in the degree to which they replace (in the case of VR systems) or enhance/augment (AR) the real world. The similarity is that this is performed with the use of computer hardware and software. Practically, virtual and augmented reality systems have common research backgrounds, but the applications of each field are distinctly different. Both are in the stage where mass use of these technologies is not widespread and research is ongoing. Technological developments and costs are major factors for this, and the fluid nature of computing developments in general will determine the role these technologies will play in everyday life. Below, a brief historical account of both technologies is presented, describing the major features of each, in terms of hardware, software, user experience, and applications.

Virtual reality is a term that encompasses a broad range of research directions and applications. In the popular mind, virtual reality is the classic futuristic technology, being showcased in science fiction works such as Star Trek, where crew members of a spaceship can experience realistic worlds simulated by a sophisticated computer. A technical definition is offered in Heim (1998, p. 6):

> Virtual Reality is an immersive, interactive system based on computable information.

The term itself was first used by Jaron Lanier in 1986 (Behr, 2002), replacing various descriptions such as virtual worlds. The latter was used by Ivan Sutherland, who built what is considered the first head-mounted display (HMD), an early VR prototype called the Sword

of Damocles attempting to realize what he had called earlier "the ultimate display" (Sutherland, 1965). Other terms included synthetic enviroments, tele-existence, artificial reality, and immersive computing, the latter emphasizing a key feature of VR systems, namely immersion. Immersion refers to the feeling of being present in another reality apart from the real world. According to Heim, this goes beyond physical input and output because it involves psychological components, but it also surpasses purely mental imagination because of the sensory input involved.

A successful VR system should at least partially offer this user experience of being someplace else, in a reality created artificially. Total immersion is what most researchers refer to as strong VR.

Virtual reality differs significantly from the "regular" computer interaction in terms of input and output devices (see Figure 10). As the whole paradigm revolves around the immersive experience of being present in an artificial world, the way users interact with this world depends on these devices. The most important device is the medium that provides (primarily) the visual information that attempts to replace the physical world perceived through the eyes. There are two basic ways that are employed for this: HMDs and CAVE-type environments.

As the name suggests, HMDs are displays that fit on the user's head, often as a helmet, which block the view of the physical world and present the computer-generated images to replace it. The displays themselves are miniaturized and the technology used is usually CRT or liquid crystal display (LCD) types of screens. Issues that affect the quality of the user experience are the weight of the device, the resolution of the displays, and the field of view (FOV). The more sophisticated devices include a head-tracking system, which sends data to the computer system about the positioning of the user's head (and consequently gaze), so the image displayed is refreshed accordingly. This is essential to create an immersive experience, as the user freely moves his or her head about and views the scenery changing appropriately around him or her. This feature makes the HMD a significant input device as well. Some HMDs also include headphones to provide the audio. HMDs are also known as goggles and, together with data gloves, form the goggles-and-glove VR paradigm. The problems with HMDs, despite significant progress since the Sword of Damocles system, are still their cumbersome nature, suboptimal resolution, and limited FOV (Stanney and Cohn, 2008).

The data glove is an input device that is worn like a glove that tracks finger and hand movements and gestures and allows its wearer to manipulate virtual objects, thus bringing direct manipulation interactivity in a virtual environment. Its history can be traced back to 1977 with the Sayre Glove, which was an inexpensive, lightweight glove that was developed to track hand movements. Over the next years, this technology was enriched to include more sensors for tracking finger flexure and introducing tactile feedback to the fingertips, making the data glove an output device as well. Notable incarnations were the Digital Data Entry glove (1983), which was developed to recognize the Single Hand Manual Alphabet for the American Deaf and the 1987 Nintendo Power Glove, which was a crude data glove in terms of precision but it was the first that was widely available to the public (Sturman and Zeltzer, 1994). Data suits are the whole-body equivalent of the data glove. The user wears a suit that contains sensors that track the entire body movement. The data are then sent to the computer, which appropriately updates the virtual equivalent of the user, sometimes called a cyberbody.

CAVE-type environments are systems that are based on a configuration of large displays. They are rooms where usually projectors are employed to combine images to create a large scene. CAVE stands for Cave Automatic Virtual Environment, which was the name of the first such system, developed by the University of Illinois in 1992, the name also pointing to Plato's allegorical cave from *The Republic*. CAVE-type systems offer some significant advantages over HMDs. They allow multiuser immersion and collaboration, without

**Figure 10**   VR input and output devices.

cumbersome wearable devices, user mobility (which is only achievable through expensive omnidirectional treadmills in the case of HMD-based VR), high resolution, and wider FOV (Cruz-Neira et al., 1992).

While vision and hearing are the two senses that dominate interaction with computer systems, there are however efforts to exploit another human sense, touch. This is an area that interests particularly VR researches, since touch is a channel that provides rich information in real life, particularly in situations where VR is being used, such as health care. Doctors often feel with their hands bodily areas to make a diagnosis. To realize these sorts of tasks in a virtual space, tactile interfaces or haptics have been developed. These devices use pins or small electrical currents to stimulate the nerves that cause the sensation of touching. Another method used is by using motor mechanisms to provide resistance to the user's probings (Iwata, 2008).

Perhaps VR has failed to fullfill the expectations of enthusiastic fans as well as more moderate (as they seemed at the time) expectations of widespread VR use for the average user. VR is still very costly, so its main users remain limited to large business organizations or the military. But it has found a place in many applications (Heim, 1998).

Training is the most established application area for VR (Stanney and Cohn, 2008). The first VR applications were for simulation and training, especially in aviation and the military, and still today flight or combat simulations are typical examples of VR technology use.

Entertainment has always been a major force behind VR research and development. Arcade rooms often have a VR system that provides a much more exciting gaming experience than regular gaming systems. Disney is another example. Mine (2003) described work in creating VR attractions, where guests to Disney World can enjoy 4–5-min rides in CAVE-type systems, allowing a whole family to be simultaneously immersed in the game.

Another major consumer of VR technology is the building industry. It is quite common these days to construct 3D computer representations of building projects that are used not only to determine the design but also for showcasing and presenting the project to prospective customers, who can have a virtual walkthrough or fly-by in their future home. They can then offer feedback and express their preferences before any costly construction begins. One construction company specializing in luxury homes called their VR presentations "our greatest marketing tool."* The automotive, aerospace, naval, and other industries also have been exploiting VR in product design and manufacturing. Virtual wind tunnels are favored over their physical expensive counterparts. NASA was the first to combine the HMD and data glove technology in their VIEW (Virtual Interactive Environment Workstation) system, used among other things to develop a virtual wind tunnel and, according to Mark Pesce (2000), it was then that "Virtual Reality was

born," since it was one of the first instances that the users commented they actually felt being inside the virtual environment (tele-presence).

A recent VR application that has been utilized is in treating psychological conditions, namely phobias (Stanney and Cohn, 2008) and posttraumatic stress disorder (Rothbaum et al., 1999). While these treatments are fairly new and expensive, it is expected that they will become more common. Other areas of health care that benefit from VR is the treatment of patients who undergo painful procedures, such as skin scraping in burn victims. The immersive quality of VR actually distracts patients from the pain when they become absorbed in the VR program (Mueller, 2002).

Finally, VR has been used successfully in surgery education, where the surgeon examines and "operates" on 3D holographic images of a patient, obtained through normal magnetic resonance imaging (MRI) scans and computer tomographic (CT) images, before performing the procedure on the real patient (Versweyveld, 2001). This technique also takes advantage of force feedback, where the controls relate the pressure needed to be applied by the surgeon. VR has also been used in education and learning in various ways. One common example is in the reconstruction of places from history (Acevedo et al., 2001), where users can walk through sites that are either far away or have been destroyed. The exciting and entertaining aspect of VR definitely contributes to the learning experience.

## 4.9 Augmented Reality

Augmented reality began at roughly the same time as VR research, sharing a common origin and diverging in the application domain. As mentioned, AR does not seek to replace reality like VR does; instead it enhances (or augments) reality by superimposing computer-generated information over the primary visual field. In some cases, the physical view is processed to remove irrelevant data with the goal of enhancing not reality itself but the user's perception of it. The term itself is relatively recent, dating back to 1990. It was coined by Tom Caudell while he was working at Boeing. He used the term to describe a system utilizing a HMD to assist workers assembling cables into aircrafts (Mizell, 2001).

HMDs have been described above as the classic devices used in VR applications. In fact, HMDs are used extensively in AR applications, with the difference being that the displays employ semitransparent mirrors that do not block the physical view but allow computer-generated imagery to be projected on them. Alternatively, non-see-through displays can be used but they use real-time video of the outside world with superimposed graphics, effectively achieving the same result. They were first developed for use in fighter jet pilot helmets (and the H in the acronym actually stands for "helmet" instead of "head"), to replace heads-up displays (HUDs) (Defense Industry Daily, 2010), which in turn were one of the first applications of AR, long before the term was even thought of. HUDs were developed to eliminate the need for pilots to look down on their instruments (hence to keep their "heads up"). When the technology became available, the same idea was moved

---

* http://www.thefreelibrary.com/Builder+Spectrum+Skanska+using+'virtual+reality+tours'+to+sell+homes....-a097876792

into the pilots' helmet and integrated with the weapons systems. Like in VR HMDs, the helmet contains sensors to track head position, with the effect of the pilots' gaze being used to lock on enemy targets.

The field of AR really boomed in the 1990s and the past decade. Recent advances in technology, particularly in the capabilities and features of mobile devices and the fusion of different technologies in robotics and VR, have yielded a host of different applications with very promising prospects. Those are briefly summarized below. Before looking into them, however, it must be noted that AR is now more definitively defined, not as an offshoot of VR but as a particular field that blends computing and reality in real time with the ultimate goal of enhancing user perception and performance through this blending.

AR has been employed successfully in health care in various tasks, including surgery preparation, brain surgery, and laparoscopic surgery. In this context, images obtained through CT or MRI scans are projected directly on the patient's body, providing to surgeons the three-dimensional vision and feeling (Kania, 2001).

Another popular example of AR is Google Earth.* The user views satellite pictures of Earth and by setting preferences can superimpose additional information, such as borders between countries or states, roads, names of places, extra pictures submitted by users, and calculate distances between two geographical points etc.

Similarly, taking advantage of the recent advances in mobile devices, particularly the use of cameras and GPSs, there are applications for mobile devices that can display useful information over the video view of the world provided by the phone's camera. Examples include navigational directions for GPS applications or the display of points of interest in a particular area over the view the user points the camera at (see Figure 11). Such applications are expected to become more common

---

* http://www.google.com/earth/index.html

in the future as there is growing demand from the smartphone user base to exploit the capabilities of their devices (Chen, 2009).

## 4.10  Interaction in Intelligent Environments

AmI is an emerging technological paradigm which envisages an environment populated by several interoperating computing-embedded devices of different size and capabilities, which are interweaved into "the fabric of everyday life" and are indistinguishable from it (see Chapter 49 xx).

From a technological point of view, AmI targets to distribute, embed, coordinate, and interactively deliver computing intelligence within the surrounding environment. AmI technologies integrate sensing capabilities, processing power, reasoning mechanisms, networking facilities, applications and services, digital content, and actuating capabilities distributed in the surrounding environment. AmI will have profound consequences on the type, content, and functionality of the emerging products and services as well as on the way people will interact with them, bringing about multiple new requirements for the development of interactive technologies (e.g., Butz, 2010).

While a wide variety of different technologies is involved, the goal of AmI is to either hide the presence of technology from users or smoothly integrate it within the surrounding context as enhanced environment artifacts. This way, the computing-oriented connotation of technology essentially fades out or disappears in the environment, providing seamless and unobtrusive interaction paradigms. Therefore, people and their social situation, ranging from individuals to groups, and their corresponding environments (office buildings, homes, public spaces, etc) are at the center of the design considerations.

The pervasiveness of interaction in AmI environments requires the elaboration of new interaction concepts that extend beyond the current user interface

**Figure 11**  Augmented reality.

concepts like the desktop metaphor and menu-driven interfaces (Aarts and De Ruyter, 2009).

AmI environments will integrate a wide variety of interactive devices, in many cases equipped with built-in facilities for multimodal interaction and alternative input/output (e.g., voice recognition and synthesis, pen-based pointing devices, vibration alerting, touch screens, etc.) or with accessories that facilitate alternative ways of use (e.g., hands-free kits), thus addressing a wider range of user and context requirements than the traditional desktop computer. Devices will also vary in the type and specialization of the functionality they offer, ranging from "personal gadgets" (e.g., wristwatches, bracelets, personal mobile displays and notification systems, health monitors embedded in clothing) to "general-purpose appliances" (e.g., wall-mounted displays). Regarding personal devices, an important role will be played also by smart mobile phones, which already offer sensing and location awareness facilities, as well as AR applications which go in the direction of distributed and natural interactivity.

AmI will bring about new interaction techniques as well as novel uses and multimodal combinations of existing advanced techniques, such as, for example, gaze-based interaction (Gepner et al., 2007), gestures (Ferscha et al., 2007), and natural language (Zhou et al., 2007). Progress in computer vision approaches largely contributes to the provision of natural interaction in AmI environments, making available, among other things, techniques for facial expression, gaze and gesture recognition, face and body tracking, and activity recognition.

Additionally, interaction will be embedded in everyday objects and smart artifacts. This concept refers to interfaces that use physical artifacts as objects for representation and interaction, seamlessly integrating the physical and digital worlds. Such objects serve as specialized input devices that support physical manipulation, and their shape, color, orientation, and size may play a role in the interaction.

The interaction resulting from tangible user interfaces is not mediated and it supports direct engagement of the user with the environment. Consequently, it is considered more intuitive and natural than the current keyboard- and mouse-based interaction paradigm (Aarts and De Ruyter, 2009).

Interaction in AmI environments inherently relies on multimodal input, implying that it combines various user input modes, such as speech, pen, touch, manual gestures, gaze, and head and body movements as well as more than one output modes, primarily in the form of visual and auditory feedback. In this context, adaptive multimodality is prominent to support natural input in a dynamically changing context of use, adaptively offering to users the most appropriate and effective input forms at the current interaction context. Multimodal input is acknowledged for increasing interaction accuracy by reducing uncertainty of information through redundancy (Lopez-Cozar and Callejas, 2010).

However, AmI is also anticipated to introduce increased complexity for its users. As technology "disappears" to humans both physically and mentally, devices will no longer be perceived as computers but rather as augmented elements of the physical environment (Streitz, 2007). The nature of interaction in AmI environments will change radically, evolving from HCI to human–environment interaction (Streitz, 2007) and human–computer confluence (Ferscha et al., 2007). These concepts emphasize the fusion of the technology and the environment as well as the inextricable role of interaction in all aspects of everyday life.

AmI environments will be very interaction intensive, and humans will be constantly "surrounded" by a very large number of devices of different shapes and sizes. Therefore, interaction shifts from an explicit paradigm, in which the users' attention is on computing, toward an implicit paradigm, in which interfaces themselves drive human attention when required (Schmidt, 2005). Interaction in the emerging environment will be based no longer on a series of discrete steps but on a continuous input/output exchange of information (Faconti and Massink, 2001). Continuous interaction differs from discrete interaction since it takes place over a relatively longer period of time, in which the exchange of information between the user and the system occurs at a relatively high rate in real time. A first implication is that the system must be capable of dealing in real time with the distribution of input and output in the environment. This implies an understanding of the factors which influence the distribution and allocation of input and output resources in different situations for different individuals.

Due to the intrinsic characteristics of the new technological environment, it is likely that interaction will pose different perceptual and cognitive demands on humans compared to currently available technology (Gaggioli, 2005). It is therefore important to investigate how human perceptual and cognitive functions will be engaged in the emerging forms of interaction and how this will affect an individual's perceptual and cognitive space (e.g., emotion, vigilance, information processing, and memory). The main challenge in this respect is to identify and avoid forms of interaction which may lead to negative consequences such as confusion, cognitive overload, frustration, and so on. This is particularly important given the pervasive impact of the new environment on all types of everyday activities and on the way of living.

### 4.11 Summary of Interaction Paradigms

Command-based interaction (Section 4.2), most prominently (but not exclusively) demonstrated by command line interfaces, was the first major interaction style in HCI. It is still widely used, often preferred by expert users for its high speed and flexible nature and complements very well direct manipulation interfaces. The keyboard remains the most efficient text entry medium, so it is unlikely that it will go away, and as a result, the same is true for command line interaction.

Direct manipulation interaction (Section 4.3) encompasses a wide array of styles, starting from WIMP interfaces to tangible and haptic interfaces and VR interaction styles. The characteristic of direct manipulation interfaces is that it allows users to perform actions on objects directly, either through a pointing device (like

in a WIMP interface) or through any other way, such as a gesture or directly by hand (e.g., in touch screens). It is the most widely used interaction style, specifically in the form of the GUI paradigm of the desktop metaphor that is found almost universally across desktop computers. Direct manipulation interfaces are also featured in new technologies that are growing in the market, such as tablet PCs and smartphones featuring a touch screen.

Natural language and speech dialogue (Section 4.4) remains an unrealized promise in HCI, at least regarding the vision of natural interaction for all users, who seem to prefer an all-natural-language interaction or nothing. However, it has provided useful task-specific applications that have found a place in interaction with computer systems, for example, situations where the hands are busy or for people with disabilities. It is also an important input mode in multimodal systems, which complement speech input with gestures or some other input mode to overcome strict NLP limitations. It should be expected that the speech channel as input and output will be an important part of multimodal interaction in intelligent environments.

Web interaction (Section 4.5) is unique as context of use, which is a vital parameter in HCI, while the physical interaction itself in Web use does not present a specifically different paradigm from conventional application use. The Web information space and the choices offered, as well as the technology that opens vast communication capabilities, such as wireless connectivity, make Web interaction (along with mobile interaction perhaps) the most important evolution in the way people interact with computers.

Mobile interaction (Section 4.6) brought miniaturization and mobility into the fold. Starting from noninteractive tasks such as listening to music (with the Walkman) and branching into much more interactive activities such as making phone calls and surfing the Web, mobile interaction is a major step in HCI that has opened many new possibilities, including the role of the device in ubiquitous computing. Mobile interaction is characterized (and constrained) by the physical size of the device and the context of use, which varies significantly from desktop interaction. At this time, mobile interaction is undergoing a noticeable paradigm shift from scroll and select interfaces, dependent on the mobile phone keypad interface, to the more sophisticated direct manipulation interface offered by the latest smartphones.

Virtual reality (Section 4.8) is a special case of HCI, distinguished by the goal of providing an immersive experience to the user by replacing the real word with a computer-generated environment. This is achieved primarily with the use of HMDs, which isolate the user's visual perception of the real world and provide an artificial alternative and with CAVE-type environments, which use large displays that dominate the user's vision and allow for the immersive experience. How the user interacts in the various VR environments differs significantly, dependent of the nature of the VR application. For example, a training VR application mimics the real-world controls of interaction (e.g., the plane's cockpit) but a virtual environment that has no real-world equivalent (such as a fantasy world) could use

a direct manipulation interface with a "magic wand," a tangible interface, and so on. Due to the high cost of VR, its applications are still limited to the military or large business organizations and widespread adoption of this interactive paradigm seems difficult and unlikely to become a reality in the near future.

Augmented reality (Section 4.9) blends real-world information with computer-generated visualization to facilitate user perception and user tasks. The main interactive element that distinguishes AR interaction is in the form of visual feedback provided by the computer. Unlike VR, simple AR applications (such as GPS-based navigation) are starting to penetrate the market, mainly through the exploitation of the capabilities of modern smartphones. It is expected that with the rapid growth of the market share presented by these devices more applications of this sort will be quite common. Otherwise, AR is successfully being employed in health care.

Multimodal interaction (Section 4.9) integrates natural input modes, such as speech, pen, touch, hand gestures, eye gaze, and head and body movements. It represents a paradigm shift from conventional WIMP interfaces toward providing users with greater expressive power and naturalness and achieving forms of interaction closer to natural human–human communication. Recent advances in multimodal interaction also cater for passive input that requires no explicit user command, such as vision-based tracking. This way, multimodality permeates into intelligent interaction environments where interaction is to a large extent implicit and continuous.

AmI (Section 4.10) is arguably the next major step in the overall computing paradigm and consequently the next major evolutionary step in HCI. What is fundamentally changing is that users interact no longer with a single machine but with the environment surrounding them, the computer becoming a more abstract entity, fusing intelligent artifacts through an invisible network of sensors. Interaction does not occur through a single interface and can be achieved via a multimodal paradigm that can include any of the interaction styles described in this chapter, such as gestures, speech, direct manipulation, and combinations of those. At the moment, AmI environments are largely in the research stage, since they present a host of challenges that need to be overcome.

## 5  EMERGING CHALLENGES, FUTURE TRENDS, AND CONCLUSIONS

There are several trends and challenges that determine the direction of future HCI research and development and as a consequence the future evolution of interactivity. These include trends and developments in mobile interaction, concerns about universal access, multitouch-based devices, the evolution of Web interaction, and the progressive emergence of AmI environments.

Mobile Web use has evolved into a totally different paradigm from the desktop counterpart. Similarities can be drawn with some add-ons or plug-ins of Web browsers, which offer specific Web services rather than

a free net roaming experience. Examples would include a toolbar which displays the weather or stock market prices or such. Mobile users download Web applications that provide specific services as well. For example, Apple's App Store has thousands of applications that use the Web, each with its own interface, without any particular uniform design paradigm (still in its infancy) and users consume bits of information from the Web without really noticing it. Web usage is therefore spread over different small applications, from different manufacturers and providers. The competition is no longer on the website level but on the miniapplication level. There is no homogenous paradigm of Web usage, the mobile Web is "balkanized," divided into thousands of service points with thousands of interfaces. Search is not the main issue, as it is on desktop Web surfing. According to Google user experience designer Leland Rechis, "The Pangaea of the Web is gone" (Wellman, 2007). Because of carrier portals and off-portal applications, there is no one mobile standard to develop for. In the mobile world developers have to be prepared to optimize for different devices, browsers, languages, carriers, countries, and cultures. While the international and cultural factors affect desktop Web surfing as well (Marcus and Rau, 2009) and have been examined quite well, the portal and device variety remain the most challenging issue in mobile development.

An open question regarding the future of mobile devices is if there will be a convergence of devices, that is, devices that combine the capabilities of more or an increased diversity of appliances. Most mobile phones combine the capabilities of a telephone, a camera (including video recording), an electronic organizer, and more often than not a music device. Taking into account the recent trend and market acceptance of high-end touch-based phones that offer these features, as well as Internet connectivity, in a considerably more user-friendly manner, it seems that the convergence of devices case has more merit as the safest prediction, at least on the mobile phone–size scale.

This potential of mobile devices in general needs further investigation. There are many ongoing research projects that explore the mobile device as an ubiquitous computing medium, an AR device, new interaction technique opportunities as presented by high-end phones with touch screens, accelerometers and gyroscopes, cameras, and so on.

Another important concern that influences HCI is the rapid aging of the population in the developed world. This has not only socioeconomic but also accessibility implications in (especially mobile) computer interaction. Mobile devices are particularly susceptible to accessibility issues because of their inherent small size. Furthermore, mobile interaction is challenged by situational impairments and disabilities (SIIDs), due to the plethora of the contexts of use. A major challenge therefore in future HCI research is to provide a solution to the accessibility problem regarding mobile use. Universal access is a constant challenge in HCI, but desktop computing (for which most related work has been done) presents more alternative solutions and is, arguably, easier to respond to compared to mobile interaction.

The design approach of the new smartphones has been recently transferred into the tablet PC platform. While tablet PCs have been around for some time and did feature a touch screen, these devices are not merely (or, arguably, fully) PCs with a touch screen. The Apple iPad, for example, does not offer the same capabilities as a normal netbook or laptop, such as multitasking and running any type of application. Instead it is designed to offer specific services, such as multimedia, electronic reading, and connection to the Web. A major difference is the multitouch interface, which bears significant advantages over older touch interfaces, as it offers a much richer and enjoyable user experience. This type of appliance, despite its obvious shortcomings compared with a standard (and much cheaper, for now at least) netbook, seems likely to become in the future the computing interaction of choice for a significant number of users. Its multitouch interface, enjoyable user experience, and inherent mobility are a strong combination that covers many market needs. Moreover, there is a conscious effort to make smartphones and tablet PCs and information sharing between them easy. This, it can be argued, is a first step toward a more ubiquitous computing that is not constricted into one device or location. While there are still major difficulties to overcome, this trend is anticipated to move closer to a situation where abstract cloud computing is available and compatible through a host of different device types and platforms.

AR in general is expected to be more available and accessible to the everyday user, through smartphone cameras, the aforementioned tablet PCs (also equipped with HD cameras) and other promising projects, such as SixthSense,* which is a wearable device that blends the digital world with the physical.

Interacting with the Web has changed significantly since the first days of the ARPANET. The text-based presentation of the first era was mostly confined in academia and business. The wider public became familiar with the Web through GUI-based browsers, which soon were capable of providing a richer interactive experience. Today, the Web is accessible by far more devices and in a plethora of contexts of use that is significantly altering the overall user experience. Service-specific information consumption in chunks, which characterizes mobile interaction, is also affecting desktop and laptop Web interaction. An example is RSS feeds or browser plug-in (add-ons, extensions) services. What this means in essence is that Web interaction is now expanded to include more than the usual browser-based surfing style that dominated Web interaction for more than 15 years.

Gesture-based interaction, mostly familiar to the wider audience through gaming (the Wii console is a particular example†), is also being researched in the context of AmI environments and 3D interfaces (in VR applications or information visualization and navigation of large data sets, e.g., see Underkoffler's g-Speak SOE presented at TED in 2010‡) and is gaining more attention.

---

† http://www.nintendo.com/wii/console/controllers

‡ http://www.ted.com/talks/lang/eng/john_underkoffler_drive _3d_data_with_a_gesture.html

Finally, looking at the big picture and considering the technology available, it seems that the so-called third wave of computing mentioned earlier in the chapter, where the computer will gradually disappear in the background and be embedded in the surrounding environment, is approaching. AmI enviroments may take many forms. For example, in Chapter 49xx, various applications in different domains are discussed, where each installation differs in the actual size of the environment, the hardware and software involved, the interaction styles employed, and so on. Similarly, various ongoing research projects present different approaches and manifestations of the same idea of the disappearing computer, with different emphasis on the intelligent behavior, the natural interaction involved, accessibility, aesthetics, design methodology, and so on, depending on the specific domain.

Looking at the evolutionary history of interaction, the first observation is that none of the interaction styles that appeared from the first days of computing until today have actually disappeared. The oldest and most basic interaction style, command line interface, is still widely used and the same holds true for every interaction style presented in this chapter. Following the ongoing research and development of new interaction styles, such as gesture interfaces or haptic interfaces, there is no evidence that these will render any of the current popular styles obsolete. The conclusion that can be drawn is that there is no one optimal interaction method that can be devised. On the contrary, the paradigm shift toward an AmI environment that seeks to replace current methods of interaction with computing favors a multimodal approach, where every interaction style is utilized according to its appropriateness to the context of use and the task at hand. Therefore, in the AmI context, an important challenge is to approach every interaction style and determine its optimal use and appropriate place in the services offered by the intelligent environments.

More pragmatically, a huge challenge involved in AmI environments escaping the laboratory and entering the public is the complexity inherent in such a large scale. There are issues regarding integration, interoperability, and synergy between various devices and artifacts. This also includes security and privacy concerns, increased with the presence of more than one platform and devices that must all conform to the same high standards of safety. Not to be underestimated is the cost of such an environment, including the cost of use (parallels may be drawn by the Western/Japanse contrast of mobile Web use adoption).

The technology to realize ubiquitous computing exists. Theoretically and to a certain degree practically, the wide availability of the Internet everywhere (through Wi-Fi or mobile access) and the corresponding network-capable devices can form an environment in which they can communicate and exchange information to offer ubiquitous services. The question is whether (or more to the point, when) the interaction we experience with these components individually will expand to include all in a loosely perceived abstract supersystem that intelligently observes, adapts, and responds to human needs and desires.

# PART 9

## DESIGN FOR INDIVIDUAL DIFFERENCES

# CHAPTER 51

# DESIGN FOR PEOPLE WITH FUNCTIONAL LIMITATIONS

**Gregg C. Vanderheiden and J. Bern Jordan**
**University of Wisconsin–Madison**
**Madison, Wisconsin**

## 1 INTRODUCTION

### 1.1 Not a Special Population But a Continuum — And the Future for Most of Us

Often, the topic of design for human disability and aging is thought of as a special topic, vertical market, or special application. Although there are special products or assistive technologies designed specifically for use by people with disabilities, they constitute only a small portion of the total number of products that need to be designed to accommodate persons with functional limitations. In addition to the specially designed tools, everyone, including those with disabilities, needs to have access to a wide range of technologies found in their everyday lives: at home, at school, on the job, and in the community. It is toward the more accessible design of everyday products that this chapter is directed.

Another common misconception is that the population in question is small. Although there are many different types and degrees of disabilities, some of which represent smaller numbers of people, cumulatively those with disabilities represent around 19% of the population. In addition, a majority of people who live beyond age 65 will have difficulties performing activities of daily living

(a definition which includes getting around inside the home, dressing, and eating) and instrumental activities of daily living (a definition which includes going outside the home, doing light housework, and using the telephone) due to disability. Approximately 37% of those over 65 have a severe disability; the prevalence jumps to 58% for those over 80 (Brault, 2008). In addition, many of these people experience multiple functional limitations.

Finally, it is important to note that the target audience for these design guidelines includes nearly everyone as we age and acquire disabilities (functional limitations). The only exception will be for those of us who die first.

## 1.2 Multiplier Effect

If companies were designing products for individuals, this population (people with functional limitations) would cumulatively constitute a significant portion of the market. When designing products to be used by families or within industry, the impact is multiplied. Since a family unit consists of three or four people, the percentage of families who have people with disabilities is much higher. When you turn to industry, particularly large industries, you find that the percentage of industries that employ people with disabilities is very high. Thus, if you are designing products and systems for use by larger industries, you will find that almost all of the customer base will have employees with disabilities.

## 1.3 Who Is Included in the Category "Disabled and Elderly Persons"

In considering product design, it is important to note that there is no clear line between people who are categorized as disabled and those who are not. A performance or ability distribution for a given skill or ability is generally a continuous function rather than bimodal with distinctive able and disabled groups. This distribution includes a small number of people who have exceptionally high ability, a larger number with midrange ability, and another longer tail representing those with little or no ability in a particular area. In looking at such a distribution, it is impossible simply to draw a vertical line and separate able-bodied from disabled persons. It is also important to note that each aspect of ability has a separate distribution. Thus, a person who is poor along an ability distribution in one dimension (e.g., vision) may be at the other end of the distribution (i.e., excellent) with regard to another dimension (e.g., hearing or IQ). Thus, people do not fall at the lower or upper end of the distribution overall, but generally fall into different positions, depending on the particular ability being measured.

## 1.4 The 95th Percentile Illusion

It should be clear that even if elderly and disabled persons are included in the mainstream design process, it is not possible to design all products and devices so that they are usable by all people. There will always be a "tail" of people who are unable to use a given product. To include a sizable portion of the population in the category "those who can use a product with little

or no difficulty," the 95th percentile data are often used. The problem is that there are no 95th percentile data for specific designs—there are only data with regard to individual physical or sensory characteristics. Thus, there are 95th percentile data for height, vision, hearing, and so on. As a result, it is not possible to determine when a product can be used by 95% of people. It is only possible to estimate when a product can be used by 95% of the population along any one dimension. Since people in the 5% tail for any one dimension (e.g., height) are usually not the same people as those in the 5% tail along another dimension (e.g., vision) (Kroemer, 1990), it is possible to design a product using 95th percentile data and end up with a product that can be used by far less than 95% of the population.

To illustrate this phenomenon, imagine a minipopulation of 10 people. Ten percent of them (1 of 10) have one short leg, 10% have a visual impairment, 10% have a missing arm, 10% are short, and 10% cannot hear. Let us assume that we design a product that required 90th percentile ability along each of the dimensions of height, vision, leg use, arm use, and hearing. In this instance we would end up with a product that was in fact usable by only 50% of this population. This occurs because, although only 10% of this minipopulation are limited in any single dimension, different people fall into the 10% tail for each dimension, and only 50% of the population are within the 90th percentile for all five areas.

In real life, the effect is not quite this dramatic, and its calculation is not as simple. First, the percentage of people with disabilities is less than 10% along any one dimension. Second, there is often overlap where one person would have more than one disability (e.g., elderly persons). On the other hand, there is a much wider range of different individual types of disability. In addition, the data from which the 95th percentiles are calculated often exclude persons with disabilities (Kroemer, 1990), making the percentage who could use the design(s) smaller than one would first calculate.

## 2 DISABILITY IS A CONSEQUENCE, NOT A CONDITION

> Disability is the inability to accommodate to the world as it is currently designed.
>
> *Vanderheiden, 1995, rephrasing Caplan, 1992*

The quote above is a slightly different take on Ralph Caplan's quote, "Disability is the inability to accommodate poor design," with an emphasis on the fact that design can be changed, and thus so can disability. In looking at the impact of disability and its relationship to design, it is often useful to use a model such as that shown in Figure 1, which is similar to the World Health Organization model for disability (WHO, 1980).

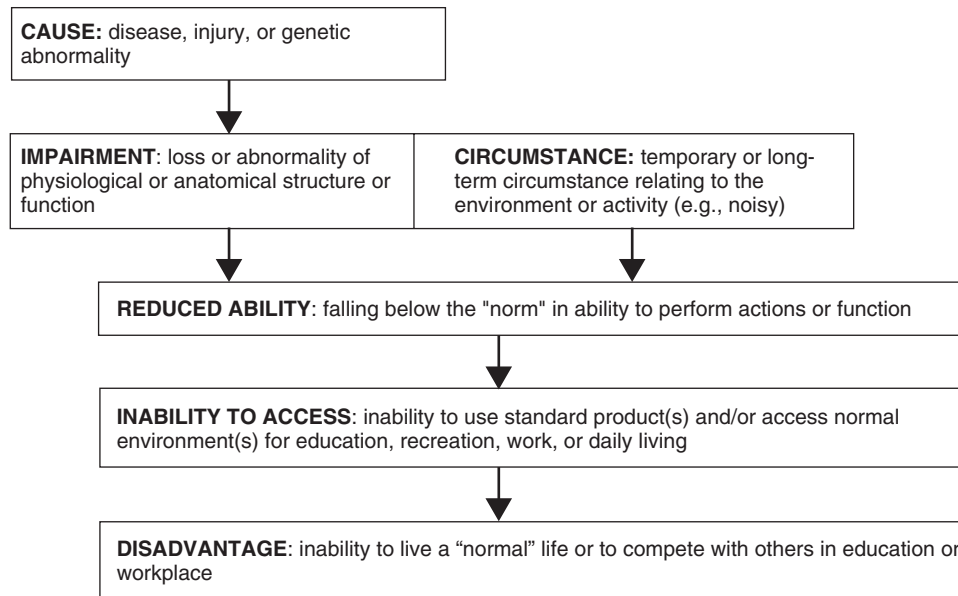
The model shows the relationship that both impairment and design have in creating disabilities. It also shows how circumstance can create similar reduced abilities in anyone, including those without functional


**Figure 1** Cause–effect model shows the role that both impairment and design play in disability as well as the parallel role that conditions or circumstances can play.

impairment. Combined with poor design, these circumstances can also lead to situations where people experience circumstantial disabilities or inabilities to carry out certain tasks. Thus, in addition to generally making products easier for everyone to use, better or more universal design can make a product usable even when people are under stressed conditions. Take, for example, a mother whose young son just fell and cut his head. She makes the mistake of mentioning the doctor and is now trying to use the phone while holding her screaming, kicking son in one arm to keep him from running off and hiding. Because of the screaming, she can hear very little and has some of the same functional problems as those of a person with a hearing impairment. Because her son is kicking and thrashing, she has poor motor control and has only one hand available. Because he is bleeding profusely, she is also highly distracted and is able to bring only limited cognitive skills and attention to the task at hand.

### 2.1 Three Approaches

There are basically three ways to address the problem faced by those who are unable to use the world around them:

*Change the person.* This may be accomplished through surgery, education, skill development, skill practice, or teaching strategies, tricks, or "secrets" for doing things or for doing things more easily. This would also include technologies that become "part of the person" such as eyeglasses, braces, and artificial limbs.

*Provide the person with bridging tools.* This includes devices and adapters that bridge between

the user and mainstream technologies [e.g., door knob adapters, screen readers, adaptive keyboards, telecommunication devices for the deaf (TDDs/TTYs)].

*Change the way that the world is designed.* Develop more universal and accessible designs for mainstream products.

Ergonomics is involved in all three of these areas by (1) developing new techniques, strategies, and technologies that can allow an unaided person to perform better in the workplace, home, or community; (2) developing specialized tools or assistive technologies that can adapt individual parts of the world to match the use of residual skills and abilities of a person; and, of course, (3) changing the design of the world in general so that it is more usable with a wider range of skills and abilities. The focus of this chapter is on the third approach: designing the world to be more universally usable.

### 3 UNIVERSAL DESIGN PROCESS

Universal design is the term that has been given to the practice of designing products or environments which can be used effectively and efficiently by people with a wide range of abilities operating in a wide range of situations. This includes people with no limitations as well as those operating with functional limitations relating to disabilities or simply by circumstance. For example, products developed using universal design principles would be flexible enough to be usable by people with no limitations as well as those:

- Who cannot see the product because they are blind or because their eyes are occupied temporarily (e.g., driving a car)
- Who cannot use their hands well because of aging or a physical disability or because their hands are temporarily full, cold, or gloved
- Who cannot speak or are in an environment where speech is not practical (library or noisy crowd)
- Who cannot hear the product because they are deaf or because they are in a very noisy environment (e.g., an airplane or a shopping mall at Christmas)
- Who have learning disabilities or who are able to divert only part of their attention to the task at hand
- Whose primary language is sign language or a foreign language
- Who are very young or very old

It is important to remember that universal design is a process, not a product. No matter how well something is designed to be accessible or "universally usable," there are going to be some people with severe disabilities or particular combinations of disabilities and circumstances that will not be able to use a product or service. An *ideal* design is one that is attractive, easy to learn, and effective and whose functions can be accessed efficiently and used by *everyone* across the full range of circumstances that occur for its intended use. Ideal designs however do not exist. A very good design is a commercially practical, mass market design that is usable by and attractive to the maximum possible number and diversity of users, given the best of today's collective knowledge, technologies, and materials. Universal design of mainstream products and services is the process of seeing how close to ideal designs you can get with a practical profitable commercial design.

## 3.1 Non-Disability-Related Reasons for Universal Design

### 3.1.1 Benefits for All

A general characteristic of good universal design is that it benefits many more people without disabilities than those with disabilities. This, of course, follows from the design benefiting everyone and the fact that there are more people without disabilities than with disabilities. The sidewalk curbcut is a prime example of this, as are ramps in general. Although originally designed for users of wheelchairs, they are also used by parents pushing baby carriages, people pulling baggage carriers, bicycle riders, skateboard users, kids on tricycles, and any number of other people. Even people walking can be observed to veer from their path to walk up a curbcut rather than stepping up a curb. In another example, a technique called "EZ Access" was used to allow persons who are blind to access and use touch screen–based kiosks. Once implemented, however, it was found that

it was also very useful for persons with low vision as well as those who could not read due to literacy or language problems.

### 3.1.2 New Insights

Studying the use of products by people with functional limitations can also provide insights into a design that might not otherwise be achieved. For example, it is much easier to determine which elements in a kitchen require greater strength by testing a person who is weak or who has poor grasp than it would be by employing someone with normal or extraordinary strength. Even if such a person were asked which things required more or less effort, the mere fact of having so much strength in reserve would cause the person to use it unconsciously.

### 3.1.3 Lower Cost Design

Universal design can also lead to insights that result in lower cost designs. Although universal designs are usually thought of as being more expensive, this is generally not the case. If one discounts the time it takes to reorient one's thinking and familiarize oneself with the characteristics and constraints of people with functional limitations, the resulting designs can be both easier to use and less expensive.

One example of this is the current design of elevators and their alert bells. In the past, people with disabilities had a problem getting onto elevators when they were arranged in elevator banks. Often, by the time the person using a wheelchair got to the elevator that had opened, the door had closed. New standards were proposed which would require that elevator doors stay open for a longer period of time to allow them to be boarded successfully by wheelchair users. This caused problems, because it increased the number of elevators that needed to be installed in buildings to ensure adequate service to all floors. In some thin, tall buildings, this could result in using up a substantial portion of the building for elevators.

After an injunction was sought to stop the standards, the designers and consumer advocates sat down to study the problem anew. It was determined that the problem was not the time it took to board the elevator but the time it took to get in front of the elevator. Since the elevators were computer controlled, and the computers knew where the elevators were going in advance of their arrival, it was quickly determined that lighting the alert light and sounding the bell in advance would allow persons with disabilities to position themselves in front of the elevator door and be able to board as it opened. Testing bore this out, and it was found that people in wheelchairs as well as everyone else could actually begin the boarding process much more quickly and in much less time than the elevators were then staying open. Following the modification in timing of the alert light and bell, designers were able to decrease the time that the doors stayed open, allowing builders either to use fewer elevators or to provide better service to the floors.

According to data from the U.S. Current Population Survey, the employment–population ratio in 2009 was approximately 19% for people with a disability compared with 65% for people without disabilities.

In 2009, nearly 900,000 people with disabilities were looking for and unable to find work (Bureau of Labor Statistics, 2010). If their annual salaries only average $25,000, that amounts to $22 billion in lost productivity as well as lost tax revenues. This is in addition to the large costs in the form of transfer payments and program costs for those who cannot live independently. Total U.S. federal, state, and local public expenditures for disability-related programs was $294 billion for 1997 and estimated at $426 billion for 2002 (Braddock, 2002). What portion of this could be saved if the design of the environment allowed people to live more independently or to stay on their jobs longer?

## 4 DEMOGRAPHICS

As shown in Figures 2.4, the prevalence of the various types of functional limitation (visual, hearing, physical, cognitive) varies significantly as a function of age. In children we see a much higher percentage of mental retardation and language and learning disabilities than of other disabilities (Figure 2). As people age, sensory and physical disabilities become more prevalent (Figure 3). Not evident from these charts is the fact that in older persons we see a much higher incidence of multiple disabilities, including combinations such as hearing and visual impairments, which interfere with many of the adaptive strategies developed for those who have hearing or visual impairments alone. Finally, we can see that the percentage of people who have functional limitations within the population increases sharply as a function of age. In fact, a wide majority of those over the age of 75 (Figure 4) will have functional limitations, and almost half will have severe functional limitations of one type or another. Thus, over our lifetimes (if we live long enough), most of us will not only benefit from but will require more universal design.

### 4.1 Characteristics of Users with Functional Limitations

In considering design for people with functional limitations, it is important to examine their abilities both without and with tools and strategies that they normally employ. For example, it is important to look at an amputee's abilities both with and without different types of artificial limbs. These present very different mechanical and manipulative characteristics. Many touch buttons, for example, cannot be activated using different

**Figure 2** Prevalence of impairment (primary diagnosis for school-aged children (3–21 years) in the United States. Each child is counted in only one category. (Data from Kraus and Stoddard, 1989, based on reports of the Office of Special Education and Rehabilitation Services, 1988. OSEP state reported date, 1986–1987 school year.)

types of artificial arms. Acoustic wave touch screens may be accessible using soft plastic cosmetic arms, but not hooks.

It is also important to consider people without their assistive devices, since many people do not have them, either because they cannot afford them or because they prefer to avoid the stigma (e.g., not wanting to use hearing aids or even very strong glasses). This, of course, adds to the variability and complicates any attempts at comprehensive surveying of needs, abilities, or characteristics. Although a comprehensive survey of the types of assistive technologies used by persons with different disabilities cannot be presented here, a partial listing is provided in Table 1. For a more comprehensive review, readers are referred to Galvin and Scherer (1996) or Cook and Polgar (2007).

## 5 RESEARCH IN ERGONOMICS AND PEOPLE WITH FUNCTIONAL LIMITATIONS

Most of the research on people with functional limitations is taken not from research on people with disabilities but rather from experiments done with "normal" persons operating under stress or adverse conditions (e.g., blinded by smoke, encumbered by a spacesuit). These studies represent much more controlled conditions than those represented by the great diversity of types, combinations, and degrees of disability but do yield interesting information that can be used by people with disabilities. As noted above, the results of work with persons with disabilities can also be applied to these other environments/locations where people have reduced abilities due to circumstance.

There are major problems in carrying out research in that the variation and range of ability or constraint is so great. Visual impairments, for example, can take a very wide range of forms, and each of these can vary in degree from very mild to severe reduction or total loss. As a result, it is not possible to make blanket statements about these populations. Instead, the research generally tries to characterize the diversity, to quantify numbers of people within particular ranges, and/or to chart the functional characteristics for major groups. For example, people who are experiencing hearing loss due to aging tend to lose hearing at certain frequencies more than others. (These results are reflected in the design guidelines that follow.) People with photosensitive epilepsy tend to be much more susceptible to certain frequencies than to others. The fact that there are no set patterns and that one can find people with just about any type, degree, and combination of disabilities makes developing design guidelines difficult. However, design principles do exist, as well as strategies that can significantly increase the accessibility and usability of products by a much wider range of people.

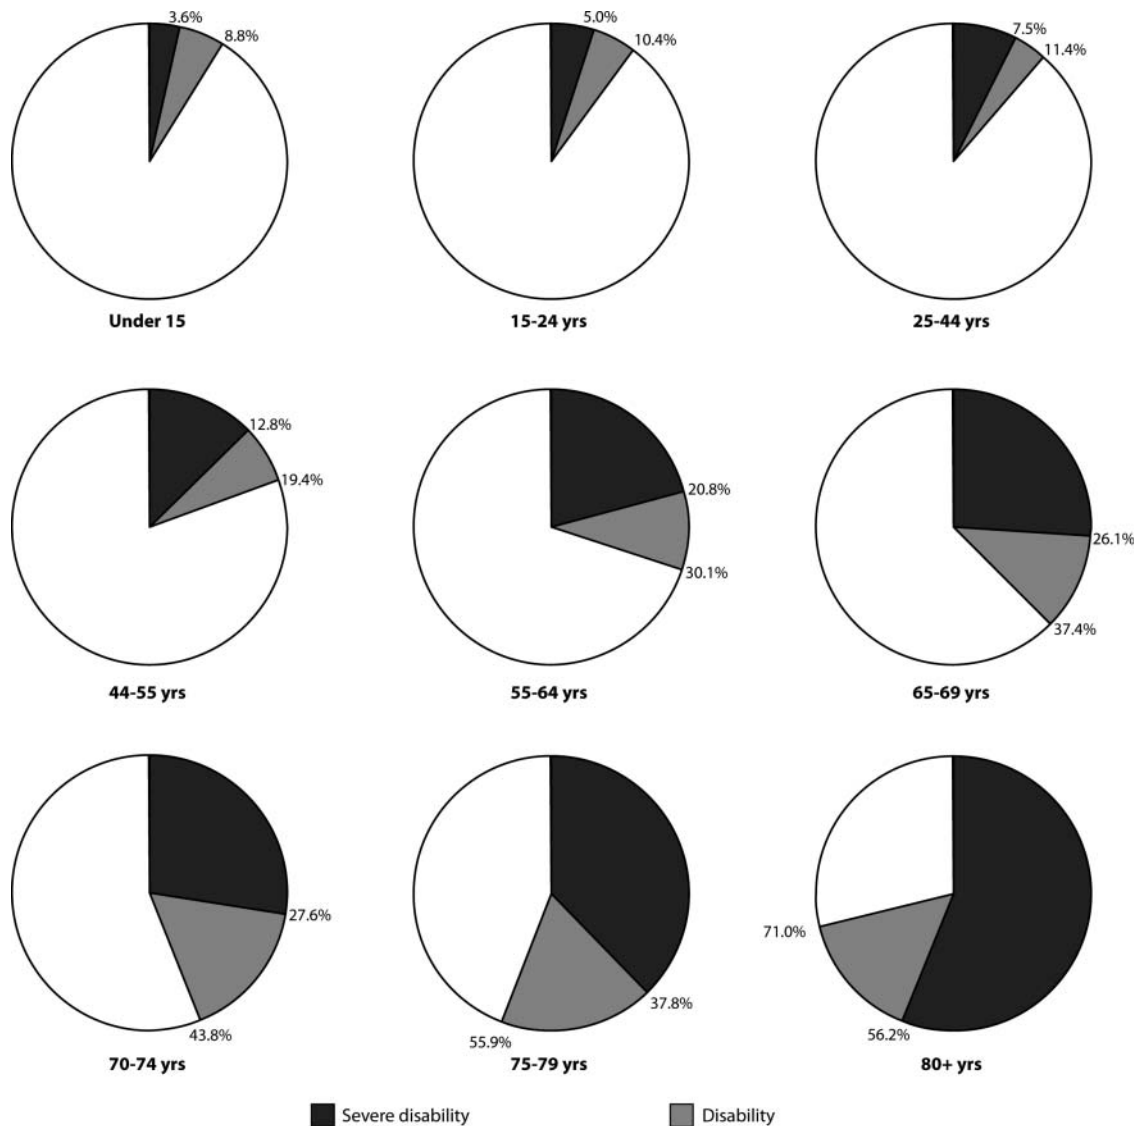
Note that this chapter refers to persons rather than populations. *Population* tends to imply somewhat homogeneous groups (although there may be variance within the group). When talking about people with functional limitations, we are talking about something that is a continuum that flows across many dimensions simultaneously. A classic example is people who are older who may have reductions in visual, hearing, physical, and/or cognitive abilities simultaneously. These abilities will also take different tracks and combinations in different people and will be progressive over time, making design of environments and products challenging. Clearly, designs must be flexible to accommodate


**Figure 4**  Disability as a function of age. Pie charts show the percentage of people who report having a disability within each age group. (Data from Brault, 2008, based on the 2004 Survey of Income and Program Participation, U.S. Census Bureau.)

different people, but in these cases they must be flexible to accommodate the same person over time or sometimes during different periods of the same day.

## 6   REGULATIONS AND GUIDELINES

There has been a steady advancement in both the capabilities of technology and the extensiveness of its use. Growing along with the advancement of technology is recognition of the importance of accessible technology, both in the United States and abroad.

In the United States, the U.S. Access Board (http://www.access-board.gov/) develops accessibility guidelines and regulations. Some of the notable accessibility legislation that applies to information and communication technology includes the American with Disabilities Act Accessibility Guidelines (civil rights legislation), Section 508 of the Rehabilitation Act of 1973 (which relates to federal procurement of accessible products and services and is being updated at the time of this publishing), and Section 255 of the Telecommunications Act of 1996 (which relates to the manufacture and sale

of telecommunication devices and is being updated and harmonized with the Section 508 regulations).

Many standards are developed at the international level and are often used in part or adopted by countries as legislation or guidance. The International Organization for Standardization (ISO) has a number of standards that relate to accessibility, the most noteworthy of which are ISO/International Electrochemical Commission (IEC) Guide 71:2001 ("Guidelines to address the needs of older persons and people with disabilities when developing standards"), ISO 9241-20:2008 ["Accessibility guidelines for information/communication technology (ICT) equipment and services"], and ISO 9241-171:2008 ("Guidance on software accessibility"). The Web Accessibility Initiative (WAI) of the World Wide Web Consortium (W3C) has published extensive guidelines on Web accessibility: Web Content Accessibility Guidelines (WCAG) 2.0, 2008. The Education and Outreach Working Group of the W3C WAI also maintains a list of policies relating to Web accessibility available at http://www.w3.org/WAI/Policy/.

Readers who are interested in more information about standards, regulations, and guidelines are referred to Hodgkinson (2009), ISO/IEC (2009b), or Vanderheiden (2009b).

## 7 OVERVIEW BY MAJOR DISABILITY GROUPS

Although there is a tremendous variety of specific causes, as well as combinations and severity of disabilities, we can most easily relate their basic impact to the use of consumer products by looking at five major categories of impairment: (1) visual impairments, (2) hearing impairments, (3) physical impairments, (4) cognitive/language impairments, and (5) seizure disorders. In addition, we discuss some of the common situations of multiple impairments.

### 7.1 Visual Impairments

Visual impairment represents a continuum from people with very poor vision, to people who can see light but no shapes, to people who have no perception of light at all. However, for general discussion it is useful to think of this population as representing two broad groups: those with low vision and those who are legally blind. In 2000, there were an estimated 3.3 million people with visual impairments (including blindness) (Congdon et al., 2004). In the elderly population the percentage of persons with visual impairments is very high.

As established by the American Medical Association in 1934, a person is termed *legally blind* when their visual acuity (sharpness of vision) is 20/200 or worse *after correction* or when their field of vision is less than $20°$ in the best eye after correction (Hoover and Bledsoe, 1981). There are approximately 937,000 people in the United States who are legally blind (Congdon et al., 2004). *Low vision* includes problems (after correction) such as dimness of vision, haziness, film over the eye, foggy vision, extreme near- or

farsightedness, distortion of vision, spots before the eyes, color distortions, visual field defects, tunnel vision, no peripheral vision, abnormal sensitivity to light or glare, and night blindness. There are approximately 2.4 million people in the United States with severe visual impairments who are not legally blind (Congdon et al., 2004). Many diseases causing severe visual impairments are common in those who are aging (glaucoma, cataracts, macular degeneration, and diabetic retinopathy). With current demographic trends toward a larger proportion of elderly, the incidence of visual impairments will certainly increase.

### 7.1.1 Functional Limitations Caused by Visual Impairments

Those who are legally blind may retain some perception of shape and contrast or of light versus dark (the ability to locate a light source) or they may be totally blind (having no awareness of environmental light). Those with visual impairments have the most difficulty with visual displays and other visual output (e.g., hazard warnings). In addition, there are problems in utilizing controls where labeling or actual operation is dependent on vision (e.g., where eye–hand coordination is required, as with a computer mouse or touch screen). Written operating instructions and other documentation may be unusable, and there can be difficulties in manipulation (e.g., insertion/placement, assembly).

Because many people with visual impairments still have some visual capability, many of them can read with the assistance of magnifiers, bright lighting, and glare reducers. Many such people with low vision are helped immensely by use of larger lettering, sans serif typefaces, and high-contrast coloring. Those with color blindness may have difficulty differentiating between certain color pairs. This generally does not pose much of a problem except in those instances when information is color coded or where color pairs are chosen that result in poor figure–ground contrast. Key coping strategies for people with more severe visual impairments include the use of braille and large raised lettering. Note, however, that braille is preferred by less than 10% of those who are legally blind (American Foundation for the Blind, 1996), normally those blind from early in life. Raised lettering must be large and is therefore better for indicating simple labels than for extensive text.

### 7.2 Hearing Impairments

Hearing impairment is one of the most prevalent chronic disabilities in the United States. From the 2009 National Health Interview Survey (NHIS), it is estimated that 34 million adults in the United States (15%) report at least some difficulty hearing (Sondick et al., 2010). From the most recent detailed NHIS about hearing impairments in 1990–1991, approximately 0.5% of the U.S population had severe to profound impairments, where people can at best understand words shouted into their better ear (Ries, 1994). *Hearing impairment* means any degree and type of auditory disorder; *deafness* means an extreme inability to discriminate conversational speech through the ear. Deaf people, then, are those who cannot use their hearing for communication. People with a lesser

**Table 1  Partial List of Assistive Technologies and Strategies**

| Type of Disability of Functional Limitation | Assistive Technologies and Strategies Used |
|---|---|
| Hearing impairment | <ul><li>Hearing aids</li><li>Cochlear implants</li><li>Amplifiers</li><li>Assistive listening devices (remote microphone that transmits to a receiver worn by the user)</li><li>Headphones</li><li>Inductive loops (that couple to the hearing aid)</li><li>Direct connection (wire from audio device to the hearing aid)</li><li>*(See also deafness strategies and technologies)*</li></ul> |

| Type of Disability of Functional Limitation | Assistive Technologies and Strategies Used |
| --- | --- |
| Speech impairment | • Voice amplifiers<br>• Voice synthesizers<br>• Artificial larynxes |
| Cognitive impairment | • Memory aids<br>• Cuing systems<br>• Calculators<br>• Text-to-speech aids<br>• Network-based assistance on demand |

degree of hearing impairment are called *hard of hearing*. Usually, a person is considered deaf when sound must reach at least 90 dB (5–10 times louder than normal speech) to be heard, and even amplified speech cannot be understood.

Hearing impairments can be found in all age groups, but loss of hearing acuity is part of the natural aging process. Of those aged 55–64, 15.4% have hearing impairments, and 29.1% over age 65 have hearing impairments (Ries, 1994). The number of people with hearing impairments will increase with the increasing age of the population and the increase in the severity of noise exposure.

Hearing impairment may be sensorineural or conductive. *Sensorineural hearing loss* involves damage to the auditory pathways within the central nervous system, beginning with the cochlea and auditory nerve and including the brain stem and cerebral cortex (this prevents or disrupts interpretation of the auditory signal). *Conductive hearing loss* is damage to the outer or middle ear, which interferes with sound waves reaching the cochlea. Causes of both types of hearing loss include heredity, infections, tumors, accidents, and aging (presbycusis, or "old hearing") (Schein, 1981).

### 7.2.1 Functional Limitations Caused by Hearing Impairments

The primary difficulty for people with hearing impairment in using standard products is receiving auditory information. This problem can be compensated for by presenting auditory information redundantly in visual and/or tactile form. If this is not feasible, an alternative solution to this problem would be to provide a mechanism, such as a jack, which would allow the user to connect alternative output devices. Increasing the volume range and lowering the frequency of products with high-pitched auditory output would be helpful to some less severely impaired persons. (Progressive hearing loss usually occurs in higher frequencies first.)

Basic voice input is now becoming more widespread as a feature of mobile and smartphones and may be extended to more commercial products in the future as the technology advances. This, too, will present a problem for many deaf persons. Whereas many have some residual speech, which they work to maintain, those who are deaf from birth or a very early age often are also nonspeaking or have speech that cannot be

recognized using current voice input technology. Thus, alternatives to voice input will be necessary for these people to access voice input products.

Familiar coping strategies for hearing-impaired people include the use of hearing aids, sign language, lip reading, TDDs (telecommunication devices for the deaf), and text communication (e.g., instant messaging, text messaging, and real-time text). Some hearing aids are equipped with a T-coil as well, which provides direct inductive coupling with a second coil (such as in a telephone receiver) to reduce ambient noise. Some other commercial products could make use of this capability. ASL (American Sign Language) is commonly used by people who are deaf. It should be noted, however, that this is a completely different language from English. Thus, deaf people who primarily use ASL may understand English only as a second language and may therefore not be as proficient with English as are native speakers. TDDs used to be the major mechanism for communication over the phone. These have largely been replaced by the use of SMS text messaging on mobile phones and instant messaging on computers. As we move to telephony via Voice over Internet Protocol (VoIP), real-time text can be built directly into any phone with a display—opening up text communication on almost any device used for voice telecommunication.

## 7.3 Physical Impairments

### 7.3.1 Functional Limitations Caused by Physical Impairments

Problems faced by people with physical impairments include poor muscle control, weakness and fatigue, difficulty walking, talking, seeing, speaking, sensing, or grasping (due to pain or weakness), difficulty reaching things, and difficulty doing complex or compound manipulations (push and turn). People with spinal cord injuries may be unable to use their limbs and may use mouth- or headsticks for most manipulations. Some people may not be able to perform simultaneous actions. Twisting motions may be difficult or impossible for people with many types of physical disabilities (including cerebral palsy, spinal cord injury, arthritis, multiple sclerosis, and muscular dystrophy).

Some people with severe physical disabilities may not be able to operate even well-designed products

directly. They usually must rely on assistive devices that take advantage of their specific abilities and standard products that are compatible with or can be used with their assistive devices. Commonly used assistive devices include mobility aids (e.g., crutches, wheelchairs), manipulation aids (e.g., prosthetics, orthotics, reachers), communication aids (e.g., single switch-based artificial voice), and computer–device interface aids (e.g., eyegaze-operated keyboard).

## 7.3.2 Nature and Causes of Physical Impairments

Neuromuscular impairments include:

- Paralysis (total lack of muscular control in part or most of the body)
- Weakness (paresis; lack of muscle strength, nerve enervation, or pain)
- Interference with control, via spasticity (where muscles are tense and contracted), ataxia (problems in accuracy of motor programming and coordination), and athetosis (extra, involuntary, uncontrolled, and purposeless motion)

*Skeletal impairments* include joint movement limitations (either mechanical or due to pain), small limbs, missing limbs, or abnormal trunk size. Some major causes of these impairments are described next.

**Arthritis**   Arthritis is defined as pain in joints, usually reducing range of motion and causing weakness. Rheumatoid arthritis is a chronic syndrome. Osteoarthritis is a degenerative joint disease. It was estimated that, in 1990, 38 million people in the United States had some form of arthritis or rheumatic condition. That number is expected to increase to 59 million by the year 2020 (Lawrence et al., 1998).

**Cerebral Palsy (CP)**   Cerebral palsy is defined as damage to the motor areas of the brain prior to brain maturity (most cases of CP occur before, during, or shortly following birth). Annually the incidence of CP is between 2.0 and 2.5 of every 1000 live births (Odding et al., 2006). CP is a type of injury, not a disease (although it can be caused by a disease), and does not get worse over time; it is also not "curable." Some causes of CP are problems with fetal development, lack of oxygen, and injuries related to preterm birth (Pellegrino, 2002). The most common types are (1) spastic, where a person moves stiffly and with difficulty; (2) ataxic, characterized by a disturbed sense of balance and depth perception; and (3) athetoid, characterized by involuntary, uncontrolled motion. Most cases are combinations of the three types.

**Spinal Cord Injury**   Spinal cord injury can result in paralysis or paresis (weakening). The extent of paralysis or paresis and the parts of the body affected are determined by how high or low on the spine the damage occurs and the type of damage to the cord. Quadriplegia involves all four limbs and is caused by injury to the cervical (upper) region of the spine; paraplegia involves only the lower extremities and occurs where injury was below the level of the first thoracic vertebra (mid-lower back). There are 229,000–306,000 people with spinal cord injuries in the United States, with 12,000–15,000 new cases projected annually (Foundation for Spinal Cord Injury Prevention, Care and Cure, 2009; Wyndaele and Wyndaele, 2006). Car accidents are the most frequent cause (42%), followed by falls and jumps (27%), gunshot wounds or other violent acts (15%), and sports and recreational injuries (7.6%) (Foundation for Spinal Cord Injury Prevention, Care and Cure, 2009).

**Traumatic Brian Injury (TBI)**   The term *head injury* is used to describe a wide array of injuries, including concussion, brain stem injury, closed head injury, cerebral hemorrhage, depressed skull fracture, foreign object (e.g., bullet), anoxia, and postoperative infections. Like spinal cord injuries, head injury and stroke often result in paralysis and paresis, but there can be a variety of other effects as well. Annually, about 1.7 million Americans sustain a traumatic brain injury. However, many of these are not disabled permanently or severely; nearly 80% are treated and released from an emergency department (Faul et al., 2010)

**Stroke (Cerebral Vascular Accident; CVA)**   The three main causes of stroke are thrombosis (blood clot in a blood vessel blocks blood flow past that point), hemorrhage (resulting in bleeding into the brain tissue; associated with high blood pressure or rupture of an aneurism), and embolism (a large clot breaks off and blocks an artery). Worldwide, it is the second most common cause of death and a major cause of disability (Donnan et al., 2008). The response of brain tissue to injury is similar whether the injury results from direct trauma (as above) or from stroke. In either case, function in the area of the brain affected either stops altogether or is impaired (Anderson, 1981).

**Loss of Limbs or Digits (Amputation or Congenital)**   This may be due to trauma (e.g., explosions, mangling in a machine, severance, burns) or surgery (e.g., due to cancer, peripheral arterial disease, diabetes). Usually, prosthetics are worn, although these do not result in full return of function. There are approximately 1.6 million persons living with the absence of a limb in the United States. Annually, approximately 185,000 Americans undergo an amputation of a limb (Ziegler-Graham et al., 2008).

**Parkinson's Disease**   This is a progressive disease of older adults characterized by muscle rigidity, slowness of movements, and a unique type of tremor. There is no actual paralysis. The usual age of onset is over 50 with increasing prevalence with age. Approximately 1% of the population over 60 and 4% of those over 80 have Parkinson's disease (de Lau and Breteler, 2006).

**Multiple Sclerosis (MS)**   Multiple sclerosis is defined as a progressive disease of the central nervous system characterized by the destruction of the insulating material covering nerve fibers. The problems these

patients experience include poor muscle control; weakness and fatigue; difficulty walking, talking, seeing, sensing, or grasping objects; and intolerance of heat. Onset is between the ages of 10 and 40. This is one of the most common neurological diseases, affecting 250,000–350,000 people in the United States alone (Anderson et al., 1992).

***ALS (Lou Gehrig's Disease)***    ALS (amyotrophic lateral sclerosis) is a fatal degenerative disease of the central nervous system characterized by slowly progressive paralysis of the voluntary muscles. The major symptom is progressive muscle weakness involving the limbs, trunk, breathing muscles, throat, and tongue, leading to partial paralysis and severe speech difficulties. This is an uncommon disease (with an estimated annual incidence of three to five cases per 100,000 people in the United States). It occurs mostly to those between ages 45 and 74 with men affected more often than women (Cronin et al., 2007).

***Muscular Dystrophy (MD)***    Muscular dystrophy is a group of hereditary diseases causing progressive muscular weakness; loss of muscular control; contractions; and difficulty in walking, breathing, reaching, and use of hands involving strength.

## 7.4   Cognitive/Language Impairments

### 7.4.1   Functional Limitations Caused by Cognitive/Language Impairments

The type of cognitive impairment can vary widely, from severe retardation to inability to remember, to the absence or impairment of specific cognitive functions (most particularly language). Therefore, the types of functional limitations that can result also vary widely.

Cognitive impairments are varied but may be categorized as memory, perception, problem solving, and conceptualizing disabilities. Memory problems include difficulty getting information from short-term, long-term, and remote memory. This includes difficulty recognizing and retrieving information. Perception problems include difficulty taking in, attending to, and discriminating sensory information. Difficulties in problem solving include recognizing the problem; identifying, choosing, and implementing solutions; and evaluation of outcome. Conceptual difficulties can include problems in sequencing, generalizing previously learned information, categorizing, cause and effect, abstract concepts, comprehension, and skill development. Language impairments can cause difficulty in comprehension and/or expression of written and/or spoken language.

There are very few assistive devices for people with cognitive impairments. Simple cuing aids or memory aids are sometimes used. As a rule, these people benefit from use of simple displays; low language loading; use of patterns; simple, obvious sequences; and cued sequences.

### 7.4.2   Types and Causes of Cognitive/Language Impairments

***Intellectual Disability***    A person is considered to have an intellectual disability if he or she has an IQ below 70 (average IQ is 100) and if they have difficulty functioning independently. The prevalence of intellectual disabilities is estimated at 0.87% in the United States (Larson et al., 2001), meaning that in 2010 there were approximately 2.6 million Americans with intellectual disabilities For most, the cause is unknown, although infections, Down syndrome, premature birth, birth trauma, or lack of oxygen may all cause intellectual disabilities. Those with mild intellectual disability have an IQ between 55 and 69 and achieve the fourth- to seventh-grade levels in education. They usually function well in the community and hold semiskilled and unskilled jobs. People with moderate intellectual disability have an IQ between 40 and 54 and are trainable in educational skills and independence. They can learn to recognize symbols and simple words, achieving approximately a second-grade level. They often live in group homes and work in sheltered workshops.

***Language and Learning Disabilities***    Aphasia, an impairment in the ability to interpret or formulate language symbols as a result of brain damage, is frequently caused by left cerebral vascular accident (stroke) or head injury. Specific learning disabilities are chronic conditions of presumed neurological origin that interfere selectively with the development, integration, and/or demonstration of verbal and/or nonverbal abilities. Aside from their specific learning disability, many people with learning disabilities are highly intelligent. Approximately 8% of children age 6–11 years have learning disabilities (Pastor and Reuben, 2002).

***Age-Related Disease***    Alzheimer's disease is a degenerative disease that leads to progressive intellectual decline, confusion, and disorientation. Dementia is a brain disease that results in the progressive loss of mental functions, often beginning with memory, learning, attention, and judgment deficits. The underlying cause is obstruction of blood flow to the brain. Some kinds of dementia are curable, whereas others are not.

## 7.5   Seizure Disorders

A number of injuries or conditions can result in seizure disorders. Epilepsy is a chronic neurological disorder. It is reported that approximately 150,000 children and adolescents will be medically evaluated because of seizures each year. Of these, approximately 30,000 will be diagnosed with epilepsy (Hauser, 1994). A seizure consists of an explosive discharge of nervous tissue, which often starts in one area of the brain and spreads through the circuits of the brain like an electrical storm. The seizure discharge activates the circuits in which it is involved, and the function of these circuits will determine the clinical pattern of the seizure. Except at those times when this electrical storm is sweeping through it, the brain is working perfectly well in a person with epilepsy. Seizures can vary from momentary loss of attention to grand mal seizures, which result in the severe loss of motor control and awareness. Seizures can be triggered in people with photosensitive epilepsy by rapidly flashing lights, particularly in the range 10–25 Hz (Harding and Jeavons, 1994).

### 7.6 Multiple Impairments

It is common to find that whatever caused a single type of impairment also caused others. This is particularly true where disease or trauma is severe or in the case of impairments caused by aging. Deaf blindness is one commonly identified combination. Most of these people are neither profoundly deaf nor legally blind but are both visual and hearing impaired to the extent that strategies for deafness or blindness alone will not work. People with developmental disabilities may have a combination of mental and physical impairments that result in substantial functional limitations in three or more areas of major life activity. Diabetes, which can cause blindness, also often causes loss of sensation in the fingers. This makes braille or raised lettering impossible to read. Cerebral palsy is often accompanied by visual impairments, by hearing and language disorders, or by cognitive impairments.

### 8 USER NEEDS–BASED APPROACH

It can be very difficult to keep track of the myriad of disabilities when practicing universal design. Using the framework of user needs allows a different view of the design problem. Instead of trying to keep track of all the different disabilities and things they need, the practitioner can consider three general needs that all users have (users need to be able to perceive, operate, and understand) with one additional need that applies only to some people with disabilities (compatibility with their assistive technology).

**Perceive**   People must be able to perceive all of the controls, operation feedback, and information that is displayed either passively or dynamically that is necessary to use the product. People must be able to find and refind all of the controls and perceive their status (e.g., the state of an on/off control or position and setting of a dial). Displayed information includes dynamic information on a screen, labels, instructions, printed output, and manuals and may be provided visually or through audio (usually speech).

**Operate**   People must be able to safely invoke and carry out all of the functions of a product within the time allowed and with equivalent privacy and security to other users. While the time allowed may be time limits that are imposed by a system, they are also time imposed by efficiency, competition, or productivity requirements. Everybody needs to be able to operate a device safely, and some disabilities may pose an additional risk to injury if people have difficulty seeing, moving, or changing their behavior to avoid potential seizures or physical injury.

**Understand**   People must be able to understand both how to use a product and all the output and displayed information. If there are helpful features or an access mode that a person needs to activate to use the product, they need to be able to discover the features and activate them.

**Assistive Technology (AT) Compatibility**   Unless direct, cross-disability access is built into a product, a person must be able to use their assistive technology with the product. With personal-use products, people may still prefer to be able to use their assistive technology rather than the built-in access.

An overview of all user needs organized in this fashion is available in Vanderheiden (2009a) or in ISO/IEC (2009a). For this chapter, we have chosen to organize the design guidelines by component to aid its use as a handbook for active designers.

### 9 DESIGN GUIDELINES

To facilitate use by product design teams, this section is organized by the functionality of products and user needs rather than by disability area. Functional categories are as follows:

- *Output/displays:* includes all means of presenting information to the user
- *Input/controls:* includes keyboards and all other means of communicating to the product
- *Manipulations:* includes all actions that must be performed directly by a person in concert with the product or for routine maintenance (e.g., inserting disk, loading tape, changing ink cartridge)
- *Documentation:* primarily operating instructions
- *Safety:* includes alarms and protection from harm

Each guideline is phrased as an objective, followed by a statement of the problem(s) faced by people with disabilities. The problem statement is accompanied by more specific examples. Next, design options are presented to provide some suggestions as to how the objective could be achieved. The guidelines are stated as generically as possible. Therefore, all, some, or none of the design options and ideas presented may apply in the case of any specific product. The recommended approach is to implement those options that together go the farthest toward achieving the objective of the guideline for your product. It is understood that this is not an ideal world, so it may currently be too expensive to implement all those ideas that would best achieve the objective. It is also anticipated that there will be other ways of meeting accessibility objectives than those discussed here, and such discoveries are encouraged.

### 9.1 Output/Displays

Maximize the number of people who can/will . . .

O-1 hear auditory output clearly enough (Perceive).

O-2 not miss important information if they cannot hear (Perceive).

O-3 have a line of sight to visual output and reach printed output (Perceive).

O-4 see visual output clearly enough (Perceive).

O-5 not miss important information if they cannot see (Perceive).

O-6 understand the output (visual, auditory, other) (Understand).

O-7 view the output display without triggering a seizure (Operate).

### 9.1.1 O-1 Maximize the Number of People Who Can Hear Auditory Output Clearly Enough (Perceive)

**Problem** Information presented auditorily (e.g., synthesized speech, cuing and warning beeps, buzzers, tones, machine noises) may not be heard effectively.

*Example*: People who have mildly to moderately impaired hearing may not be able to discern sounds that are too low in volume. People who have mild hearing impairments may be unable to turn the volume up sufficiently in some environments (e.g., libraries, where others would be disturbed, or in noisy environments, where even the highest volume is insufficient). People with moderate hearing impairments are often unable to hear sounds in higher frequencies (above 2000 Hz) (Hunt, 1970). People with hearing aids may have difficulty separating background noise from the desired auditory information. People with cognitive impairments may easily be distracted by too much background noise. Auditory information that is short or not repeated or repeatable (e.g., a short beep or voice message) may be missed or not understood.

*Note*: Severely hearing impaired (and deaf) people cannot use audio output at all. See Section O-2 for guidelines to address this problem.

### Design Options and Ideas to Consider

- Providing a volume adjustment, preferably using a visual volume indicator; sound should be intelligible (undistorted) throughout the volume range
- Providing automatically adjusted volume that is relative to the environmental noise level
- Making audio output (or volume range if adjustable) as loud as practical
- Using sounds that have strong middle- to low-frequency components (500–3000 Hz)
- Providing alerts and other auditory warnings that include at least two strong middle- to low-frequency components, with recommended ranges of 300–750 Hz for one component and 500–3000 Hz for the other (Berkowitz and Casali, 1990)
- Providing adjustable pitch for tones and sounds and selectable voices for speech
- Providing a headphone jack to enable a person with impaired hearing to listen at high volume without disturbing others, to enable such a person to isolate themselves effectively from background noise, and to facilitate use of neck loops and special amplifiers (Figures 5 and 6)
- Providing a separate volume control for the headphone jack so that people without hearing impairments can listen as well (at standard listening levels)
- When a headphone jack is not possible:
  - Placing the sound source on the front of the device and away from loud mechanisms would facilitate hearing.

- Locating the speaker on the front of the device would also facilitate use of a small microphone and amplifier to pick up and present the information (via speaker, neck loop, or vibrator).
- Facilitating direct use of the telecoil in hearing aids by incorporating a built-in inductive loop in a product (e.g., in telephone receiver's earpiece)
- Reducing the amount of unmeaningful sound or background noise produced by the product
- Having a warning beep precede the message to allow people to attend
- Using a male (lower) voice for speech synthesis
- Providing control of speech rate or speed
- Repeating the message or providing a mechanism for users to have the message repeated
- Providing methods for pausing, rewinding, and repeating speech
- Presenting auditory information continuously or periodically until the desired message is confirmed or acted upon

**Figure 5** A neck ring or ear loop can be plugged into a headphone jack on an audio source and provide direct inductive coupling between the audio source and a special induction coil on a person's hearing aid. This cuts out background noise that would be picked up by the hearing aid's microphone and provides clearer reception of the audio signal.

**Figure 6** A headphone jack permits the connection of headphones, neck/ear loops, amplifiers, or sound indication lights.

### 9.1.2 O-2 Maximize the Number of People Who Will Not Miss Important Information If They Cannot Hear (Perceive)

**Problem** Audio output (e.g., synthesized speech, cuing and warning beeps, buzzers, tones) may not be heard at all or may be insufficient for communicating information effectively.

*Example*: People who are severely hearing impaired or deaf may not hear audio output, even at high volume and low frequencies (Figure 7). People with language or cognitive impairments may not be able to respond to information given only in auditory form. (This may also be true if the language used is not a person's primary language.) People who are deaf-blind may not hear audio output. People with unimpaired hearing must sometimes use products in environments where the sound must be turned off (e.g., libraries) or where the environment is too noisy to hear any sound output reliably.

#### Design Options and Ideas to Consider

- Providing all important auditory information in visual form as well (or having it available; includes any speech output as well as auditory cues and warnings)
- Providing a tactile indication of auditory information (e.g., vibrating alarms)
- Facilitating the connection or use of tactile aids
- Providing an optional remote audio/visual or tactile indicator

### 9.1.3 O-3 Maximize the Number of People Who Will Have Line of Sight to Visual Output and Reach Printed Output (Perceive)

**Problem** Visual displays or printouts may be unreadable due to their placement.

*Example*: People who are in a wheelchair or who are extremely short may be unable to read displayed information due to the physical placement or angle of the display screen. People in wheelchairs, with missing or paralyzed arms, or with the ability to move limited by cerebral palsy or disease (e.g., severe arthritis, MS, ALS,

muscular dystrophy) may be unable to reach printed output (e.g., receipts produced by an automatic teller machine), due to printer placement.

#### Design Options and Ideas to Consider

- Locating display screens so they are readable from varying heights, including a wheelchair (see Section I-1 for specific anthropomorphic data and Section O-4 regarding image height)
- Locating printed output within easy reach of those who are in wheelchairs
- Facilitating manipulation of printouts by reaching and grasping aids
- Providing displays that can be adjusted in angle or height
- Providing redundant audio output in addition to visual display if the visual display cannot be made physically accessible to a person in a wheelchair (see Section O-5)

### 9.1.4 O-4 Maximize the Number of People Who Can See Visual Output Clearly (Perceive)

**Problem** Visual output (e.g., information presented on screens, paper printouts, cuing and warning lights or dials) may not be seen effectively.

*Example*: People who are visually impaired may not be able to see output that is too small. Those who are visually impaired may have difficulty discerning complex typefaces or graphics. People who are color blind may not be able to differentiate between certain color pairs. People with poor vision have more difficulty seeing letters or pictures against a background of similar hue or intensity (low contrast). People with visual impairments may be much more sensitive to glare (Figure 8). Those who have visual impairments may not be able to see detail in low lighting. Some people with severe lack of head control (e.g., cerebral palsy) may not be able to maintain continuous eye contact with a display and therefore may miss portions of dynamic (i.e., moving, changing) displays.

See Section O-5 for guidelines for people who cannot use visual output at all and Section O-6 for problems in understanding displayed output.

**Figure 7** (*a*) Hearing loss as a function of age; (*b*) recommended frequency for alerting devices. [(*a*) From Schow et al., 1978; (*b*) based on Hunt, 1970, and Berkowitz and Casali, 1990.]
**Figure 8** Ability to tolerate glare decreases sharply as a function of age. Data are based on a 1° glare source size and a background luminance of 1.6 foot-lamberts. (From Bennet, 1977.)

### Design Options and Ideas to Consider

- Making letters and symbols on visual output as large as possible or practical
- Using upper- and lowercase type (title or sentence case) to maximize readability
- Making sure that letter spacing, the space between lines (leading), and the distance between messages are sufficient that the letters and messages stand out distinctly from each other
- Providing zoom or adjustable display image size
- Providing a video jack for attaching larger image displays or utilizing special assistive devices (e.g., electronic magnifiers)
- Using high contrast between text, graphics, user interface elements, and background
- Keeping letters and symbols on visual output as simple as possible; using sans serif typefaces for non-body-text lettering (e.g., labels, dials, displays) (see Section D-1)
- Using only black and white or using colors that vary in intensity or luminosity so that the color itself carries no information
- Providing adjustable color selection (hue and/or intensity)
- Replacing or supplementing color coding with different shape or relative position coding
- Providing contrast and/or brightness adjustment
- Minimizing glare (e.g., by employing filtering devices on display screens and/or avoiding shiny surfaces and finishes)
- Providing the best possible lighting for displays or areas containing instrumentation (good even illumination without hot spots and brighter than background illumination)
- Providing adjustable speed for dynamic displays (so they can be slowed down for those who lack motor control of their head and who must read with repeated glances)

- Avoiding use of light blue color to convey important information (harder for aging eyes to perceive as they yellow)
- Increasing contrast on liquid crystal displays (LCDs) by allowing user to adjust viewing angle
- Providing a pause control for text or other information that moves or scrolls

### 9.1.5  O-5 Maximize the Number of People Who Will Not Miss Important Information If They Cannot See (Perceive)

**Problem**  Visual output (e.g., information presented on screens, paper printouts, cuing and warning lights, and dials) may not be seen at all by some users.

*Example*: People who are severely visually impaired or blind may not be able to see visual output, even when magnified and clarified (as recommended in Section O-4). People who cannot read may be unable to use visually presented text. People who are deaf and blind may only be able to perceive tactile output. People who do not have any visual impairment may miss warnings, cues, or other information if it is presented only in visual form while their attention is diverted.

### Design Options and Ideas to Consider

- Providing all important visual information (redundantly) in audio and/or tactile form.
- Accompanying visual cues and warnings by a sound, one component of which is of middle to low frequency (500–3000 Hz) (see Section O-1)
- Making information that is displayed visually (both text and graphics) also available electronically at an external connection point (standard or special port) to facilitate the use of special assistive devices (e.g., voice synthesizers, braille printers), preferably in an industry or company standard format (see Figure 16)

### 9.1.6  O-6 Maximize the Number of People Who Can Understand the Output (Visual, Auditory, Other) (Understand)

**Problem**  Visual and/or auditory output may be confusing or difficult to understand.

*Example*: Some people with specific learning disabilities or with reduced or impaired cognitive abilities are easily confused by complex screen layouts (e.g., multiple "windows" of information), have difficulty understanding complex or sophisticated verbal (printed or spoken) output, or have a short attention span and are easily distracted when reviewing a screen display. For many people who are deaf as well as many other U.S. citizens, English is a second language and not well understood. People who are using a device in an alternate mode (e.g., speech output mode on a kiosk) may not understand instructions that are meant for people using the primary mode.

### Design Options and Ideas to Consider

- Using simple screen layouts
- Providing the user with the option to look at one thing at a time

- Shortening menus
- Hiding (or layering) seldom used commands or information
- Keeping language as simple as possible
- Accompanying words with pictures or icons (Note, however, that the use of graphics may present more difficulty for people who are blind. See Section O-5.)
- Using Arabic rather than Roman numerals (i.e., 1, 2, 3 instead of I, II, III)
- Using attention-attracting (e.g., underlining, boldfacing) and grouping techniques (e.g., putting a box around things or color blocking) to emphasize important information
- Highlighting key information
- Putting most important information at the beginning of written text (but not spoken announcements, where it might be missed)
- Providing an attention-getting sound or words before audio presentation
- Keeping auditory presentations short
- If providing menu choices, always state the choice first and the action second (e.g., use, "For deposits, press 1." Do not use, "Press 1 for deposits.")
- Providing auto-repeat or a means to repeat auditory messages
- Presenting information in as many (redundant) forms as possible/practical (i.e., visual, audio, and tactile) or providing as many display options as possible
- Providing digital readouts for product-generated numbers where the numeric or precise value is important
- Providing dials or bar graphs where qualitative information is more important (e.g., half full, full) (See Sections I-4 and I-6)

### 9.1.7  O-7 Maximize the Number of People Who Can View the Output Display without Triggering a Seizure (Operate)

**Problem**  People with seizure sensitivities (e.g., epilepsy) may be affected by some dynamic animations and screen cursor or display update frequencies, increasing the chance of a seizure while working on or near a display screen.

### *Design Options and Ideas to Consider*

- Avoiding screen refresh or update flicker or flashing frequencies which are most likely to trigger seizure activity (Figure 9 provides a general overview of the frequencies most likely to trigger a seizure.)
- Avoiding flashing where there are more than three flashes within any 1-s period where the combined area of the flashing would occupy more than 25% of the central vision (central $10°$) (Harding and Jeavons, 1994)

**Figure 9**  Percentage of photosensitive patients in whom a photoconvulsive response was elicited by a 2-s train of flashes with the eyes open and closed. As can be seen, the greatest sensitivity is at 20 Hz, with a steep drop-off at higher and lower frequencies. (From Jeavons and Harding, 1975.)

- Following the guidelines established for the Web Content Accessibility Guidelines 2.0 (http://www.w3.org/TR/WCAG20/#seizure), which allow exceptions to the general guideline of three flashes in 1 s for small or weak flashing, as well as other guidance on this

For the general flash threshold, a flash is defined as a pair of opposing changes in luminance (i.e., an increase in luminance followed by a decrease, or a decrease followed by an increase) of 20 candelas per rectangle meter ($cd/m^2$) or more and where the screen luminance of the darker image is below 160 $cd/m^2$. For the red flash threshold, a flash is defined as any pair of opposing transitions to or from a saturated red at any luminance level.

*Note*: Video waveform luminance is not a direct measure of display screen brightness. Not all display devices have the same gamma characteristic, but a display with a gamma value of 2.2 may be assumed for the purpose of determining electrical measurements made to check compliance with these guidelines. For the purpose of measurements made to check compliance with these guidelines, pictures are assumed to be displayed in accordance with the home viewing environment described in the International Telecommunication Union recommendation ITU-R BT.500, in which peak white corresponds to a screen illumination of 200 $cd/m^2$. Specifications are based on "ITC Guidance Note for Licensees on Flashing Images and Regular Patterns in Television" (revised and reissued in July 2001).

### 9.2  Input/Controls

Maximize the number of people who can . . .

I-1 reach the controls (Operate).

I-2 find the individual controls/keys if they cannot see them (Perceive).

I-3 read the labels on the controls/keys (Perceive).

I-4 determine the status or setting of the controls if they cannot see them (Perceive).

I-5 physically operate controls and other input mechanisms (Operate).

I-6 understand how to operate controls and other input mechanisms (Understand).

I-7 connect special alternative input devices (AT Compatibility).

### 9.2.1  I-1 Maximize the Number of People Who Can Reach the Controls (Operate)

**Problem**  Controls, keyboards, and so on, may be unreachable or unusable.

*Example*: People who use a wheelchair, who are very weak, or who are extremely short may be unable to reach some controls, keypads, and so on, well enough to use them. People with poor motor control may be able to reach the controls but may find the knobs, buttons, and so on, too small or close together to operate accurately. People with severe weakness may be able to reach the controls but may find the act of reaching or holding position in order to manipulate the controls too tiring.

#### Design Options and Ideas to Consider

- Locating controls, keyboards, and so on, so they are within easy reach of those who are in wheelchairs or have limited reach
- Locating controls so that the user can reach and use them with the least change in body position
- Locating controls that must be used constantly in the closest positions possible and where there is wrist or arm support
- Using keys with smaller radiuses of curvature (with sharper edges)
- Providing a (redundant) speech recognition input option
- Offering remote controls (wired, wireless, or bus operated)

### 9.2.2  I-2 Maximize the Number of People Who Can Find the Individual Controls/Keys If They Cannot See Them (Perceive)

**Problem**  People with visual impairments may be unable to find controls.

*Example*: People who are severely visually impaired may be unable to locate controls tactilely because they are on a flat membrane or glass panel (e.g., calculators, microwave ovens) or because they are placed too close together or in a complicated arrangement. People who have diabetes may have both visual impairments and failing sensation in fingertips, making it difficult to locate controls that have only subtle tactile cues.

#### Design Options and Ideas to Consider

- Varying the size of controls (also texture or shape), with the most important controls being larger to facilitate their location and identification
- Using keys, buttons, and controls that are raised or project from the background

- Providing controls whose shapes are associated with their functions
- Providing sufficient space between controls for easy tactile location and identification as well as easier labeling (large print or braille)
- Using keys with small radius of curvature on edges (sharper edges)
- Locating controls adjacent to what they control
- Using standard control arrangements (e.g., telephone number arrangement, direction pad)
- Making layout of controls logical and easy to understand, to facilitate tactile identification (e.g., stove burner controls in corresponding locations to actual burners)
- Providing a raised lip or ridge around flat (membrane or glass) panel buttons
- Providing a redundant speech recognition input option

See Figures 10 and 11.

### 9.2.3  I-3 Maximize the Number of People Who Can Read the Labels on the Controls/Keys (Perceive)

**Problem**  Labels on controls, keys, and so on, are difficult or impossible to see, due to their size, color, or location.

*Example*: People with low vision may have difficulty identifying controls or keys on a keyboard because the label lettering is too small and/or because the contrast between letters/graphics and background is poor. People with color blindness may have difficulty distinguishing controls that are color coded or use certain pairs of colors for labels and background. People with physical impairments may have difficulty reading labels on the sides or backs of objects. People who are blind may not be able to see printed labels at all.

#### Design Options and Ideas to Consider

- Making lettering used for labels as large as possible or practical
- Making sure that letter spacing, the space between lines (leading), and the distance between labels are sufficient so that the letters and labels stand out distinctly from each other
- Placing important labels or instructions on the front or an easily accessible side of large or stationary devices, where they can be read from wheelchairs
- Using sans serif fonts for non-body-text lettering (e.g., labels, dials)
- Using title case or all lowercase letters rather than all caps
- Using high contrast between letters/graphics and background
- Providing sufficient illumination of controls and instructions
- Providing backlit controls
Keypad on which bottom-edge views below are based.

A flat membrane or glass keypad provides no tactile indication as to where the keys are, even if one memorize the arrangement.

Providing a slight raised lip around the keys allows their location to be discerned easily by touch. The ridge around the key also helps prevent slipping off of the key when using a mouthstick, reacher, etc., to press the keys.

Raised bumps are tactilely discernable, but it is harder to press the key without slipping off, particularly if you are using a mouthstick, reacher, or other manipulative aid unless there is a flat on top of the key,

Using indentations or hollows on the touchpad provides most of the advantage of ridges but is easier to clean. Hollows can be the same size as the key or of a consistent small circular size centered on the keys. Shallow edges, such as those on the left button, are harder to sense with fingers than the sharper curve of the middle button.

Raised keys with indents provide better feedback than just indents (as in example above), especially if the keys have different shapes or textures that correspond to their functions.

**Figure 10** The shape of a key or button can have a significant effect on people's ability to accurately locate and operate it.

- Supplementing color coding with use of different button/key shape or letter/graphic labels
- Providing tactile labels
- Avoiding use of blues, greens, and violets to encode information (since the yellowing of the cornea with age can cause confusion with some shades of these colors)
- Using easily interchangeable keycaps to allow replacement with special or optional keycaps
- Arranging controls in groupings that facilitate tactile identification (e.g., using small groups of keys that are separated from the other keys, or placing frequently used keys near tactile landmarks such as along the edges of a keyboard)
- Using established or standard layouts for keypads and keyboards (e.g., typewriter, adding machine, phone)
- Using voice output to speak the names of keys or buttons as they are pressed (This capability would need to be turned on and off as needed.)

- If a flat membrane panel cannot be avoided, providing a stick-on tactile overlay that provides tactile demarcation of the key locations and functions

See Sections O-4 and O-6 for related guidelines for output/displays.

### 9.2.4 I-4 Maximize the Number of People Who Can Determine the Status or Setting of the Controls If They Cannot See Them (Perceive)

**Problem** Determination of control status or setting may depend solely on vision.

*Example*: People with visual impairments may be unable to see a control setting or on/off indicator (e.g., where a dial is set, whether a button is pushed in, whether a light is on, flashing or off, or what a numeric setting on a visual display reads).

### Design Options and Ideas to Consider

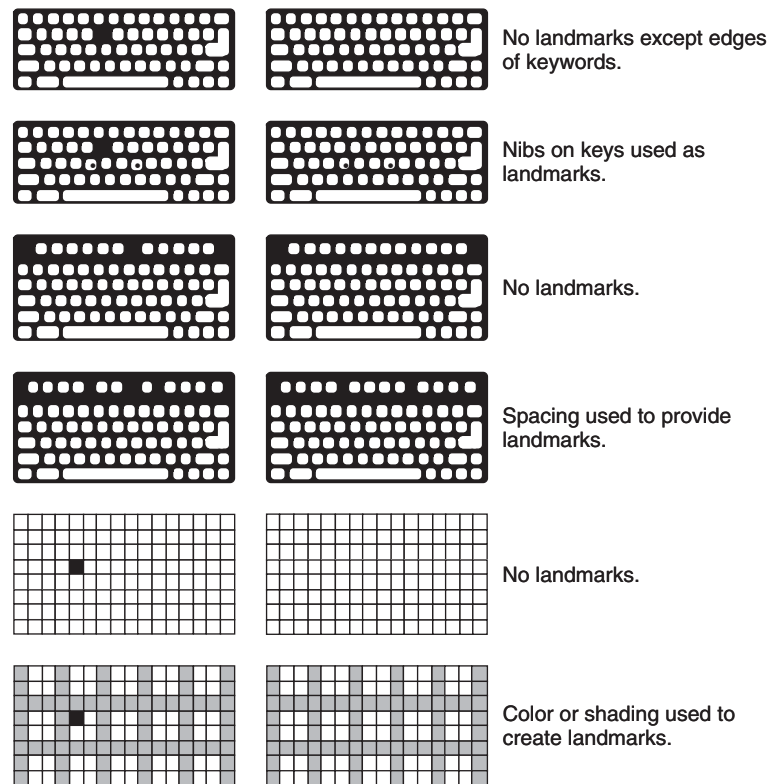
- Providing multisensory indication of the separate divisions, positions, and levels of the controls


**Figure 11**   Quick self-demonstration of the impact of landmarks on key finding by people who cannot see labels on a key due to blindness or very low vision. *Instructions*: For each keyboard, visually locate the key on the right-hand keyboard that corresponds to the key marked on the left. Note the increase in speed and accuracy when landmarks (nibs or breaks in the key patterns) are provided.

(e.g., use of detents or clicks to indicate center position or increments, raised lines)
- Using absolute reference controls (e.g., pointers) rather than relative controls (e.g., pushbuttons to increase/decrease, or round, unmarked knobs)
- Using moving pointers with stationary scales
- Providing multisensory indications of control status (e.g., in addition to a status light indicating "on," provide an intermittent audible tone and/or tactilely discernable vibration)
- Using direct keypad input
- Providing speech output to read or confirm the setting

See Sections O-3, O-4, and O-5 for design options covering visual displays. See Figures 12 and 13.

### 9.2.5   I-5 Maximize the Number of People Who Can Physically Operate Controls and Other Input Mechanisms (Operate)

**Problem**   Controls (or other input mechanisms) may be difficult or impossible for those with physical disabilities to operate effectively.

*Example*: People with severe weakness may be unable to operate controls at all or may have great difficulty performing constant, uninterrupted input. People with only one arm or without arms (but utilizing assistive devices such as headsticks or mouthsticks) may not be able to activate multiple controls or keys at the same time. People with artificial hands or reaching aids may have difficulty grasping small knobs or operating knobs or switches which require much force. People with poor coordination or impaired muscular control have slower or irregular reaction times, making time-dependent input unreliable. People lacking fine movement control may be unable to operate controls requiring accuracy (e.g., a mouse or joystick) or twisting or complex motions. People with limited movement control (including tremor, poor coordination, or those using headsticks or mouthsticks) can inadvertently bump extra controls on their way to a nearby desired control.

### Design Options and Ideas to Consider

- Minimizing the need for strength by minimizing force required as much as possible or by providing adjustable force on mechanical controls
- No nonvisual indication of setting. If vision blurred, one cannot tell setting.

- Difficult to put large print or braille labels on knob.

- Harder to grasp and requires twisting motion.

- Highly visible raised pointer.

- Instant tactile indication of orientation allows setting to be read even if user is blind.

- Easy to put larger-print or braille labels on back panel.

- Use of detents (large and small) can facilitate internumeral settings.

- Black base disk provides high contrast and helps in control location/orientation on panel.

- Design is also easy to grasp and can be turned by pushing the point around — no twisting if the knob turns freely enough.

FOR EXAMPLE: What are the settings of the knobs below?

**Figure 12**  The design of a knob can greatly affect its usability by people with low vision or blindness.

POOR:
Round smooth knob,
no tactile orientation cue.

BETTER:
Has tactile orientation cue but
user has to feel around to find it.

BETTER:
Orientation cue is less
ambiguous. However, the user
must still feel the ends to be
sure which is the pointer end.

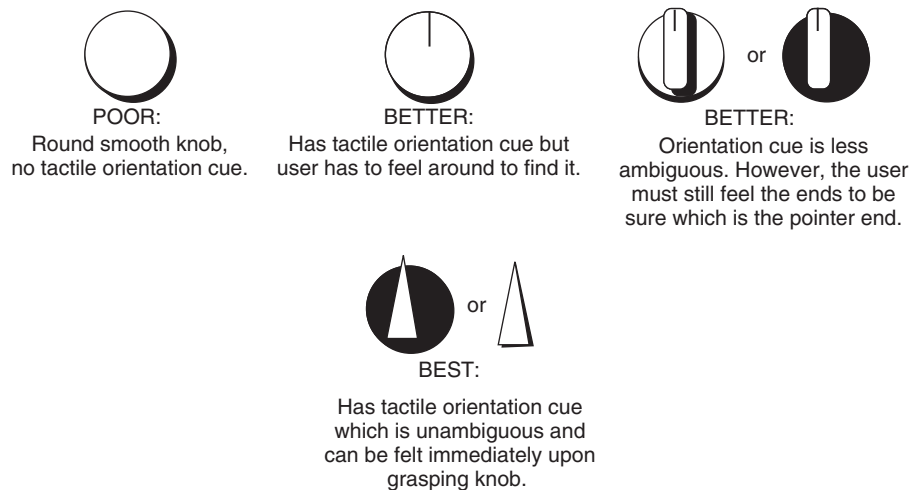
BEST:
Has tactile orientation cue
which is unambiguous and
can be felt immediately upon
grasping knob.


**Figure 13**  Knob and pointer design can have substantial effect on usability by people who are blind.

- If stiff resistance is provided to prevent accidental activation, it could drop off after activation. Other non-strength-related safety interlocks could also be considered.
- Spacing the controls to provide a guard space between controls, thus also leaving room for adaptations such as attaching levers to hard-to-turn knobs or room to replace knobs with larger, easier-to-turn knobs or cranks
- Minimizing or providing alternatives to performing constant, uninterrupted actions (e.g., button locks or push on–push off buttons to eliminate the need to press and hold some buttons continuously)
- Where simultaneous actions are required (e.g., pressing shift or control key while typing another key), providing an alternative method to achieve a result that does not require simultaneous actions (e.g., sequential option as in StickyKeys)
- Providing for operation with the left or right hand
- Using concave and/or nonslip buttons (see Figure 10 for a discussion), which are easier to use with mouthsticks or headsticks; on flat membrane keypads, providing a ridge around buttons
- If product requires a quick response (i.e., a reaction time of less than 5 s or release of a key or button in less than 1.5 s), allowing the user to adjust the time interval or to have a non-time-dependent alternative input method
- If product requires fine motor control, providing an alternative mechanism for achieving the same objectives that does not require fine motor control (e.g., on a mouse-based computer, provide a way to achieve mouse actions from the keyboard)
- Avoiding controls that require twisting or complex motions (e.g., push and turn) (*Note*: There are rotating knobs that can be turned by brushing the control with a hand and do not require twisting of the wrist.)
- Spacing, positioning, and sizing controls to allow manipulation by people with poor motor control or arthritis
- Where many keys must be located in close proximity, providing an option that delays the acceptance of input for a preset, adjustable amount of time (i.e., the key must be held down for the preset amount of time before it is accepted), thus helping some users who would otherwise bump and activate keys on the way to pressing their desired key (*Note*: This option must be difficult to invoke accidentally and be provided on request only, as it can have the effect of making the keyboard appear to be "broken" to naive users.)
- Making keyboards adjustable from horizontal ($0°–15°$ is standard) (Grandjean, 1987; Mueller, 1990)
- Providing an optional keyguard or keyguard mounting for keyboards
- Providing optional redundant voice control
- Providing textured controls and avoiding slippery surfaces/controls
- Providing means to stabilize body part used to operate the device (e.g., a wrist rest)

See Figure 14.

**Figure 14** People with arthritis, artificial hands, hooks, disabilities that restrict wrist rotation, or disabilities that cause weakness have difficulty with knobs or controls that require twisting. Such controls are also difficult to use for people with loss of upper body strength, range of motion, and flexibility, as is common with elderly persons. These really should be avoided in bathrooms where soap and water create a slippery environment. (Lever handles, now required in many building codes, facilitate access.)

### 9.2.6 I-6 Maximize the Number of People Who Can Understand How to Operate Controls and Other Input Mechanisms (Understand)

**Problem** The layout, labeling, or method of operating controls and other input mechanisms can be confusing or unclear.

*Example*: People with reduced or impaired cognitive function may be confused by complex, cluttered control layouts, with many and/or many types of controls; may have difficulty making selections from large sets; may have trouble remembering sequences (see also Section M-5); may be confused by dual-purpose controls; or may not relate appropriately to control settings indicated solely by notches/dots or numbers. People with reduced or impaired cognitive function, language impairments, and illiteracy or for whom English is a second language may have difficulty relying solely on textual labels, especially where abbreviations are used. They sometimes have difficulty making associations between label and control or may have trouble with timed responses involving text.

### Design Options and Ideas to Consider

- *Reducing the number of controls*
  - Limiting the number of choices where practical
  - Using layering of controls where only the most frequent or necessary controls or commands are visible unless you open a door or ask for additional levels of commands (e.g., hiding less frequently used controls, or at least grouping the most frequently used controls together and placing them prominently)
  - Where possible, making products automatic or self-adjusting, thus removing the need for controls (e.g., TV fine tuning and horizontal hold)
- *Simplifying the controls*
  - Minimizing dual-purpose controls
  - Using direct selection techniques where practical (selection techniques where the person need only make a single, simple, non-time-dependent movement to select)
  - Using visual/graphic indications for settings along with, or instead of, numbers or notches/dots (i.e., substitute concrete indications for abstract indications)
  - Reducing or eliminating lag/response times
  - Minimizing control or mode ambiguity
  - Providing a busy indicator or, preferably, a progress indicator when a product is busy and cannot take further input or when there is a delay before the requested action is taken
  - Integrating, grouping, and otherwise arranging controls to indicate function or sequence of operation

- *Making labels easy to understand*
  - Placing the label on or, less preferably, immediately adjacent to the control (does not apply to scales, which should not be on the controls but on the background)
  - Placing a line around the button and label (or from button to label) to show association (should be kept away from any lettering, especially if it is raised to avoid tactile confusion with the lettering)
  - Using simple concise language
  - Using redundant labeling (e.g., color code plus label)
  - Avoiding abbreviations in labeling (e.g., PrtScr, FF, C)
  - Leaving space around keys (makes it easier to match labels to keys and easier to add special labels)
  - Using multisensory presentation of feedback information
  - Providing labels on interinterval marks
- *Reducing, eliminating, or providing cues for sequences*
  - Allowing use of programmable function keys or using a "default" mode
  - Using preprogrammed buttons for common sequences
  - Allowing entry of a short code or scanning of a barcode to program a longer sequence
  - Simplifying required sequences, limiting the number of steps
  - Arranging controls to indicate sequence of operation
  - Adding memory cues or simple operating instructions on the device where possible
  - Cueing required sequences of action
  - Providing an easy exit that returns the user to the original starting point from any point in the program/sequence (exit should be prominent and clear)
  - Using wizards or step-by-step dialogues for a task sequence
- *Building on users' experiences (make the similarity obvious)*
  - Laying out controls to follow function
  - Making operation of controls follow movement stereotypes
  - Using common layouts or patterns for controls
  - Using common color-coding conventions in addition to textual or graphic labeling
  - Standardizing by using the same shape/color/icon/label for the same function or action (within and across products and manufacturers)

### 9.2.7 I-7 Maximize the Number of People Who Can Connect Special Alternative Input Devices (AT Compatibility)

**Problem** Standard controls (or other input mechanisms) cannot be made accessible for all of those with severe impairments.

*Example*: People with paralysis of their arms, severe weakness, tremor, or other severe physical impairments may not be able to use controls or input mechanisms that require the use of hands. People who are blind cannot use input devices that require constant eye–hand coordination and visual feedback (e.g., a standard computer mouse, trackball, or touch screen without special accommodation).

### *Design Options and Ideas to Consider*

- Providing a standard infrared remote control (e.g., audio/visual equipment)
- Providing alternative means for eye–hand coordination input devices (e.g., mice, trackballs,

relative joysticks) or allowing special devices to be substituted by the user, which will achieve as many of the functions as possible

- Using standard human interface device universal serial bus (USB) drivers and input so users can connect their own USB devices
- Providing tactile or auditory cues to allow direct use of touch pads or techniques to allow touch screens to function alternatively as auditory or tactile touch pads
- Providing a standard connection point (connector, infrared link, or wireless) for special alternative input devices (e.g., eyegaze keyboards, communication aids)
- Providing a network connection and accessible Web-based interface for control

See Figures 15 and 16.

**Figure 15** By using standard USB human interface driver protocols, it is possible for users who cannot use the standard keyboard and mouse to create ''authentic'' keystrokes and mouse movements with their own input devices. This would allow these people to access the computer and all of its software.

People who are blind or unable to read the displayed information could use an assistive device and have information presented in auditory or tactile (braille) form and to provide input to the terminal.

People who are unable to operate the standard controls could use an assistive device to control the terminal using an input system they can control (eyegaze, sip and puff, single-switch scanning, etc.).

- **Public information terminal**
- **Restaurant and hotel guide at airport**
- **Automated teller machine**
- **Electronic building directory**
- **Point-of-sale terminal**
- **Information or sales kiosk at airport or mall or other public information/transaction terminal**

**Figure 16** A wireless bidirectional link could provide a low-cost environment and vandal-resistant mechanism for connecting assistive devices to information, control, and transaction terminals.

## 9.3   Manipulations

This includes all actions that must be directly performed by a person in concert with the device or for routine maintenance (e.g., inserting disk, loading tape, changing ink cartridge)

Maximize the number of people who can ...

M-1 physically insert and/or remove objects as required to operate a device (Operate).

M-2 physically handle and/or open the product (Operate).

M-3 remove, replace, or reposition often-used detachable parts (Operate).

M-4 understand how to carry out the manipulation necessary to use the product (Understand).

### 9.3.1   M-1 Maximize the Number of People Who Can Physically Insert and/or Remove Objects as Required to Operate a Device (Operate)

**Problem**   Insertion and/or removal of objects required to operate some devices (e.g., removable media, USB flash drives, Blu-ray discs, DVDs, credit cards, keys, coins, currency) may be physically impossible. In addition, damage to the object or device can occur from unsuccessful attempts.

*Example*: People using mouthsticks or other assistive devices may have difficulty grasping an object and manipulating it as required to insert or retrieve it from the device. People with poor motor control may be unable to place a semifragile object accurately into the device and retrieve without damage (e.g., bending of a credit card). People with severe weakness may have difficulty reaching the slot or positioning the object for insertion or removal. People who are blind may be unable to determine proper orientation or alignment for insertion (e.g., hotel key card may be held upside down, backward, or at the wrong angle).

### Design Options and Ideas to Consider

- *Facilitating orientation and insertion*
  - Ensuring that objects can be inserted (and removed) with minimal user reach and dexterity
  - Providing a simple funneling system or other self-guidance/orienting mechanism that will position the object properly for insertion
  - Allowing receptacles to be repositioned or reangled to be more reachable
  - Whenever possible, allowing the object to be inserted in several ways (e.g., a six-sided wrench can be positioned on a mating bolt six different ways; two-sided keys can be inserted upside down)
  - Providing visual contrast between the insertion point and the rest of the device (making a more obvious "target")
  - Clearly marking the proper orientation both visually and tactilely

**Figure 17**   Mechanisms that eject items at least 1 in. and preferably 2 in. facilitate grasping the item with tools, reachers, teeth, or fists for those who cannot use their hands or fingers effectively.

- *Facilitating removal*
  - Providing ample ejection distance to facilitate easy gripping and removal (ejection distance as large as possible while retaining a stable ejection; see Figure 17)
  - Using pushbutton ejection or automatic (motorized) ejection mechanism
- *Facilitating handling*
  - Making objects to be inserted rugged and able to take rough handling
  - Using objects with high friction surfaces for ease in grasping

### 9.3.2   M-2 Maximize the Number of People Who Can Physically Handle and/or Open the Product (Operate)

**Problem**   Handles, doorknobs, drawers, trays, and so on, may be impossible for some people to grasp or open.

*Example*: People using mouthsticks or other assistive devices may be unable to grasp handles, doorknobs, and so on, in order to open or operate the product and may find it impossible to open doors or drawers without handles (e.g., those using recessed "lips" or those utilizing only side pressure to open). People with limited arm and hand movement (e.g., due to arthritis or cerebral palsy) may have problems grasping handles that are in-line (straight). People with only one hand or with poor coordination may have difficulty opening products that require two simultaneous actions (e.g., stabilizing while opening or operating two latches that spring closed).

### Design Options and Ideas to Consider

- Using doors with open handles, levers, or doors that are pushed, then spring open
- Avoiding use of knobs or lips to open products

- Avoiding dual latches that must be operated simultaneously
- Using latches that are operable with a closed fist
- Using bearings for drawers or heavy objects that must be moved
- Providing electric pushbutton or remote control power openers
- Shaping product and door handles, and so on, to minimize the need for bending the wrist or body
- Using components that can be operated with either hand

See Section I-5 for additional suggestions.

### 9.3.3   M-3 Maximize the Number of People Who Can Remove, Replace, or Reposition Often-Used Detachable Parts (Operate)

***Problem***   Covers, lids, and other detachable parts may be difficult to remove, replace, or reposition.

*Example*: People with poor motor control may be unable to replace a cover or lid once it has been detached because it was dropped to the floor or into an inaccessible part of the product. People with weakness may have difficulty repositioning a keyboard, monitor, or TV set if the resistance to movement is high.

***Design Options and Ideas to Consider***

- Employing devices with covers or lids that could be hinged, have sliding covers, or be operated electronically
- Tethering covers and lids with a cord or wire
- Making device components repositionable with a minimum of force
- Eliminating or limiting tasks needed for consumer assembly, installation, or maintenance of product

### 9.3.4   M-4 Maximize the Number of People Who Can Understand How to Carry Out the Manipulations Necessary to Use the Product (Understand)

***Problem***   Some people may have difficulty remembering how to operate the product, performing tasks in the correct order or within the required time, making choices, doing required measurements, or problem solving.

*Example*: Some people (particularly those with learning disabilities or cognitive impairments) have difficulty remembering passwords or codes required to operate a device (e.g., PIN for automated teller machine). They may also be unable to remember which control to push to start or stop the device or have difficulty with serial order recall (the ability to remember items or tasks in sequence) and thus cannot follow complex or numerous steps. Others may have a slower or delayed reaction time, due to their inability to remember things quickly or to make responses that are dependent on timed input. Some get confused when there is a time lag for a response after they issue a command or when they expect an immediate result and have trouble in choosing from available selection options (e.g., selecting paper size on a printer, choosing settings on a stereo set). Some cannot understand the concept of measuring or quantifying. Some have significant difficulty finding out what and where the problem is when a device is not functioning properly and may have difficulty identifying solutions to problems they have identified.

***Design Options and Ideas to Consider***   Many of the problems in this category are similar to the problems outlined in Section I-6 and many of the same design ideas would apply, including the following:

- Keeping things as simple as possible
- Providing cues or prompts for sequences of actions required
- Writing the instructions directly on the device
- Having programmable keys for commonly used sequences
- Providing an easy way out of any situation
- Eliminating any timed responses (or make the times adjustable)
- Providing feedback to the user when the device is busy or "thinking"
- Hiding seldom-used controls which are not used primarily, to limit available choices

Other design suggestions include:

- Incorporating premeasuring methods whenever a quantifiable amount is required
- Providing prompts to inform users about the source(s) of problems and lead them to action to be taken to solve the problems (e.g., lights and color-coded pictorials used in copying machines)
- Eliminating or simplifying consumer assembly, installation, and maintenance of the product
- Providing a "standard" key or default mode to operate standardized functions (e.g., a key on a copier to give standard-sized copies)
- Providing an automatic mode so that the machine will make self-adjustments

## 9.4   Documentation

Maximize the number of people who can . . .

D-1 access the documentation.
D-2 understand the documentation.

### 9.4.1   D-1 Maximize the Number of People Who Can Access the Documentation (Perceive)

***Problem***   Printed documentation (e.g., operating or installation instructions) may not be readable.

*Example*: People with low vision may not be able to read documentation due to small size or poor format.

Poor choice of colors may make diagrams ambiguous for people with color blindness. People who are blind cannot use printed documentation, especially graphics. People with severe physical impairments may find it difficult or impossible to handle printed documentation.

### Design Options and Ideas to Consider

- Providing documentation in alternate formats: electronic, large-print, audio tape/disc, and/or braille
- Using large fonts
- Using sans serif fonts
- Making sure that letter spacing, the space between lines (leading), and the distance between topics are sufficient that the letters and topics stand out from each other distinctly
- Supplementing any information that is presented via color coding so it can be interpreted in some other way which does not rely on color (e.g., bar charts may use various black-and-white patterns under the colors or patterns in the colors)
- Providing a text description of all graphics (this is especially important for use in electronic, audio, and large-print forms)
- Providing basic instructions directly on the device as well as in the documentation
- Making printed documentation "scanner/OCR friendly"

### 9.4.2 D-2 Maximize the Number of People Who Can Understand the Documentation (Understand)

**Problem** Printed documentation (e.g., operating or installation instructions) may not be understandable.

*Example*: People with cognitive impairments may have difficulty following multistep instructions. People with language difficulties or for whom English is a second language (including people with deafness) may have difficulty understanding complex text. People with learning difficulties may have difficulty distinguishing directional terms.

### Design Options and Ideas to Consider

- Providing clear, concise descriptions of the product and its initial setup
- Providing descriptions that do not require pictures (words and numbers used redundantly with pictures and tables), at least for all the basic operations
- Formatting with plenty of white space used to create small text groupings and bullet points
- Highlighting key information by using large, bold letters and putting it near the front of the text
- Frontloading key information by putting it near the front of the text
- Providing step-by-step instructions which are numbered or bulleted or have check boxes

- Using affirmative instead of negative or passive statements
- Keeping sentence structure simple (i.e., one clause)
- Supplying a glossary
- Avoiding directional terms (e.g., left, right, up, down) where possible
- Providing a Quick Start or basic "bare bones" form or section to the documentation that gets you up and running with just the basic features

See also Sections O-6, I-6, and M-4.

## 9.5 Safety

Maximize the number of people who can . . .

S-1 perceive hazard warnings (Perceive).

S-2 use the product without injury due to unperceived hazards or the user's lack of motor control (Operate).

### 9.5.1 S-1 Maximize the Number of People Who Can Perceive Hazard Warnings (Perceive)

**Problem** Hazard warnings (alarms) are missed, due to single-sensory presentation or lack of understandability.

*Example*: People who are deaf may not hear auditory alarms. People with hearing impairments may not hear auditory alarms that have only a narrow frequency spectrum. People with visual impairments may not see visual warnings. People with cognitive impairments may not understand the nature of a warning quickly enough.

### Design Options and Ideas to Consider

- Using a broad-frequency spectrum with at least two frequency components between 500 and 3000 Hz for alarm signals
- Using redundant visual and auditory format for alarms (e.g., flashing lights plus alarm siren)
- Reducing glare on any surfaces containing warning messages
- Using common color-coding conventions and/or symbols along with simple warning messages
- Providing an optional, portable, vibrating module for use by persons who are deaf

### 9.5.2 S-2 Maximize the Number of People Who Can Use the Product without Injury Due to Unperceived Hazards or the User's Lack of Motor Control (Operate)

**Problem** Users are injured because they are unaware of an "obvious" hazard or because they lack sufficient motor control to avoid hazards.

*Example*: People with visual impairments may not see a hazard that is obvious to those with average sight. People with lack of strength or muscle control may inadvertently topple a device while in use so that it injures them. People with a lack of muscle control may inadvertently put their limbs or fingers in places not

**Table 2  Principles of Universal Design**

**Principle 1:** Equitable Use

The design is useful and marketable to people with diverse abilities.

    Guidelines:

    1a.   Provide the same means of use for all users: identical whenever possible; equivalent when not.

    1b.   Avoid segregating or stigmatizing any users.

    1c.   Make provisions for privacy, security, and safety equally available to all users.

    1d.   Make the design appealing to all users.

**Principle 2:** Flexibility in Use

The design accommodates a wide range of individual preferences and abilities.

    Guidelines:

    2a.   Provide choice in methods of use.

    2b.   Accommodate right- or left-handed access and use.

    2c.   Facilitate the user's accuracy and precision.

    2d.   Provide adaptability to the user's pace.

**Principle 3:** Simple and Intuitive to Use

Use of the design is easy to understand, regardless of the user's experience, knowledge, language skills, or current concentration level.

    Guidelines:

    3a.   Eliminate unnecessary complexity.

    3b.   Be consistent with user expectations and intuition.

    3c.   Accommodate a wide range of literacy and language skills.

    3d.   Arrange information consistent with its importance.

    3e.   Provide effective prompting and feedback during and after task completion.

**Principle 4:** Perceptible Information

The design communicates necessary information effectively to the user, regardless of ambient conditions or the user's sensory abilities.

    Guidelines:

    4a.   Use different modes (pictorial, verbal, tactile) for redundant presentation of essential information.

    4b.   Provide adequate contrast between essential information and its surroundings.

    4c.   Maximize ''legibility'' of essential information.

    4d.   Differentiate elements in ways that can be described (i.e., make it easy to give instructions or directions).

    4e.   Provide compatibility with a variety of techniques or devices used by people with sensory limitations.

**Principle 5:** Tolerance for Error

The design minimizes hazards and the adverse consequences of accidental or unintended actions.

    Guidelines:

    5a.   Arrange elements to minimize hazards and errors: most used element most accessible; hazardous elements eliminated, isolated, or shielded.

    5b.   Provide warnings of hazards or errors.

    5c.   Provide fail-safe features.

    5d.   Discourage unconscious action in tasks that require vigilance.

**Principle 6:** Low Physical Effort

The design can be used efficiently and comfortably and with a minimum of fatigue.

    Guidelines:

    6a.   Allow user to maintain a neutral body position.

    6b.   Use reasonable operating forces.

    6c.   Minimize repetitive actions.

    6d.   Minimize sustained physical effort.

**Principle 7:** Size and Space for Approach and Use

Appropriate size and space are provided for approach, reach, manipulation, and use regardless of user's body size, posture, or mobility.

    Guidelines:

    7a.   Provide a clear line of sight to important elements for any seated or standing user.

    7b.   Make reach to all components comfortable for any seated or standing user.

    7c.   Accommodate variations in hand and grip size.

    7d.   Provide adequate space for the use of assistive devices or personal assistance.

*Source*: B. R. Connell, M. Jones, R. Mace, J. Mueller, A. Mullick, E. Ostroff, J. Sanford, E. Steinfeld, M. Story, and G. Vanderheiden, © 1997 NC State University, The Center for Universal Design.

intended for contact or other hazardous places (e.g., the cassette tape drive of a stereo or VCR contains sharp edges that can cut fingers jammed inside with force). People with cognitive impairments may be unable to remember to shut off devices when not in use.

### Design Options and Ideas to Consider

- Avoiding pinch points on moving parts
- Eliminating or audibly warning of hazards that rely on the user's visual ability to avoid
- Making all surfaces, corners, protrusions, and device entrances free of sharp edges or extreme heat
- Deburring any internal parts accessible by a body part, even if contact with a body part is not normally expected (e.g., inside an open cassette tape door on a stereo set)
- Providing automatic shutoff of devices that would present a hazard if left on (e.g., irons)
- Ensuring that devices have stable, nonslip bases, or the ability to be attached to a stable surface
- Providing guards that are difficult to defeat where components present a danger of injury

### 9.6 Universal Design Tools

A group of architects, product designers, and human factors engineers have gotten together to develop a common set of universal design principles and guidelines (see Table 2). Members of the team also have developed tools that work with the principles including a Guide to Evaluating the Universal Design Performance of Products. The most current version of the principles and guidelines can be found at the author's website, listed at the end of the chapter.

The Trace Center at the University of Wisconsin–Madison has also developed an online design tool. The tool facilitates the design of more accessible mainstream products by highlighting aspects that contribute to enhanced and expanded usability. It also provides strategies, techniques, and examples for various product types.

### 10 CONCLUSION

Universal design should not really exist as a separate topic. In fact, it is just an extension of good human factors design today. The fact that it is currently a separate topic is probably an artifact of both the heavy military influence in the early ergonomic design process and the focus on serving the largest and most homogeneous segment of the population. However, legislation and commercial interests, a shifting and aging population, and the high costs of health care are combining to provide increased emphasis on this area. In the computer area, Apple, IBM, Microsoft, and other computer companies are all expanding the human interface and general design of their products to allow them to accommodate people with a much wider range of skills and abilities. Similarly, homebuilders, household product manufacturers,

and others are extending and modifying their lines to serve people with more diverse abilities. There is an acute shortage, however, of people with background and experience in what might be universal design. It is to be hoped that over time the term and the field of universal design will fade as it becomes part and parcel of the standard design process.

### 11 FOR FURTHER INFORMATION

Further information on topics covered in this chapter as well as updated versions of design guidelines, resource materials, and references can be found at http://trace.wisc.edu/.

## ORGANIZATIONS

**AccesslT**
National Center on Accessible Information
    Technology in Education
Box 357920
University of Washington
Seattle, WA 98195-7920
866-968-2223 (V)
866-866-0162 (TTY)
http://www.washington.edu/accessit/index.php/

AccesslT, at the University of Washington, promotes the use of electronic and information technology (E&IT) for students and employees with disabilities in educational institutions at all academic levels. The website contains a searchable, growing database of questions and answers regarding accessible E&IT. Funding for AccesslT is provided by the National Institute on Disability and Rehabilitation Research and the National Science Foundation.

**Center for Assistive Technology and Environmental Access (CATEA)**
Georgia Institute of Technology
School of Architecture
490 Tenth Street, NW
Atlanta, GA 30332-0156
404-894-4960 (V/TTY)
http://www.catea.gatech.edu/

CATEA is a multidisciplinary engineering and design research center dedicated to enhancing the health, activity, and participation of people with functional limitations through the application of assistive and universally designed technologies in real-world environments, products, and devices. CATEA's work is organized under four laboratories: the Rehabilitation Engineering and Applied Research Laboratory (REAR Lab; http://rearlab.gatech.edu/), the Accessible Workplace Laboratory (http://www.catea.gatech.edu/work.php), the Enabling Environments Laboratory (EE lab; http://www.catea.gatech.edu/eelab.php), and the Accessible Education and Information Laboratory (http://www.catea.gatech.edu/aei.php).

**Center for Inclusive Design and Environmental Access (IDeA)**
378 Hayes Hall, School of Architecture and Planning
3435 Main Street
University at Buffalo
Buffalo, NY 14214-3087
716-829-5902
http://www.ap.buffalo.edu/idea/

The IDeA Center is dedicated to making environments and products more usable, safer, and healthier in response to the needs of an increasingly diverse population. The IDeA Center's activities are based on the philosophy of inclusive design, often called "universal design" or "design for all." It is a way of thinking that can be applied in any design activity, business practice, program, or service involving interaction of people with the physical, social, or virtual worlds. Maintains the Universal Design E-World site, which is a participatory environment with Web-based tools to support the community of practice in universal design.

**Center for Universal Design**
College of Design
North Carolina State University
Campus Box 8613
Raleigh, NC 27695-8613
919-515-8359
http://www.ncsu.edu/www/ncsu/design/sod5/cud/

The Center for Universal Design (CUD) is a national information, technical assistance, and research center that evaluates, develops, and promotes accessible and universal design in housing, commercial and public facilities, outdoor environments, and products. Its mission is to improve environments and products through design innovation, research, education, and design assistance.

**Inclusive Technologies**
Temper Complex
37 Miriam Drive
Matawan, NJ 07747
908-907-2387 (V/TTY)
http://www.inclusive.com/

Inclusive Technologies provides a full range of consulting services to companies, public agencies, consumers, researchers, purchasers, and policymakers on how mainstream products can better meet the needs of all users, including users with disabilities and elders.

**Institute for Human Centered Design**
200 Portland Street
Boston, MA 02114
617-695-1225 (V/TTY)
http://humancentereddesign.org/

The Institute for Human Centered Design (IHCD), founded in 1978 as Adaptive Environments, is an international nongovernmental educational organization committed to advancing the role of design in expanding opportunity and enhancing experience for people of all ages and abilities through excellence in design. IHCD's work balances expertise in legally required accessibility with promotion of best practices in human-centered or universal design.

IHCD has been the lead organization in the international universal design movement, having hosted or cohosted five international conferences as well as international student design competitions, smaller regional meetings, and publication of Web and print materials.

**J.L. Mueller, Inc.**
4717 Walney Knoll Court
Chantilly, VA 22021
703-222-5808
http://www.jlmueller.com/index.html/

J.L. Mueller, Inc. was founded in 1982 by Jim Mueller, an industrial designer who has worked in the field of design for people with disabilities since 1974. He is recognized as one of the most experienced designers in working with people with disabilities to increase independence at home, at school, and at work through design. The website includes information about the principles of universal design, applicable legislation, and workplace accommodations.

### National Center for Accessible Media (NCAM)
http://ncam.wgbh.org/

The Carl and Ruth Shapiro Family National Center for Accessible Media (NCAM) at Boston public broadcaster WGBH is a research and development facility dedicated to addressing barriers to media and emerging technologies for people with disabilities in their homes, schools, workplaces, and communities. NCAM is part of the Media Access Group at WGBH which includes two production units, The Caption Center (est. 1972) and Descriptive Video Service® (DVS®) (est. 1990).

### R.L. Mace Universal Design Institute (UDI)
410 Yorktown Drive, Suite 203
Chapel Hill, NC 27516
919-960-6734 (office)
http://udinstitute.org/index.php/

The Ronald L. Mace Universal Design Institute is a nonprofit organization based in North Carolina dedicated to promoting the concept and practice of accessible and universal design. The institute's work manifests the belief that all new environments and products, to the greatest extent possible, should and can be usable by everyone regardless of age, ability, or circumstance.

The institute advances the concept of universal design in all design disciplines, including housing, public use buildings, outdoor and urban environments, and related products.

### Technology Access Program
Gallaudet University
800 Florida Avenue, NE
Kendall Hall
Washington, DC 20002
202-651-5257 (V/TTY)
http://tap.gallaudet.edu/

The Technology Access Program (TAP) conducts research related to communication technologies and services, with the goal of producing knowledge useful to industry, government, and deaf and hard-of-hearing consumers in the quest for equality in communications.

### Trace Research and Development Center
University of Wisconsin—Madison
2107 Engineering Centers Building
1550 Engineering Drive
Madison, WI 53706
608-262-6966 (V)
608-263-5408 (TTY)
http://trace.wisc.edu/

The Trace R&D Center at the University of Wisconsin—Madison focuses on the design of mainstream information and communication technology for use by all people. Trace is also the home of the Rehabilitation Engineering Research Center (RERC) on Information Technology Access and (in partnership with Gallaudet University) the RERC on Telecommunication Access, both funded by the National Institute on Disability and Rehabilitation Research.

### Universal Design Education Online
http://www.udeducation.org/

This site supports educators and students in their teaching and study of universal design. It provides a place where educators can interact with each other and where a growing community of learners exchange information for the benefit of all. The site is designed for use by faculty members, students (of any age and stage), and user/experts. It supports professional design education as well as professional development/continuing education, featuring a variety of materials for a range of disciplines, levels, and interests

### Web Accessibility Initiative
http://www.w3.org/WAI/

The Web Accessibility Initiative (WAI) works with organizations around the world to develop strategies, guidelines, and resources to help make the Web accessible to people with disabilities. It is one of the four domains of the World Wide Web Consortium (W3C); the WAI develops its work through W3C's consensus-based process, involving different stakeholders in Web accessibility. These include industry, disability organizations, government, accessibility research organizations, and more.

### WebAIM (Web Accessibility in Mind)
http://webaim.org/

WebAIM's mission is to expand the potential of the Web for people with disabilities by providing the knowledge, technical skills, tools, organizational leadership strategies, and vision that empower organizations to make their own content accessible to people with disabilities. They are known for their online instructional media and software tools.

**Atlanta, Georgia**

## 1 INTRODUCTION

Age is a critical variable relevant to design considerations in human factors research and practice. This conclusion is founded on three primary facts:

1. The number of older adults in developed countries today is higher than ever and is increasing.
2. There are critical age-related differences between younger and older adults which necessitate specific design considerations.

3. The proportion of older adults within the global workforce and of all users of systems and products is increasing steadily (Figure 1).

### 1.1 Increasing Population over Age 65

The world's older adult (65+ years) population is increasing by approximately 800,000 each month (Kinsella and Velkoff, 2001). U.S. Census data show clearly the increasing trend for adults over age 65 and over age 85, as the average lifespan is increasing (U.S. Bureau of the Census, 1996; Figure 2).
**Figure 1**    Percentage of men and women between 60 and 64 and 65+ in selected countries who are in the workforce.

**Figure 2**    Population estimates for the age groups 65+ and 85+ through the year 2060.

## 1.2 Design-Critical Age-Related Differences

Why is it important to consider older adult users? The statistics of older adult population rates alone are not cause for the field of human factors to take notice. The meaningful issue is whether older adults require significantly different design considerations than younger adults. This issue is addressed in the present chapter by specifying the cognitive, perceptual, motor, and motivation differences between the two age groups and also considering whether these differences translate into functional differences. For example, age-related response time differences of 1.5 s may not be functionally meaningful when searching for information on the Internet, but this age-related difference could be critical in the driving environment or when responding to a medical emergency in the home where delayed responses can lead to serious consequences. Primary goals of this chapter are to describe functionally meaningful changes that occur with age and their effects on performance and to recommend design considerations and design principles.

## 1.3 Older Adults' Use of Technology

Given the need for age-specific design considerations, a critical third issue for human factors researchers and practitioners is to understand the extent to which older adults interact with systems and products. Certainly, if older adults comprise only a very small proportion of users of systems and products, this would temper the degree to which the field must be concerned with the age-related changes and characteristics of older adults. However, this is not the case. In a survey of product use (Hancock et al., 2001), adults over age 65 reportedly used a variety of household products as frequently as adults under age 65, and they used health care products more frequently. Furthermore, as discussed in Section 6, older adults express a desire to learn to use new technologies (e.g., Rogers et al., 1998) and many are using the computer and the Internet for a variety of tasks (e.g., Olson et al., 2011). In summary, the capabilities and limitations of the growing older adult population must be understood and accounted for in the design process and in human factors research to ensure that this segment of the population can interact with products and systems in a safe, efficient, and effective manner.

## 1.4 Definitions

### 1.4.1 Age

The focus of the chapter is on the relevance of "age" to design. However, age is no more than a chronological marker for the myriad changes that people undergo as they age—hence the term age-*related* changes. The changes discussed here are not caused by a person's age but rather are correlated with age, and there is substantial variability in the degree to which individual older adults show some changes and the degree of change for a particular person. Furthermore, given the continuous nature of this variable, is it proper or even useful to think of age in discrete chunks (e.g., younger vs. older)? In fact, there are several reasons to do so (see Nichols et al., 2003, for a review). For research purposes, we recommend defining "older" adults as 65–85 years,

"middle-aged" adults as 40–55, and "younger" adults as 18–30. Subgroups such as young–old (e.g., 56–64) and old–old (85+), are often used in aging research, and the younger group may at times be extended (e.g., 18–39). These age range decisions are often, in part, based on the user population to which the research is intended to generalize as well as the age-related changes that are being investigated. For example, younger and older groups in a study of air traffic controllers would be based on different age ranges than a study of normal driving. The standard maximum age for an air traffic controller is 56, whereas the maximum age of drivers extends into the 80s and 90s. Thus, what is older in one context differs from what is older in the other context. We recommend that researchers and practitioners follow the above age range guidelines for the following reasons:

- *Variability in Performance*. Age-related variance will be controlled to some degree (as opposed to a study that uses a sample ranging from 40 to 75). As will be highlighted, considerable age-related changes occur across the lifespan, and those changes may have a significant impact on behavior and task performance.

- *Precision and Consistency*. By following appropriate age classification guidelines and reporting participants' age, the field of human factors will better provide precise and useful information on the performance of adults of different ages and design will better fit the user.

- *Parsimony*. For many studies, it may be simpler to think of a single variable than the host of variables affected by age. Although age is merely a marker predicting performance, age provides a broad and useful designate for many of the age-related changes discussed in this chapter.

### 1.4.2 Products and Systems

The design issues discussed in this chapter are intended to be relevant to a wide range of products and systems (i.e., any system or product older adults might use). This is necessarily general, as older adults interact with a wide range of products and systems in their daily activities. Although the guidelines are intended to be general, their applicability will differ as a function of the demands of the task at hand (e.g., a technology that requires fine motor control will be more influenced by age-related changes in movement control). Guidelines specific to particular devices and contexts are available in Fisk et al. (2009).

## 1.5 How to Use the Recommendations

The recommendations presented in this chapter provide a means of reducing the potential solution space for resolving design-related questions. However, these recommendations do not provide a complete solution. Variability at all levels of behavior in older adults is a hallmark characteristic of aging, making iterative design and user testing with older adults crucial. The design issues discussed here should be beneficial in understanding and predicting older adults' performance, but

the chapter is not intended to replace necessary human factors methods such as iterative design and user testing. For the implications and design recommendations, our goal is to provide general design principles relevant to design for older users. However, many of the age-related changes discussed in this chapter occur gradually and improvements in design and training targeted at older adults are likely to benefit younger and middle-aged adults as well (Fisk, 1999).

## 1.6 Overview of the Chapter

The remainder of this chapter is organized as follows: First we discuss aspects of behavior from the perspective of age-related differences. Within each section we present general implications for design. We then present a "case study" of a hand-held gaming system designed for older adults. This case study illustrates the implications of the age-related changes for system design.

### 1.6.1 Age-Related Changes

To guide the discussion of age-related changes, consider a general model of information processing as presented in Figure 3. The three general categories of activities are perceptual encoding, central processing, and responding; each is influenced to some degree by the normal aging process. As such, the following categories of age-related changes are reviewed briefly and then discussed in terms of the relevance of such changes to design: (1) perception, (2) cognition, and (3) movement control. In addition, given their general overarching role we also discuss briefly (4) beliefs, attitudes, and motivation.

### 1.6.2 Design Implications and Suggestions

Following each section on age-related changes, the implications of these data for design will be described. We also present an in-depth hypothetical case study of a hand-held gaming system for older adults. While the discussion accompanying each age-related change will involve specific consequences for design, the goal of the latter case study is to provide robust design recommendations based on consideration of multiple age-related changes.

In providing design suggestions, there is a tension between providing overly general suggestions that are not specific enough to be useful versus overly specific suggestions that do not generalize across products or systems. Our approach is to focus on implications and recommendations for those systems and products particularly relevant to a given age-related change. Thus, when we present design implications at the end of each section, these will be reasonably broad (i.e., the design implications for the selective attention section will be relevant to the design of automobiles but not to the design of furniture).

### 1.6.3 Consistent Themes and Guidelines

There are consistent themes that are relevant to design considerations for an older population (Table 1). These themes are evident in many of the design suggestions and implications in this chapter.

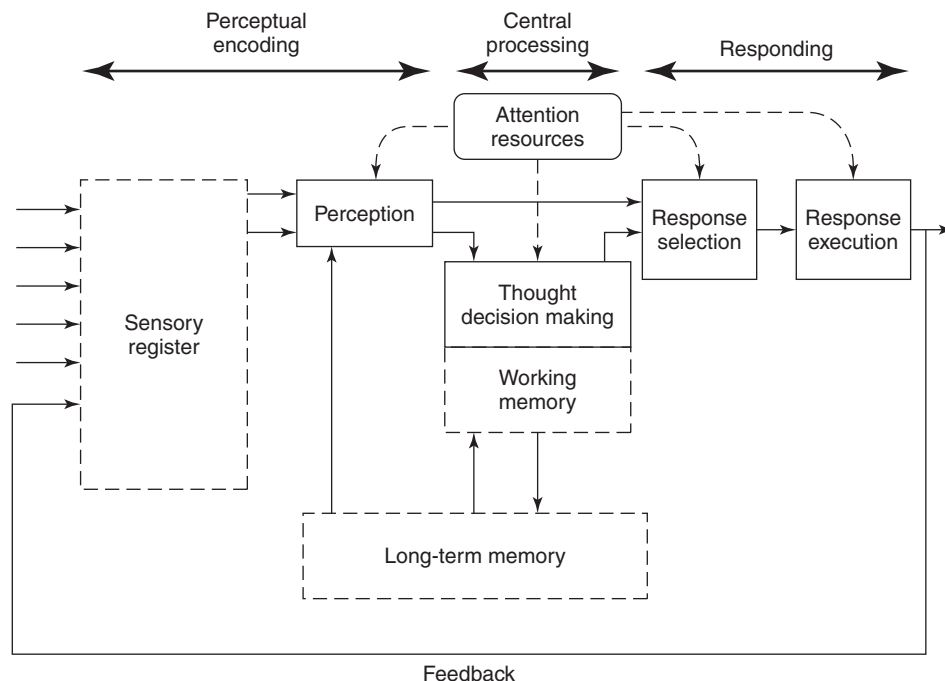

**Figure 3**   A schematic representation of information processing. (Adapted from Wickens et al., 1998.)

**Table 1 Six Major Themes of Designing for Aging**

| Design Theme | Definition |
|---|---|
| Provide environmental support through context, cues, and organization | Performance can be supported by placing information in the task environment, which reduces cognitive demands on the user. |
| Improve the physical stimulus | Age-related perceptual declines can be offset to some degree by improving the physical stimulus and increasing older adults' ability to perceive and recognize the stimulus. |
| Display information consistently | Some level of consistency is required for learning to occur, and with greater degree of consistency, learning is more efficient. |
| Provide training | Through appropriate training, older adults' performance can be brought closer in line with that of younger adults. |
| Capitalize on crystallized knowledge | Fact knowledge is generally unaffected by aging, and design can take advantage of this knowledge. |
| Recognize knowledge, interest, and motivation | Older adults' motivation and desire to interact with technology are often underestimated. |

**Table 2 Age-Related Perceptual Changes in Vision, Audition, and Haptics**

| | |
|---|---|
| ***Visual Changes*** | |
| Visual acuity | The ability to resolve detail decreases. |
| Visual accommodation | The ability to focus on close objects decreases. |
| Color vision | The ability to discriminate and perceive shorter wavelength light decreases. |
| Contrast detection | The ability to detect contrast decreases. |
| Dark adaptation | The ability to adapt quickly to darker conditions decreases. |
| Glare | The susceptibility to glare increases. |
| Illumination | More illumination is required to see adequately. |
| Motion perception | Motion is not as readily detected and motion estimation is reduced. |
| Useful field of view | The useful visual field is reduced. |
| ***Auditory Changes*** | |
| Auditory acuity | The ability to detect sound decreases, particularly at higher frequencies and particularly for males. |
| Auditory localization | The ability to localize sound decreases, particularly at higher frequencies and when directly in front of or behind the user. |
| Audition in noise | The ability to perceive speech and complex sounds decreases. |
| ***Haptic Changes*** | |
| Haptic control | Older adults have more variability in maintaining constant force when grasping an object. |
| Proprioceptive perception | Threshold to differentiate being touched at a single point versus two points is higher for older adults. |
| Temperature perception | Thresholds increase with age. |
| Vibration perception | Thresholds increase with age. |

## 2 PERCEPTION

Most products and systems are designed to provide information via the visual and auditory modalities, and these two sensory systems have been well studied in the aging population (see Table 2 for a summary of the visual and auditory changes; see Fisk et al., 2009, for more in-depth discussion). These systems show significant and substantial declines in older adults. For information to affect behavior, the information must first enter the sensory system and then be encoded. If, due to sensory system degradation, information is sensed or perceived incompletely, it may be processed incorrectly.

Haptic perception (i.e., the sense of touch) also provides an important channel for information. Consider the vehicle shaking when the car is misaligned or the feedback from a computer keyboard that informs the typist if the key has been pressed sufficiently. Haptic cues are also being designed into systems to provide information such as rumble strips on the roadway or the vibration of a mobile phone. As such, we need to understand the degree to which older adults show changes in these perceptions (see Table 2).

### 2.1 Vision

In general, the ability to resolve an image accurately is dependent on the available luminance and the contrast of the scene. The most common age-related causes of visual impairment are age-related macular degeneration (ARMD), cataracts, and glaucoma (Desai et al., 2001)

(Figure 4). Due to changes in the structure of the aging eye and visual processing system, older adults are less able to resolve details and are less sensitive to critical environmental characteristics such as luminance, contrast, color, and motion.

### 2.1.1 Acuity

Although visual impairment can affect people across the lifespan, age is the best predictor of visual decline. Visual acuity, the best known measure of visual ability, is typically measured relative to what a "normal" person
**Figure 4** Prevalence of ARMD, cataracts, and glaucoma across three groups of older adults. (Adapted from Desai et al., 2001.)

can see at 20 ft away (thus, the measure 20/20) (Snellen, 1862, cited in Bennett, 1965). Acuity is affected by various eye pathologies (many of which are more commonly observed with age) as well as deterioration of the brain's visual pathways. In ARMD, the most common cause of vision loss in older adults, people experience a reduced ability to resolve fine detail (Bellman and Holz, 2001). People with ARMD suffer from reduced central vision due to degeneration of the *macula*, an area in the center of the retina. Cataracts also affect acuity, resulting in a clouding of the lens, but these are often treatable, whereas vision loss due to ARMD cannot currently be restored. Glaucoma results from damage to the optic nerve due to an increase in pressure in the eye, as fluid flow through the front of the eye is hindered. The buildup of fluid at the front of the eye results in increased pressure at the back of the eye, causing irreparable degeneration of the optic nerve fibers (Goldstein, 1999). As a result, peripheral vision deteriorates, and if not treated, central vision will deteriorate as well.

Older adults are able to compensate for loss of acuity. For example, despite poorer visual acuity, older adults were shown to perceive blurred text signs better than younger adults (Kline et al., 1999). In this study, the acuity of both younger and older adults was reduced artificially and the size at which blurred text signs could be read was measured. The primary findings were that both age groups were better able to read familiar text

signs than novel text signs and, when both age groups' acuity was comparably impaired (e.g., at 20/40), older adults could read text at a smaller size than younger adults. Presumably the nature of optical blur is such that low-vision persons are less affected (Legge et al., 1987a). Thus, older adults' ability to deal with blurred information may be related to their ability to adapt to changes in visual acuity as well as to rely on *top-down processing* (i.e., interpreting information based on well-learned, crystallized knowledge).

***Design Implications and Suggestions*** The loss in acuity has profound effects on the way in which information should be displayed for older adults. Increasing the size, brightness, and contrast of an item will improve older adults' perception of information. For example, text should typically be displayed in a 12-point font size or greater. It is especially important for novel information to be made perceptually salient for older adults. Top-down processing can result in the correct identification of a perceptually indistinct stimulus (Kline et al., 1999), but when processing is primarily bottom-up (as with novel stimuli), clarity of the stimulus is crucial. For example, a driver who has reduced near vision may not be able to perfectly discriminate the points on the odometer, but the consistent spacing and common look of the odometer should provide sufficient information about the vehicle's speed. Thus, it is important to design for such

consistent aspects of a system, because users who rely on these consistent aspects to aid their top-down processing interpretation of displays can be supported (this is a form of environmental support).

If a display cannot be changed to accommodate low-acuity people, it is important to maximize the effect of top-down processing. Contextual cues, another form of environmental support, can be provided to increase the likelihood that a stimulus will be recognized. For example, a driver who has trouble reading traffic control signs from afar may rely on the color and shape of the signs, which allows the driver to identify the type of sign. However, acuity is not the only age-related decrement in visual perception that must be considered.

### 2.1.2   Accommodation

Older adults have difficulty with visual accommodation (termed *presbyopia*), which involves adjusting the curvature of the lens to focus on objects of different depths. In fact, reductions in accommodative ability are primarily responsible for losses in acuity in near vision, typically starting at age 40. By age 65, lens accommodation is so reduced that only objects at a certain distance can be focused on the retina, meaning that information not displayed at this distance cannot be clearly perceived by the person (Schneider and Pichora-Fuller, 2000).

***Design Implications and Suggestions***   The need to focus at different distances should be minimized as much as possible. In a system with multiple displays, all of the displays should be placed as close to the optimal reading distance from the user as possible. This will reduce the necessity for head movement to bring information into perfect clarity as the multiple displays are scanned.

### 2.1.3   Color Vision

Older adults are less able to discriminate shorter wave-length light, such as blues and greens, due to a yellowing of the lens (Said and Weale, 1959). Furthermore, the ability to discriminate color declines with age (Kraft and Werner, 1999), and age-related differences in color discrimination increase at lower light levels and lower color saturations (Pinckers, 1980; Knoblauch et al., 1987).

***Design Implications and Suggestions***   Color coding is still a feasible option in information visualization (e.g., representing multidimensional data at a single time), but color codes should avoid shorter wavelength light as a general rule or use only a single blue or green, thus eliminating the need to compare within this range of color. Color coding should not be used when many distinct levels are required, and colors should be well saturated.

### 2.1.4   Contrast Detection

The importance of high contrast in detecting stimuli and in tasks such as reading is important for adults of all ages, but particularly for older adults. People with poorer acuity are more affected by reductions in contrast whether they are younger adults (Legge et al., 1987b) or older adults (Fozard, 1990). However, even if matched for visual acuity, older adults have reduced contrast sensitivity (Mitzner and Rogers, 2003). Reduced contrast sensitivity is due in part to the scattering of light as it enters the eye, such that light from the image is scattered across the retina, creating a more uniform dispersal of light on the retina (Schneider and Pichora-Fuller, 2000).

***Design Implications and Suggestions***   Optimal contrast in which text should be presented is a bright white on black, or vice versa. If colors are used to present information, colors close together on the spectrum should not be used together (e.g., a red icon on an orange background). Furthermore, the deleterious effects of reduced contrast can be alleviated through the use of context, essentially allowing top-down processes to aid the older user in identifying the stimulus correctly (Mitzner and Rogers, 2003).

### 2.1.5   Illumination, Glare, and Dark/Light Adaptation

In the aging eye, changes in the cornea scatter light before it reaches the retina, the lens absorbs more light, and pupil size is reduced, allowing less light to reach the retina (Schneider and Pichora-Fuller, 2000). Even though less light reaches the retina, glare is problematic for older adults. Glare occurs when a person is exposed to levels of light higher than the eye is currently adapted. Thus, glare is a notable problem when driving at night. Similarly, bright sunlight can cause glare from either direct line of sight or reflected surfaces. Due to the scattering of light in the older eye, glare is more of a problem for older adults, as the excess light is more distributed across the eye, essentially reducing perception for a greater degree of the visual field. The aging eye also is slower to adapt to light and dark. With reductions in the amount of light that reaches the retina, the retina is therefore slower to adapt to the changing light conditions. Furthermore, the chemical processes that cause dark adaptation are slowed with age (Jackson et al., 1999).

***Design Implications and Suggestions***   These age-related changes in the sensation of light cannot be solved via an external perceptual aid, as they are specifically due to deterioration of the cornea. Older adults will benefit from increased illumination in all environments, including driving and activities at home and work. Unfortunately, Charness and Dijkstra (1999) demonstrated that the homes of older adults are not lit optimally, particularly at night (although older adults appeared to compensate for their visual impairments by using significantly more light in their homes than younger adults).

Appropriate lighting is critical in optimizing the perception of information. If possible, increase the level of illumination to at least 100 cd/m$^2$, as measured by the reflection from reading surfaces (Charness and Dijkstra, 1999). Lighting levels should be even when possible, in roadways and in office and home layouts. To reduce glare, light sources should be diffused and positioned to create ambient light as opposed to direct light. Mirrors and shiny surfaces should be avoided, as the undiffused reflections can cause glare. Multiple light sources serve

to reduce harsh shadows and to even out the light in the environment.

These age-related changes in vision are critically relevant in the driving domain, which is one of the most perceptually and cognitively demanding tasks as well as one of the most widely and frequently performed. When driving at night, illumination levels are already extremely low. Glare can occur as the result of passing headlights and streetlights, causing older adults to be blinded temporarily by the dispersed light across their retinas. When driving from daylight into a tunnel, older adults' visual perception will suffer relative to younger adults. In the design of roads and tunnels, lighting should be made as constant as possible to reduce the negative effects of low illumination, glare, and slower adaptation to dark and light.

### 2.1.6  Perception of Motion

Older adults are less able to detect motion relative to younger adults. To investigate sensitivity to motion, researchers have created sets of elements, a subset of which move synchronously (Trick and Silverman, 1991; Tran et al., 1998). Older adults appear to have a higher element threshold than younger adults, indicating that they required more movement of elements to detect motion in the array.

Age-related differences in perception of motion have been investigated in a driving scenario (Atchley and Andersen, 1998; Andersen et al., 2000). A three-dimensional display was used to simulate a vehicle windshield and display an environment at one of two velocities followed by a constant deceleration. The deceleration occurred such that the car would either stop short of an obstacle, stop directly at the obstacle, or crash into the obstacle. The display was stopped prior to stopping or crashing, and the participants were required to indicate what the outcome would be. Relative to younger adults, older adults were less sensitive to detecting collisions, indicating that a crash was inevitable when no collision occurred.

***Design Implications and Suggestions***  Motion detection findings suggest that in combination with age-related declines in movement speed and visual perception, older adults' declining perception of potential collision information could be a factor in their ability to safely avoid vehicular collisions. When motion is a critical cue, it must be accentuated for older adults. However, this design implication must be incorporated carefully because, all other things being equal, motion can be more of a distraction for older adults than for younger adults.

### 2.2  Audition

Auditory information is presented in a wide variety of environments. Museums and exhibition halls may play descriptive recordings at displays, training materials may include a video with a model explaining how to perform some task, computers in the office or home emit alerts and other auditory signals, and many systems rely on auditory stimuli to communicate system status information. Safe and efficient system interaction can depend on the user's

ability to hear normally, but audition is another perceptual domain wherein older adults show declines.

### 2.2.1  Auditory Acuity

In addition to an overall decrement in auditory acuity, age-related losses in hearing occur differentially across frequency ranges, with greater loss occurring for higher frequencies (greater than 8000 Hz) (Schneider and Pichora-Fuller, 2000; Fozard and Gordon-Salant, 2001). Furthermore, men have worse high-frequency perception than women (Moscicki et al., 1985).

***Design Implications and Suggestions***  A high-frequency stimulus is sometimes used as an alert or indicator in computer applications. Older adults, particularly males, may not perceive these stimuli. In fact, the age-related changes in auditory acuity suggest that high-frequency sounds should be avoided in any system or product that older adults might use. A high-frequency alert or indicator may be differentiated from background noise better than lower frequencies, but if it is not perceived, it is useless. If auditory stimuli are designed to attract attention when the user's vision is elsewhere, auditory alerts should not exceed 4000 Hz (Fisk et al., 2009). For non-alert-related stimuli, it is important to provide the user with control over the intensity of the stimulus. Because of individual differences in overall thresholds, volume control should be provided so that people can calibrate for themselves. However, often it is not sufficient to provide overall volume control but rather the ability to modulate various frequencies.

### 2.2.2  Localization

Data suggest that older adults are less adept at localizing sounds in space, specifically being prone to front/back localization errors (Abel et al., 2000). When high-frequency deficits occur, localization is more difficult in the elevation dimension (up vs. down) than in the azimuth (right vs. left) (Noble et al., 1994). Furthermore, higher frequency stimuli are harder to localize for all ages because high-frequency stimuli reach both ears at the same time (Lorenzi et al., 1999).

***Design Implications and Suggestions***  The reduced ability to localize high-frequency sounds is another reason to avoid high-frequency auditory stimuli. When an auditory stimulus is intended to direct the older user's attention to the source of the stimulus, the stimulus should be presented at between 5000 and 8000 Hz. Furthermore, auditory stimuli designed to orient attention should not be presented directly behind or in front of the user. This is especially relevant in workstations or other scenarios where the user is likely to remain in the same space. Sounds that must be localized should be presented for durations long enough for people to turn their heads and localize the sound, thus eliminating the error-prone front/back scenario.

### 2.2.3  Degraded Stimulus Environment

Noises are not often pure auditory stimuli. Many auditory signals as well as speech occur within a noisy environment—for example, at a workstation with the

hum of computer fans and conversing co-workers in the background. Research has shown that older adults have greater difficulty than younger adults perceiving speech in such degraded auditory conditions. There is some debate concerning whether the locus of the difference is primarily cognitive or perceptual (Schneider et al., 2000). Regardless of the absolute locus of the effect, noise degrades auditory perception more for older than for younger adults.

***Design Implications and Suggestions***   This difficulty in perception under noisy conditions demonstrates the importance of using cues in the visual modality instead of the auditory when presenting information in a potentially noisy environment. However, auditory cues can be used to augment visual cues via redundant or dual coding. Dual coding is beneficial even in quiet environments, as users' visual attention may be directed elsewhere when information needs to be communicated to them. Younger adults may perceive an auditory stimulus easily, but older adults will have more difficulty. Speech perception specifically can be hindered in high-noise environments, particularly if the people have poor hearing (Schneider et al., 2000). However, given that the locus of the problem is perceptual (as opposed to cognitive), age-related differences are likely to be evident for auditory stimuli other than speech.

For optimal perception, the signal should be presented independent of any noise. For example, in training materials, there should be no sound except for the relevant instructional materials (e.g., no background music). If the auditory signal can be amplified independent of background noise, users should be offered this capability (e.g., headphones at a museum display). If this is not possible (such as in the automated speech in an elevator or subway car), text should be presented to provide redundant information. Compressed speech is more difficult for older adults to perceive [although Sharit et al. (2003) indicate that 10% compression has little effect on young, middle-aged, or older adults]. It is recommended that speech rates not exceed 140 words per minute (Fisk et al., 2009). In public presentation of information, where ambient speech and other noise may be present, provide wireless headphones to amplify the signal, if feasible. Sound-absorbing materials on floors, walls, and ceilings may be used.

## 2.3   Haptics

Haptics can be defined as the sense of touch. Haptic sensitivity is assessed in a number of ways including thresholds (Grünwald, 2008). In many instances, older adults have higher thresholds for detecting an increase in temperature or an increase in vibration. Likewise, the ability to detect being touched by a single point versus two points shows a decline for older adults.

Grasping an object and maintaining a constant force require haptic control which also shows age-related deficits. Older adults have even more difficulty maintaining force control when simultaneously engaged in a cognitively demanding task (Voelcker-Rehage et al., 2006).

***Design Implications and Suggestions***   Together, these age-related changes in haptics degrades the quality of haptic information processing, with implications for successful interaction with technology. For example, if vibration is used as a cue, care should be taken in selecting vibration frequency. Sensitivity to low-frequency (25-Hz) vibration is relatively unimpaired with age through the decade of the 60s, but sensitivity to higher frequency vibration (60 Hz and above) shows linear decline with age from the teenage years.

With respect to sensititivey of touch, there is general more age-related loss in sensitivity for lower limbs compared to upper limbs. Therefore, upper body sites (e.g., hands) should be preferred to lower body ones (e.g., feet) for conveying haptic information.

## 3   COGNITION

### 3.1   Attention

Attention is not a unitary scientific construct. Indeed, there are well-known varieties of attention (James, 1890/1950; Parasuraman and Davies, 1984). Closely linked to visual perception is the construct of useful field of view which incorporates both visual processing speed and attentional capacity.

Two general categories of attention are selective attention and attentional capacity. Research on selective attention has focused on the ability to focus on and process a restricted set of goal-relevant information while ignoring available information that is not relevant to the goal (Johnston and Dark, 1986). Attentional capacity research has investigated the amount of "mental work" that humans can perform at a given time, often employing dual-task methods, where the trade-off in performance between the two tasks can provide a measure of attentional capacity given to each task. Selective attention and attentional capacity are affected deleteriously by age (see Rogers and Fisk, 2001, for a review), but certain interventions and design provisions have been shown to reduce these decrements to some degree.

### 3.1.1   Useful Field of View

Useful field of view (UFOV) refers to the size of the visual field that may be perceived in a single glance and is a measure of both processing speed and attention (Owsley et al., 1991; Roenker et al., 2003). That is, UFOV can be thought of as the subset of the total visual field that is available for processing (thus, the similarity with the construct of attention). The UFOV may change within a person, depending on the nature of the task being performed (Owsley et al., 1991). For example, one's UFOV may be larger when driving on a road with no traffic, whereas one may experience the phenomenal sense of constricted vision when driving in the rain and heavy traffic. Research has shown that older adults have a restricted UFOV which has been linked to driving accidents (Owsley et al., 1991; Roenker et al., 2003).

***Design Implications and Suggestions***   The broad implications for changes in UFOV are that practitioners cannot assume that a user will necessarily notice, use, or respond to information falling within the visual field.

Age must be considered, and under some circumstances the UFOV of the user population might need to be assessed directly. With training, as people are able to perform subtasks more efficiently, the UFOV can effectively be increased. Thus, the implications for design are to know the UFOV of the user population in the context of the task, to ensure that stimuli are presented within their UFOV, and if necessary to provide training to increase UFOV for the users.

### 3.1.2 Selective Attention

Selectively attending to goal-relevant stimuli and ignoring goal-irrelevant stimuli are required for efficient performance in any task. Selective attention involves purposefully shifting attention to different stimuli and categories of stimuli in the environment. For example, when driving, a person may be actively searching for certain elements or groups of elements, such as other cars, pedestrians, and traffic signs and signals. Irrelevant stimuli such as a car alarm or brightly colored or waving advertising sign can distract the driver momentarily. The degree of susceptibility to distraction and the duration of the distraction can obviously have severe consequences in this task domain and in others. Older adults are susceptible to distracting effects of irrelevant stimuli in the environment (Rogers and Fisk, 2001).

***Selective Inhibition Deficits*** There has been considerable research in the field of cognitive aging, suggesting that older adults have relatively more difficulty inhibiting irrelevant information (e.g., Hasher and Zacks, 1988; Stoltzfus et al., 1993). However, there is not a general deficit of inhibition because certain inhibitory systems appear unaffected by aging (e.g., Connelly and Hasher, 1993; Kramer et al., 1994). For example, younger and older adults were equally able to adjust their focus of attention to include or exclude information (Hartley et al., 1992), suggesting that older adults, in this case, did not have greater difficulty inhibiting irrelevant information. Older adults were also able to inhibit the location of irrelevant stimuli as well as younger adults, although they were impaired relative to younger adults in their ability to suppress the identities of irrelevant stimuli (Connelly and Hasher, 1993).

This reduced efficiency in selectively deploying attention can have deleterious consequences for performance, especially in highly attention-demanding tasks such as driving. Older adults seem to be inefficient in searching novel visual environments, for example, searching in the same area repeatedly (Maltz and Shinar, 1999), suggesting that they are not monitoring where they have searched previously. In this driving-based task, adults were less likely to maintain attention in a search task, less likely to discriminate previously attended areas, and less likely to attend selectively all relevant areas of the display. It is important to note that after extensive consistent training search performance is still slower for older adults, but the qualitative aspects of the search, such as the learning curve, are similar for younger and older adults (Fisk and Rogers, 1991).

***Attending to Multiple Tasks*** Younger and older adults appear to deploy attention differently across multiple simultaneous tasks after training (Sit and Fisk, 1999). Younger and older participants viewed a screen with a different task in each quadrant and were encouraged (via a points-based system) to attend primarily to one task over the other three (but overall performance was encouraged as well). After training on the multiple-task display, older adults were still performing at a lower level than younger adults, although age-related differences in performance had lessened over training. They were then required to attend more to a different task at transfer—that is, the task demands did not change, but the way in which attention was deployed was changed. Older adults focused primarily on the newly important task to the exclusion of the rest of the tasks. Younger adults were able to perform effectively on three of the four tasks, including the newly important task. The findings suggested: (1) age-related differences in a divided attention task requiring different selective attention allocation strategies are attenuated after training and (2) older adults are less able than younger adults to strategically change the way in which they perform a previously learned task.

***Design Implications and Suggestions*** Age-related changes in selective attention must be carefully considered in any environment in which multiple stimuli are presented. Tasks and environments with multiple displays and controls, such as driving, cockpits, security and surveillance tasks, medical displays, and industrial control panels, all require the user to attend to a subset of a multitude of auditory and visual stimuli in the environment.

One way to improve older adults' ability to select goal-relevant stimuli from a distraction-filled environment is to increase the perceptual salience of the goal-relevant stimuli (or decrease the salience of distracting stimuli) (Shaw, 1990, 1991). When the physical stimulus is improved, the contrast between goal-relevant and goal-irrelevant stimuli is increased, and the relevant cue can be used more efficiently. This form of environmental support can help guide a user's selective attention to relevant stimuli (for review see Morrow and Rogers, 2008).

In addition to increasing the perceptual salience of relevant stimuli, whenever possible, these stimuli should be made salient to the user via explicit means as well. For example, older users should be told how best to differentiate and ignore distracting stimuli (i.e., essentially giving older adult users a specific strategy to follow). Consider using an instructional manual to put together a complex product. The manual may include information about safety, rebates, warranty information, and so on, in addition to the specific, sequential assembly information. In designing this manual, the actual assembly steps should be perceptually salient, relative to other information in the manual. For example, assembly steps should be boxed in a particular color or set off with bold header information. This enables older users to better identify the relevant assembly information in a field of irrelevant information (for the assembly

task). Furthermore, the designers of the manual should explicitly inform the user of the cues they should be looking for, as opposed to requiring users to recognize the relevance or meaning of different cues on their own.

Older adults' attention is more likely to be drawn to perceptually salient stimuli in the task environment. It is important to minimize the attention-attracting nature of irrelevant stimuli. Attention-attracting perceptual characteristics include flashing, moving, bright, loud, and unexpected stimuli. Through training, older adults can improve their ability to successfully select a subset of relevant stimuli. This critical finding suggests that the decrement in selective attention is, at least in part, a more labile age-related change and that, with training, older adults are capable of selecting important stimuli among distracting stimuli. Hence, in situations requiring selective attention, training should be given to users until the criterion performance level is reached.

### 3.1.3  Attentional Capacity

**Divided Attention**   Users can attend to and cognitively process a limited amount of information at a time. The hypothetical construct of attentional resources has been used to explain the capacity to process, think about, and cognitively manipulate information at a given time (Wickens, 1984). Older adults are presumed to have a reduction in the processing resources available to them to perform attention-demanding tasks (e.g., Crossley and Hiscock, 1992). For example, older adults have relatively more difficulty maintaining appropriate levels of performance when required to perform multiple tasks at once (Kramer and Larish, 1996), that is, under divided-attention conditions. Clearly, older adults experienced a greater decrement in performance transferring from single to dual tasks than did younger adults (see, e.g., McDowd and Craik, 1988). In a study of dual-task performance, testing the efficacy of various vehicular travel aids for different age groups (e.g., automated visual map aids, synthetic speech, paper maps), older drivers had more safety-related errors in this dual-task environment than did younger adults (Dingus et al., 1997). However, when redundant auditory guidance was provided in addition to the automated map aid, older adults performed more safely than without the redundant information.

**Visual Clutter**   Even within what seems to be a single task, attention can be overloaded and performance can suffer. In a search-type task performed on a busy, noisy visual display, people are required to orient and reorient their attention as they scan the display. As stimuli become more similar or increase in number, identifying and comparing stimuli become more demanding (Shiffrin, 1988). In general, older adults have more difficulty in higher clutter environments (e.g., Schieber and Goodspeed, 1997). In an investigation of the effect of clutter in a typical driving scene (i.e., a typical two-lane rural highway, a commercial district in a small city, and a downtown metropolis scene), older adults' speed and accuracy at detecting target signs were considerably poorer than younger adults (Schieber and Goodspeed, 1997). This pattern was observed whenever even a small amount of clutter was present.

**Automatic Processing**   With repeated exposure to consistent stimulus mappings, people can be trained to automatically attend to and respond to stimuli that are consistently meaningful in the task (e.g., targets in a search task). This has been termed an automatic attention response (Schneider and Shiffrin, 1977; Shiffrin and Schneider, 1977). Consistent mapping refers to the degree to which stimuli belong to a given category when they appear. In experimental search tasks, consistent mapping occurs when target stimuli never appear as distractor stimuli and distractor stimuli never appear as targets. The concept of consistent mapping (and conversely, varied mapping) extends directly to natural tasks such as driving (brake lights are consistently paired with a slowing of the vehicle) and computing (icons are consistently mapped with the applications they represent, and keyboard keys are consistently mapped with respect to their location and function). For these consistent features in the environment, younger and older users can develop very quick and accurate responses, but older adults' responding will be less efficient than younger adults'.

An automatic attention response can be important in the fast, accurate detection of stimuli in the environment. For example, brake lights may cause a driver automatically to attend to the lights and respond by braking, given enough exposure to consistent instances of brake lights co-occurring with the slowing of the vehicle ahead. Older adults may not develop new automatic attention responses to learned stimuli in visual search tasks, but considerable performance improvements occur under consistent conditions (Fisk et al., 1988; Fisk and Rogers, 1991; Rogers, 1992).

### Design Implications and Suggestions

**Performance Gains with Training**   Consider the plight of novice drivers. In this new environment, with new displays and controls, there are a host of stimuli to monitor, to search for, and perhaps to respond to. Each and every scenario is completely new, and even after some experience, novel instances occur with high frequency (e.g., rarer scenarios such as passing a cyclist or avoiding a large pothole). For these novice drivers, speaking to a passenger (let alone speaking on a mobile phone), adjusting the radio, or waving to someone on the sidewalk can be difficult and error prone (in either the main driving task or the secondary task). However, over time, considerable learning occurs. Similar instances occur multiple times and are remembered, allowing faster responses subsequently. The location of the gas, clutch, and brake pedals are quickly located and never confused. Eventually, attention can safely be divided between driving and other tasks. In the same way, through sufficient, appropriately designed training, performance on a task can become considerably more efficient. Older adults' performance can improve greatly through such experience, and this is the goal of training programs. For example, initial age-related differences in a divided-attention task can be attenuated (though still present) after training (e.g., Rogers et al., 1994; Sit and Fisk, 1999).

**Part-Task Training** To reduce the demands on attention in dual-task conditions, participants can be trained on certain parts of the task at different times before being trained on the whole task—that is, part-task training. For example, participants without computer experience must often undergo mouse training before beginning a study involving computers with mice as the control. Thus, participants are able to devote a majority of their attention to the experimental task instead of dividing their attention between an untrained, novel device and the task. To assess the benefits of part-task training, Kramer et al. (1995) presented a dual-task condition to older adults, with half of the participants required to devote an equal amount of attention to each task and the other half required to pay more attention to one task at certain times and to the other task at other times. Thus, the second group practiced on, essentially, only part of the task at different times throughout training. By the end of training, older adults in the part-task group demonstrated considerably more learning than those in the first group.

**Redundant Information** When information can be presented redundantly in certain dual-task conditions, older adults benefit from the reduction in task demands (e.g., Dingus et al., 1997). Redundant information has been shown to be important in cluttered environments as well. Thus, providing redundant information may be a means of providing environmental support to compensate for age-related reductions in attentional capacity.

**Clutter in the Visual Environment** The effects of clutter in a visual environment such as driving can be very detrimental to performance, particularly for older adults. Older adults spend more time than younger adults searching in a cluttered environment and spend more time making decisions about stimuli (Ho et al., 2001). This can obviously be detrimental to driving performance and to one's safety. However, this situation can be ameliorated if the user is provided attentional cues designed to support the user's performance. This sort of environmental support was tested for younger and older participants in a driving simulation task that involved making quick decisions about whether a left-hand turn could be performed safely (Staplin and Fisk, 1991). When normal driving contextual information was present in the task (i.e., clutter stimuli such as lampposts, trees, and houses), both younger and older adults benefited from receiving a cue about the future status of the intersection, thus aiding their left-hand-turn decision.

### 3.2  Memory

Memory can be divided into three general stages. If information is to be remembered, it must first be encoded, then it must be stored or represented in some way in the brain, and then it must be retrieved from storage. Within this basic framework, researchers have focused on various types of memory, such as memory for information that occurred at a certain time and place, memory for facts, memory for procedures, memory to do something in the future, and memory for the source of information.

**Table 3  Five Conclusions about Memory and Aging**

| Conclusion | Examples |
| --- | --- |
| Older adults maintain their semantic memory, but their ability to retain episodic memories is decreased. | Older adults can remember the names of friends they would like to email, but remembering a new email password will be difficult. |
| Maintenance of episodic memories can be particularly hampered when atypical, distracting elements are present when retrieval is attempted. | Older adults are more likely to forget to pick up milk on the way home if traffic is unusually hectic. |
| The retention of habits, or processes performed automatically, is relatively spared in older adults. | Although learning a new software package may be difficult, older adults retain the learned ability to type. |
| Working memory capacity is reduced in older adults. | Older adults will need to play back a set of auditory instructions more times than younger counterparts. |
| When older adults are required to perform self-initiated processes, memory is more difficult. Environmental support can reduce these difficulties. | Older adults will have difficulty recalling the color, make, and model of a hit-and-run vehicle, but if given a lineup, they will probably be able to identify the correct vehicle. |

*Source*: Adapted from Fisk and Rogers (2002).

Age-related declines in some aspects of memory (such as working memory and episodic memory) are well documented (Zacks et al., 2000). In some cases, these age-related declines can be improved by placing information in the task environment, instead of requiring people to maintain the information in memory (Morrow and Rogers, 2008; see Table 3 for several memory conclusions). In other cases, there are minimal changes across the lifespan, such as in semantic memory (memory for facts) and procedural memory (memory for how to perform an activity or sequence of actions; Zacks et al., 2000).

### 3.2.1  Working Memory

Working memory can be thought of as information that is actively being processed and "used" (Baddeley, 1986). Similar to the concept of capacity limitations on attentional processing, it is typically measured via span tasks, which measure the number of elements that can be kept activated in working memory. Reduced working memory capacity in older adults is a hallmark finding in the cognitive aging literature (see Zacks et al., 2000, for a review), and a meta-analysis of the literature revealed a sizable age-related difference (Verhaeghen et al., 1993).

***Design Implications and Suggestions*** The well-documented age-related decrement in working memory capacity has clear implications for designers. Older users should not be required to keep multiple items in memory. E-commerce websites should provide comparison programs that allow customers to compare similar products as opposed to keeping in memory variables such as price and features. A telephone voice menu should have deep as opposed to broad menu structures, so that users do not have to keep too many options in memory before they make a selection. In general, information should be displayed to the user (i.e., putting the information in the environment), as opposed to requiring users to rely on their working memory.

### 3.2.2   Episodic Memory

Significant age-related differences exist in the ability to recall various events and instances which are referred to as episodic memories. In a typical episodic memory study, participants are shown stimuli and asked to recall them at a later time (see Tulving, 2002, for a review). Age-related deficits in these tasks are commonly found. In this section we discuss two ways that this fundamental age-related difference in memory can be addressed and supported: memory strategies and supportive information.

***Memory Strategies*** When older adults are required to elaborate internally the stimulus to be remembered, it is later recalled with greater accuracy (Park et al., 1990b; Verhaeghen et al., 1993; Dunlosky and Hertzog, 1998). For example, when older adults are required to generate words for later recall as opposed simply to reading a list, they recall more accurately (Hirshman and Bjork, 1988; Johnson et al., 1989). Some studies have demonstrated that older adults may engage in suboptimal encoding strategies, which may explain their relative deficit in remembering (Rogers and Gilbert, 1997; but see Dunlosky and Hertzog, 1998).

In assessing older adults' associative learning ability, Rogers and Gilbert (1997) found that some older adults chose continually to use an inefficient strategy to perform a task, whereas nearly all the younger adults employed the optimal strategy. The task presented a consistent set of word pairs at the top of the screen and a test word pair in the center. Participants were required to indicate whether the test pair was one of the pairs at the top of the screen. The task involved multiple trials, such that it was optimal to attempt to memorize the word pairs above as opposed to searching for a match on each trial. Older adults were less likely than younger adults to adopt optimal strategies spontaneously in this associative learning task, but they were able to use the optimal strategy if encouraged to do so. A larger study of individual differences with this same task replicated the finding that older adults were less likely overall to adopt an optimal strategy (Rogers et al., 2000). However, for those older adults who did adopt the appropriate strategy, the age-related differences in learning were reduced. Taken together, these studies suggest that in certain cases older adults' performance may be improved by providing optimal strategies for performing a task.

***Cognitive Support*** Memory researchers have conducted numerous studies testing the effects of memory cues and aging. Relatively few studies have shown a greater benefit of memory cues for older adults than for younger adults; however, in general, these studies show that older adults' memory can be improved through the use of memory cues. For example, adults of all ages increase their recall when some aspect of the stimulus is present at recall (e.g., a word fragment vs. freely recalling a word); this is the basis for Craik's environmental support framework (Craik, 1986). Memory retrieval has also been shown to increase when stimuli are studied in a visually distinctive context (Park et al., 1990a). Younger and older participants studied a set of different objects on either a colorfully distinctive background or a plain background. They were later asked to place either labeled note cards or the original items back in the original spatial arrangement. Both age groups benefited equally from the distinctive background condition as well from the use of the original items.

In another study, researchers presented target words (i.e., words to be remembered) to older and younger adults, either integrating the target with an object in the environment (e.g., "The key fit the lock on the file cabinet," where a file cabinet was in the test room) or integrating the target with an object not in the environment (e.g., "The key fit the lock on the car," where no car was present in the test room) (Earles et al., 1996). Younger adults benefited more than older adults from this combination of environmental cues and the target word.

***Design Implications and Suggestions***

**Strategy Suggestions** Older adults' episodic recall can be improved through the use of different strategies. One of the more commonly used is a form of encoding elaboration. For example, to remember a pair of words better, it can be helpful to construct a distinctive, imagistic sentence or concept that links the two words (e.g., "dog" and "spoon" → "The dog balanced the spoon on its nose"). Other heuristics can be employed, such as creating acronyms from a series of words to be remembered, repeating a set of instructions, or creating a link between a stimulus and some internal concept. However, many people do not use such memory strategies spontaneously outside the lab. Therefore, a training system should provide strategy suggestions when memory is required.

Although older adults are not as likely as younger adults to adopt optimal strategies spontaneously, they are able to utilize these optimal strategies if encouraged to do so. There are a number of workable methods for encouraging participants to use memory strategies. These include explicitly instructing the participants (Hulicka and Grossman, 1967; Haider and Frensch, 1996; Nichols and Fisk, 2001), pretraining on an orienting task that makes apparent the optimal strategy (Hulicka and Grossman, 1967; Doane et al., 1996; Rogers and Gilbert, 1997), or giving intertask tests that will encourage use of the desired strategy (Rogers and Gilbert, 1997).

**Physical Reminders** Given older adults' knowledge about their memory capabilities, physical reminders can play an important role in older adults' lives. Older adults

reportedly use various physical reminders for medications (Park et al., 1992; Sanchez et al., 2003), and adults over age 71 years benefited most from the physical reminders (Park et al., 1992). Some suggestions for reminders include the following:

1. Physical reminders should be placed in visually salient places, where the person will see them. For example, one can place medications for the following day next to one's toothbrush at night.

2. Given age-related issues in *source monitoring*, the ability to remember the source of an event, the reminder should provide relevant information instead of simply reminding that there is *something* to be remembered.

3. Automated visual and auditory reminders, such as those used in calendaring software, can minimize the need for older adults to search actively for the reminder.

**Environmental Support Framework**  Older adults' memory should benefit from distinctive contexts insofar as the context is present when retrieval occurs. The context serves to provide additional retrieval cues for the person. Thus, if the context is absent, recollection may be harmed. The environmental support framework is based on the notion that older adults appear to have more difficulty with effortful, internally driven processes, such as freely recalling an event or appropriately employing a task strategy (Craik, 1986; McDowd and Shaw, 2000; Morrow and Rogers, 2008). Because of these difficulties, older adults rely more on contextual or environmental information to aid their performance. Thus, providing useful information in the environment of a task can aid performance. However, because there is inevitably distracting stimuli in the environment in addition to the supportive information, older adults may have difficulty ignoring the irrelevant stimuli.

If memory requirements in a task are offset by the existence of readily accessible information in the environment, attentional and memory processes can be allocated elsewhere, to more demanding aspects of a task. For example, in a typical software application, instead of using function buttons with icons only, at least provide the option for turning on text labels, which eliminates the need for novice users to experiment with and memorize the functions of the buttons.

Environmental support can come in various forms:

1. Provide some characteristic of the stimulus to be recalled to aid, or cue, recollection.

2. Provide an outline or map of the material. For Web browsing tasks, navigation aids should be provided if desired by the user. These can provide a visual history of where the user has been, reducing the reliance on memory for the structure of the website.

3. Physical aids constitute a form of environmental support. They serve to remind the user of the previous encoding instance. Specific aids, or cognitive prosthetics, can be used to assist older adults' memory (Morrow, 2003)—for example,

software designed to store grocery lists and to recommend items that have been purchased commonly in the past.

4. Structuring text appropriately can benefit recall of the text.

5. Search and detection of target stimuli benefit from consistent arrays of irrelevant stimuli (Chun and Jiang, 1998; Jiang and Chun, 2001). That is, attention can be guided to targets by the knowledge gathered from the consistent arrays of distractor stimuli.

### 3.2.3  Prospective Memory

Prospective memory involves remembering to do something in the future and is essential in planning and completing general daily activities (e.g., fulfilling appointments, performing household chores). It can also be critically important for safety, such as remembering to take medications or turn off the oven. There are two categories of prospective memory—time based and event-based—which differ in the degree to which the rememberer must rely on self-initiated cues (Einstein et al., 1995; Park et al., 1997). In event-based prospective memory, the person is cued about the to-be-remembered information by some external event or stimulus (e.g., remembering to take a medication when a timer goes off); whereas in time-based prospective memory, the person must remember after some amount of time has passed (e.g., remembering to take a medication at two o'clock in the afternoon). As is typically found in cognitive aging, when self-initiated processing is required, older adults' performance suffers (Craik, 1986), and age-related differences in prospective memory are greater for time-based situations (Einstein et al., 1995).

Although older adults' prospective memory is impaired relative to younger adults (Park et al., 1997; Zacks et al., 2000), the memory phenomenon under heavy task demands may provide a better representation of prospective memory in real tasks. Under these demanding conditions, age-related differences are exacerbated. Einstein and colleagues (1997) investigated prospective memory in the context of additional, distracting activities (essentially, a divided-attention manipulation). They found that older adults had a more difficult time remembering to do the to-be-remembered action than younger adults when attentional demands were high.

***Design Implications and Suggestions***  Older adults' difficulty with prospective memory has important implications for the design of memory aids and reminders. Physical reminders such as cognitive prosthetics are critical in reducing the functional effects of the prospective memory age-related difference. Whenever prospective memory is required (such as in remembering to take one's medications at various points throughout the day), time-based prospective memory tasks should be turned into event-based memory tasks. Alerts can be built into cell phones or personal digital assistants (PDAs) or other small, unobtrusive devices, providing users with a memory aid. Essentially, these

function as environmental supports, reducing older adults' need to rely on self-initiated memory processes.

### 3.2.4 Source Errors

As with all human memory, recall for the context in which a memory was first created is not necessarily reliable (Johnson et al., 1993). For example, one might recall that a car owner's manual provided information about an automotive repair but not in which section of the manual it occurred in (i.e., external source monitoring). Several studies have shown that older adults are poorer than younger adults at source monitoring (Cohen and Faulkner, 1989; Ferguson et al., 1992; Johnson et al., 1995). For example, when the source of information was distinct (i.e., the gender and appearance of two speakers), older adults' source monitoring was on par with younger adults (Ferguson et al., 1992; Johnson et al., 1995). However, older adults were less able to utilize multiple cues to aid their memory for source (Ferguson et al., 1992), and when additional cognitive processing was performed between source and test, older adults had difficulty retaining the link between the distinctive perceptual source information and other aspects of the source, such as what the source said (Johnson et al., 1995).

***Design Implications and Suggestions*** Older adults' memory for source can benefit from perceptual disambiguation. In the repair manual example above, the chapters may be made more distinct by using different-colored paper in each chapter. The memory for a given chapter includes the color of the paper, and this memory for color may be cued when the user flips past that color in the manual. Thus, the user does not need to actively retrieve the section of the manual but, instead, can easily recognize a particularly salient feature.

Because memory for source is impaired in older adults, particularly under intervening cognitively demanding conditions, memory aids should be provided to reduce the need for older adults to rely on self-initiated retrieval processes. For example, an older adult may not recall whether medical advice was given to them by their doctor or by a friend. This problem could be reduced if all medical advice given by their physician was also provided to them via a text file or printed transcript. This added information would serve as a redundant cue to the information source and provide the information in the world, rather than requiring the person to rely on memory for the source.

### 3.2.5 Semantic Memory

Despite the general negative view of aging and memory presented thus far, there are several characteristics of memory and knowledge that remain relatively robust across the lifespan, most notably, semantic memory (memory for facts or general knowledge, sometimes referred to as crystallized knowledge; Cattell, 1963). Designers should take advantage of older adults' relatively preserved semantic memory.

Semantic memory has been used to improve older adults' memory for events in the future, specifically in the domain of medication instructions and health appointments. For example, using older adults' schemata (or crystallized knowledge structures about some domain) about a given memory task can be used to construct aids to help them in the memory task (Morrow et al., 1998, 2000). Younger and older adults share a schema for how medication reminders should be worded and arranged—specifically, they preferred shorter messages, incorporating, in order, time to take a medication, required dosage, duration one should take the medication, health warnings, and side effects (Morrow et al., 2000). When this schema knowledge was incorporated in an automated phone message application to present medication information in a way that followed their schema of presentation or violated the schema, both younger and older adults benefited from the schema-consistent version, such that they recalled the relevant information more accurately.

***Design Implications and Suggestions*** Older adults' knowledge of existing systems and devices can be used as a tool to design systems that can easily be used and understood by older adults. Knowledge engineering, a technique that facilitates the understanding of how tasks are performed by gathering the knowledge used within a specific process, is a critical phase in the design process, particularly with older adults, given their differences in knowledge and experience. Furthermore, older adults' crystallized knowledge may be extended to novel domains, where their knowledge can be transferred to similar novel applications and technology (this idea is discussed in Section 5.2).

## 3.3 Language Comprehension

Language comprehension is heavily reliant on semantic memory (i.e., one's crystallized knowledge base) as well as on working memory capacity. Language comprehension remains a critical function of people's lives as they age. With advancing age, people must be able to efficiently read labels of new medications, the instruction manuals of novel devices such as wheelchairs and health-related devices, and the warning materials that accompany these and other products and systems.

Often, older adults perform well in comprehending spoken and written language (Wingfield and Stine-Morrow, 2000). For example, they are able to comprehend figurative language as well as younger adults (Szuchman and Erber, 1990), and they are able to create an appropriate mental representation of text (Radvansky et al., 1990). However, there are several factors that can negatively influence older adults' comprehension of spoken and written language, more so than for younger adults. In general, these are related to demands on working memory (see Wingfield and Stine-Morrow, 2000, for a review).

### 3.3.1 Sentence Structure

Comprehension can be improved by reducing processing demands on older readers. For example, working memory can be taxed if many words and clauses bisect the subject and verb in a sentence (Norman et al., 1992; Wingfield and Stine-Morrow, 2000). Left-branching sentences contain a particularly difficult clause, as it comes between the subject and verb in the main clause

and requires the maintenance of the subject while simultaneously processing the embedded clause. Left-branching sentences are particularly detrimental to older adults' comprehension (Norman et al., 1992).

***Design Implications and Suggestions***   When designing instructions, warnings, and other text-based materials, the limitations of older adults' working memory should be considered. Comprehension will be improved if subjects and predicates are near each other, minimizing the need to keep the subject of the sentence in working memory for long periods. Following the guidelines put forth by Norman et al. (1992) and Kemper (1987) can greatly improve the readability of text, primarily by reducing the demand on working memory (see Table 4). For clearest writing, subject and predicate should be within close proximity.

### 3.3.2   Inferencing and Figurative Language

Research suggests that older adults are at a disadvantage relative to younger adults in making appropriate inferences (Hamm and Hasher, 1992). Furthermore, this age-related difficulty may be exacerbated in instances where older adults cannot rely on their crystallized knowledge (Arenberg and Robertson-Tchabo, 1985; Hancock et al., 2005). Older adults interpret figurative language well (e.g., metaphors) (Szuchman and Erber, 1990). The use of figurative language taps the rich structure of knowledge that older adults have built across their lifetime and allows them to constrain their inferences with that knowledge.

***Design Implications and Suggestions***   Often, it is necessary to make inferences beyond what is present in the text. For example, if a user manual for a lawn mower tells the user to "disable the starting mechanism before replacing the blade," an important inference one might make would be that one should also disable the starting mechanism before removing debris from the undercarriage of the mower. It is important to minimize the need for inferencing beyond the text. This can be especially critical in the construction of warning materials (Hancock et al., 2005). Older adults' ability to interpret figurative language combined with their high degree of semantic knowledge suggests that considerable information may be communicated through brief figurative text. That is, the figurative text cues older adults' extensive and rich semantic network of knowledge, potentially communicating considerably more information than is solely within the figurative text. This can be especially useful in the design of space-limited text, such as warning labels on pill bottles or cleaners, where space is severely restricted.

## 3.4   Executive Control

The term "executive control" encompasses a number of cognitive abilities related to the maintenance and updating of cognitive and behavioral goals, the planning and sequencing of actions, problem solving, and the inhibition of automatic responses. These abilities tend to demonstrate substantial decline with advancing age, and the brain regions that subserve these functions demonstrate the most dramatic age-related atrophy (Resnick et al., 2003). Additionally, performance on measures of fluid intelligence suffers with increasing age (Bugg et al., 2006). Declining executive control has been demonstrated to take a substantial toll on older adults' ability to function independently (Royall et al., 2004). Thus it is reasonable to assume these changes will influence how older adults interact with products and systems.

***Design Implications and Suggestions***   Age-related declines in executive control suggest older adults may perform especially poorly in multitasking environments and on complex tasks involving the coordination of multiple subtasks. However, although task coordination and multitasking demonstrate age-related impairment, evidence suggests that training can mitigate age effects (Kramer et al., 1999). Variable priority training (VPT), in which learners practice the whole task while at different times emphasizing performance of different task subcomponents, has proven especially effective (Gopher, 2007). A number of studies have found that VPT improves the performance of older adults on complex tasks in which age-related differences in executive control are evident (Bherer et al., 2005; Kramer et al., 1995). As a general rule, the designer should also provide environmental support in the form of salient sensory cues to indicate when a particular task or subtask requires attention to minimize reliance on executive control (Wickens and Seidler, 1997). In dual-task or multitasking environments, consistent mappings between tasks and their responses should be maintained to minimize cognitive effort of switching from one task to another.

**Table 4   Examples of Cognitively Demanding Prose**

| Example | Problem | Revision |
|---|---|---|
| To change the level of the fluid in the round canister above the rotary encoder and the pressure dial, rotate it clockwise. | The reader must identify the referent for the pronoun "it." There are several intervening phrases between the pronoun and referent, causing a load on the reader's working memory. | To change the level of the fluid in the round canister, rotate the canister clockwise. The canister is located above the rotary encoder and the pressure dial. |
| The screw that is used to secure the tray above the cabinets so that the compartment is accessible is located in the yellow bag. | The subject ("screw") and predicate ("is located") are separated by a long clause, causing a load on the reader's working memory. | Locate the screw in the yellow bag. This screw is used to secure the tray above the cabinets so that the compartment is accessible. |

## 4 MOVEMENT AND BIOMECHANICS

### 4.1 Movement Speed

Movement speed is the speed with which a person can make a movement after the requisite cognitive processes to start the movement have occurred (Spirduso, 1995). In general, older adults are slower in their movements than younger adults (Stelmach and Nahom, 1992). Figure 5 shows the typical finding of greater overall time to make a reaching movement for older adults relative to younger adults and the slower peak velocity.

***Design Implications and Suggestions*** Reductions in movement speed are relevant to a wide range of activities and scenarios performed by older adults. Traffic light timers should be set to provide adequate walking time for older pedestrians. The required double-click speed for mouse buttons on public computers should be amenable to older adult users. Other examples include the speed of revolving doors, self-operated credit card terminals, and the time required for text entry in cell phones. Any task that requires relatively rapid movement is potentially difficult for many older users.

### 4.2 Movement Control

In effect, older adults will be slower in tasks that involve grasping (Carnahan et al., 1993), reaching (Seidler-Dobrin and Stelmach, 1998), and continuous movement (Wishart et al., 2000). Their movements involve more submovements and shorter initial primary submovements than those of younger adults (Walker et al., 1997; Seidler-Dobrin and Stelmach, 1998; Smith et al., 1999). This essentially results in slower, more variable movements in older adults. Furthermore, as a movement task becomes more difficult, older adults slow at a greater rate than do younger adults (Ketcham and Stelmach, 2001).

Age-related differences in computer mouse performance have been reported. For example, in four common mouse tasks—pointing, clicking, double clicking, and dragging—older adults were slower in their movements, produced more submovements, and made more

errors, particularly for double-clicking tasks (e.g., moving out of the icon range before it was double clicked) (Smith et al., 1999; see also Walker et al., 1997). Also, older adults are less able to coordinate multiple movements with multiple body parts as well as younger adults, such as bimanual tasks (e.g., twisting off a lid) (Stelmach et al., 1988).

***Design Implications and Suggestions*** The variability in movement control and speed contributes to older adults' greater variability in their use of input devices, both within and between people (Rogers et al., 2005). It is possible that with increased perceptual feedback older adults can be trained to lengthen their initial movements, thereby also reducing the required number of submovements. For example, mice could be operated in conjunction with software that provides tactile feedback as the cursor nears an icon or target. "Sticky" icons have been employed that attract the cursor, within some user-defined sensitivity range. Users should be provided with the option to increase icon size, effectively improving the physical stimulus.

Older adults have been shown to have difficulty decelerating as they approach a target and trouble staying at the target once reached (Smith et al., 1999). This is consistent with the common finding that older adults employ more submovements as they home in on a target (Walker et al., 1997). Discrete hand movements are often required in computer tasks, whether with a mouse, touch screen, light pen, or other input device.

In software design, icons should be a reasonable size, as older adults have difficulty navigating to small targets (Walker et al., 1996). Furthermore, older adults are slowed in their navigation more than younger adults by targets embedded with other stimuli (Rogers et al., 2005). Thus, in addition to making icons and target stimuli easier to select, creating appropriately sized icons can help to separate those relevant targets perceptually from irrelevant or background stimuli.

Older adults' difficulty with coupled movements and other movement coordination tasks can cause

**Figure 5** Examples of a younger adult's and an older adult's velocity profiles in a reaching task. Note the longer time to make the movement and greater variability during the deceleration stage in the older adult profile. (Adapted from Ketcham et al., 2002.)

problems for bimanual tasks, such as opening a twist-top pill bottle or reaching and grasping coordinated movements. Thus, products that require a coordination of multiple movements should be redesigned if possible. For example, pill bottles designed for older adults should employ a tabbed top.

### 4.3 Balance

Falls due to loss of balance are a serious problem for older adults (Horak et al., 1989; Agnew and Suruda, 1993). Postural sway increases with age (Borger et al., 1999; Kristinsdottir et al., 2001), leading to loss of balance and falls. Postural sway is affected by several variables, including poorer vision, which reduces older adults' ability to detect movement cues in the environment that would indicate sway; reduced sensitivity to vibrations in the lower limbs, which reduces the contraction signals sent to muscles (Kristinsdottir et al., 2001); and cognitive demands (Lajoie et al., 1993; Brown et al., 1999; Melzer et al., 2001). It appears that older adults rely more on dynamic visual cues to aid in their balance. When visual cues indicated that they were moving (although they were in fact stationary), older adults were much more likely to exhibit postural sway (Borger et al. 1999). Older adults also tend to have greater postural sway (relative to younger adults) when in a moving visual environment, and when flooring was more compliant (e.g., carpet vs. hardwood flooring), age-related differences in postural sway were greater (Redfern et al., 1997).

Balance is affected by cognitive demands. When participants were asked to perform simple subtraction while stationary and while recovering from a small movement of the platform on which they were standing, older and younger adults performed similarly on the subtraction task prior to perturbations of their platform. However, older adults were repeatedly and significantly slower after a perturbation, suggesting that the cognitive demands of maintaining balance interfered with their ability to perform the subtraction task (Brown et al., 1999).

***Design Implications and Suggestions*** Because older adults may be more prone to losing their balance while getting on and off moving sidewalks, warnings should be provided with a long lead time prior to the need to correct posture. Apparent motion and true motion in the environment can also increase the likelihood that older adults will lose their balance due to their reliance on perceptual cues. Examples include wall-sized animated advertisements and moving subway cars. Environmental support may be provided to reduce this problem. For example, in designing platforms in front of moving subway cars, a row of lights can be provided above the railway cars, resulting in a stationary stimulus to counter the perceptual cues of the train. Cues may be beneficial in other contexts as well. On walls next to stairs and pedestrian ramps, arrows can be displayed indicating the direction of the change of slope in the walkway. For any scenario where balance may be an issue, handrails are highly recommended.

### 4.4 Locomotion

The slower walking speed of older adults is due to several factors: preference/strategy, decreases in strength,

joint motion, and endurance. The decrease in locomotion speed is the primary factor in gait changes as well. Gait changes include shorter steps and an increase in the time that both feet are on the ground, increasing support and balance (Spirduso, 1995; Lockhart, 1997). However, when cognitive demands are increased, walking becomes more demanding, presenting functional problems, particularly for older adults. For example, in one study, age-related differences in a memory task were greater when both age groups were walking than when they were stationary (Li et al., 2001). The researchers interpreted the results in terms of older adults selecting the more important walking task over the memory task (presumably staying balanced was considered more important than memorizing words). Cognitive demands can also result in movement decrement as well, as older adults walked at a slower speed when performing a cognitive secondary task (Lajoie et al., 1996).

***Design Implications and Suggestions*** Older adults walk more slowly than younger adults, and dual-task data suggest that older adults may change their movement speed and their cognitive performance. Slower locomotion for older adults has implications for pedestrian crossings, vehicles with automatic doors (such as elevators and subway trains), and other situations in which older adults are expected to keep pace with younger persons. Attendants should be trained to be prepared for these locomotion limitations. Particularly in instances where cognitive demand is high, such as crossing busy streets, walking in the downtown district of a large city, or any novel walking environment, the walking speed and balance of older adults may be significantly compromised. Although several studies have shown that the cognitive task is compromised as opposed to the walking task, this is probably due to the relative insignificance of the cognitive task. When searching for landmarks in an unfamiliar business district, the cognitive task may be more important, and attention to one's walking may be reduced.

### 4.5 Strength

Muscular strength is maintained through much of adulthood, beginning to fall off around age 60 (Ketcham and Stelmach, 2001). Muscle strength, including hand-grip strength and endurance, decreases with increasing age (e.g., Kallman et al., 1990; Metter et al., 1997). Skin slipperiness also increases with age (Cole, 1991). These changes, along with the onset of disease processes such as arthritis, may reduce older adults' strength in general and for fine motor control tasks. However, strength drops off as a result of muscle mass loss, and appropriate exercise and training regimens can abate strength and muscle losses, at least to some degree.

***Design Implications and Suggestions*** As with changes in speed, changes in strength have widespread effects on the functional limitations of older adults. For those systems and products that may have older adults in the user population, designers must consider the reductions in strength for all tasks that require actions such as pushing, pulling, lifting, twisting, and pressing.

Some pill bottles are now designed to be secured such that minimal force is required to open them, and other products that require actions such as these must be designed with older adults' reductions in strength in mind. If force requirements for a product cannot be reduced, assistive aids should be provided.

### 4.6  Force Control

Controlling one's force correctly can be critical in maintaining one's safety (e.g., holding onto a grab bar in the shower), avoiding embarrassment (e.g., accidentally crushing a beverage-filled Styrofoam cup at a party), or simply manipulating an everyday device (e.g., rotating the jog dial on a PDA). We focus primarily on control of force involving the hand and fingers. Older adults employ a grip force up to twice that of younger adults, and their force beyond that required is also twice that of younger counterparts (Cole, 1991). This indicates both a perceptual component (older adults, particularly over 60 years, do not accurately perceive the friction of the object being gripped) and a strategic component (perhaps aware of their inclination to misgrip objects or misperceive friction characteristics, they overgrip intentionally) (Cole et al., 1999).

***Design Implications and Suggestions***   The ability to control the force employed in a task is decreased significantly as one reaches old age. This has design implications for the structural soundness of products and the design of controls. For example, some computer mice have scroll wheels that can function as a button when clicked. If this button is too sensitive, older adults may have considerably more trouble than younger adults in scrolling without activating the function intended by the button. In designing handles for gripping, extra texture should be provided to offset the perceptual loss experienced by older adults. This can help to reduce the overgripping behavior, which may cause early fatigue when using the product.

## 5   BELIEFS, ATTITUDES, AND MOTIVATION

*Ageism* biases include the belief that older adults are reluctant to interact with technology. Focus group research shows that older adults are actually motivated to use products when they are informed about the benefits (Melenhorst et al., 2001). In fact, reduced usage rates among older adults may be the result of a poor understanding of the benefits of the product, reduced income, and difficulty using certain products (Fisk et al., 2009). For example, many older adults appear interested and motivated to use the Web. A Web usage questionnaire of middle-aged (40–59 years), young–old (60–74 years), and old–old (75–92 years) showed usage proportions of 56, 25, and 10%, respectively (Morrell et al., 2000). When asked about their desires for Web activities, regardless of whether they currently used the Web, older adults' top three preferred activities were to use email, to obtain information on travel or pleasure, and to obtain health-related information. Of the Web users, 66% reported being online for one year or more and were using the Web for an hour or more

several times per week. Of nonusers, middle-aged users expressed the most interest in using the Web, whereas the old–old users expressed the least interest. Relative to other age groups the percentage of older adults who use computers is lower, but their usage rates continue to grow (Kinsella and Velkoff, 2001; Olson et al., 2011).

Experience with new technologies may increase older adults' willingness to use them. For example, after completing an experiment with an automated teller machine (ATM) simulator, the number of older adults who expressed interest in interacting with an ATM increased from 28 to 60% (Rogers et al., 1996). The relatively short experiment provided sufficient exposure to and knowledge about the system to motivate participants to use the technology.

Knowledge and anxiety about computers appear to directly influence interest in computers, mediating the role of age in computer interest as evidenced by significant correlations between age and computer knowledge and computer anxiety in a structural equation model (Ellis and Allaire, 1999). The $r^2$-value for computer interest was 0.49, indicating that nearly half of the variance in interest was captured by the model. The effect of age on computer interest was mediated primarily by computer knowledge and anxiety, although some age-related variance was directly related to computer interest (indicating other possible predictors; see also Czaja et al., 2006).

***Design Implications and Suggestions***   Computer knowledge is highly related to computer anxiety (Czaja et al., 2006; Ellis and Allaire, 1999), suggesting the importance of educating older adults about computers. Understanding the potential benefits of computer technology and reducing anxiety associated with computers may increase older adults' willingness to use computers and, perhaps, technology in general (e.g., Czaja and Sharit, 1998). It is important to understand older adults' attitudes for any system or product they may encounter. Once older adults are made knowledgeable about the system or product (including the knowledge of how to interact with it successfully, the knowledge that they are capable of interacting with it successfully, and the knowledge about how it can benefit them), their interest and motivation to use it will increase, which in turn will result in greater attention to the system or product and lead to more efficient learning and utilization of the technology.

## 6   CASE STUDY: A HAND-HELD GAMING SYSTEM FOR OLDER ADULTS

We next present a hypothetical case study to illustrate the design implications derived from the age-related changes reviewed in this chapter. The example we have chosen to discuss is a hand-held gaming device designed with the purpose of delivering entertainment or cognitive enrichment activities to older adults. We have chosen this system for a number of reasons. First, although far fewer older adults engage in video game play compared to younger adults, gamers who are 65 years of age or older are among the most active gamers, with almost a

third playing nearly every day (Lenhart et al., 2008). The fact that relatively few older adults choose to engage in video game play may be partly due to barriers in the form of poor design. Overcoming these barriers may open up a variety enjoyable activities to the older adult population that have the potential to impact well-being and cognition. Recent evidence suggests that cognitive engagement via commercial video game play can improve a number of perceptual and cognitive abilities, including ameliorating age-related declines in memory, reasoning ability, and multitasking performance (Basak et al., 2008; Green and Bavelier, 2008). Additionally, a number of companies have begun to market software and hardware (including hand-held devices) to older adults with implicit or explicit claims of being able to improve everyday cognitive functioning. The evidence in support of these claims is mixed (Hertzog et al., 2009). However, it is almost certain that the design quality of these technologies will ultimately influence adoption and continued use should they prove effective. For the purposes of this case study, we present a hypothetical hand-held system running a simple operating system that allows users to select from several different video games and cognitive training activities.

## 6.1 Description of the System

The system itself is similar to several commercially available hand-held gaming systems. The hardware component is approximately $5 \times 2.5 \times 0.8$ in., with a 3.5-in. (diagonal) touch-sensitive color liquid crystal display (LCD) screen (Figure 6). A stylus is included which is used to interface with the touch screen. A directional pad is located to the left of the screen and four buttons are located to the right. These serve as game input devices and also allow users to navigate menus without using the stylus. The unit also includes a built-in microphone to accept speech input and speakers to deliver music and auditory feedback. Like many hand-held devices, the system also provides haptic feedback in the form of system vibration. We will assume that this product is novel to older adult users; thus, they must learn how to interact with it efficiently through usable design and effective training.

## 6.2 Visual Information

In this hypothetical system, a small color LCD touch screen is the primary interface presented to the older adult user. Like most technology, a paper operations manual is also provided for the system and games. An icon-based operating system and menu structure allow older adult users to select games and activities to play and to

customize system options. Once a game or activity has been selected, players are presented with the opportunity to navigate menus to change game options. Information such as instructions, tutorials, and performance feedback are also presented on screen, mostly in text and icon form. During game play and tutorials, auditory and haptic feedback accompany certain events.

### 6.2.1 Text

The type of text that is most commonly used in hand-held game systems and games is instructional text, informational text, labels, and performance feedback. That is, verbose and complex writing is typically unnecessary, and clarity and precision should be the primary objectives. In creating instructional text and tutorials for a hand-held game system and accompanying printed materials, organize the relevant information following standard information display guidelines. Avoid creating an interface with multiple frames, segmentation lines, text boxes, headings, icons, and links. The goal is to present minimal distraction and to present relevant information as clearly as possible.

- Group related elements (such as icons for different types of activities).
- Align elements in a list, generally to the left.
- Utilize common symbols to convey meaning efficiently (but avoid novel symbols or highly similar symbols with different meanings).
- Base text on a grid layout. Following this layout throughout an interface creates a common look and feel to the interface.

***Perceptual Considerations*** When presenting textual information on a hand-held system or in print, the text should be presented in high contrast and in an easily readable font (e.g., sans serif fonts; Morrell and Echt, 1997). Text should be divided into sections, with perceptually salient headers or labels. Additionally, strategic use of white space will help to separate sections, reducing the need for visual search. Lines of text should not run across the length of a screen, and horizontal scrolling should be avoided. Text should be centered on the screen if possible. In printed text accompanying the system and games, lines should run for 6–8 in., reducing the need for long visual scanning (Ellis and Kurniawan, 2000). If done consistently, this organization provides support for older adults in scanning to find headings and in reading the text. Text should be presented in 12-point type, sans serif font, and the highest possible contrast should be used (see Figure 7). While color can and should be used to enhance the game experience, important instructional text should be limited to black on white.

***Cognitive Considerations*** Text should not contain left-branching sentences or sentences with many clauses in them, which overload working memory. For adults of all ages, technical text should be written at a sixth-grade level (McLaughlin, 1969). Text should be organized via a small number of organizational principles. For example, in an instructional manual, chapters, subsections, and headers should use consistent conventions (e.g., subsection headings can be presented in a unique font size or in bold type).

**Figure 6** A schematic drawing of the hypothetical hand-held game system and stylus.

| Low-contrast text is difficult to read. |
| :--- |
| *Serif and script fonts are difficult to read.* |
| Eight-point font is too small. |
| This test has appropriate font, size (12 pt), and contrast. |

**Figure 7** Examples of poor and appropriate text presentation. (Adapted from Fisk et al., 2009.)

### 6.2.2 Icons

Icons and symbols are often used in instructional manuals and software applications to convey meaning in minimum physical space. This can lead to small icons that are difficult for older adults to see and confusing icons that are difficult to interpret. In the hypothetical system, icons may be used to depict one of several games or activities available to play and they may be used to denote helpful hints and warnings in the instruction manuals.

***Perceptual Considerations*** Icon size is an obvious consideration when designing for older users, especially on hand-held systems with small screens. Distance of the system from the eyes should be considered as well. Besides icons that are too small, a graphically complex icon may be difficult for lower acuity persons to perceive correctly. Also, if icons and symbols are color coded, care should be taken to avoid multiple colors from the high-frequency end of the color spectrum (e.g., blues, greens) and to use highly distinctive hues to avoid reducing the contrast of the icon.

***Cognitive Considerations*** By serving as graphical representations of concepts and instructions, symbols and icons can be very effective in communicating a large amount of information in a small space. However, evidence suggests that older adults may have more trouble than younger adults in understanding symbols and icons, and usability testing should be conducted with older adults to ensure that all icons are interpretable (Hancock et al., 2004). Older adults may not be familiar with icons familiar to younger gamers and computer users (e.g., a disk icon representing the option to save data or progress). When used, icons should always be accompanied by a textual label and description, at least initially on the screen and always in the manual. Structurally complex icons can also be problematic, not only in terms of comprehension, but also for older adults, in terms of perception.

### 6.2.3 Information Visualization

Like many video games and training activities, feedback regarding performance is essential. Games often allow for multiple related performance variables to be presented at a single time. Data visualization can refer to a simple representation of data in a pictorial fashion, such as a pie chart. In this context, data visualization would require a multivariate display for representing the various relevant characteristics of the data in a multidimensional space. The limiting factor in data visualization can often be traced to the person viewing the representation. An understanding of human cognition and visualization constraints is essential to the development and selection of effective display characteristics. However, there has been little specific focus on age-related differences in information visualization capabilities, per se, but there is evidence that older adults have some difficulties with graph perception (Fausset, 2008). The best design approach here would be iterative user testing of the software with older adults (Fisk et al., 2009).

### 6.3 Auditory Information

Auditory information can be used in a number of ways in our hypothetical game system. For example, game tutorials might have verbal instructions to walk players through how to perform important game actions. Although this may be fine for young adults, previously discussed age-related changes in audition and speech perception should be taken into account when designing for older adults. This is especially true considering the poor sound quality often associated with the small built-in speakers common to hand-held devices and speech compression used to conserve system memory. A common game design practice is to accompany game play with background music. This may be problematic for older adults who may experience more masking of important auditory cues. Ideally, auditory information should be presented with a high signal-to-noise ratio (i.e., minimal background sounds to mask the intended message). Moreover, whenever possible, important system and in-game events should be accompanied by redundant visual or haptic cues.

### 6.4 Haptic Information

Many hand-held devices, including game systems, support haptic feedback in the form of system vibration. For example, in a racing game, a player might be alerted that he or she is off course through the use of haptic feedback. Vibration may also be used as feedback to let the user know an icon has been successfully selected. When using haptic feedback, vibration frequency should be carefully selected as high-frequency vibration is selectively impaired with age. As recommended for auditory cues, haptic cues should not be used alone and should be accompanied by redundant cues from other modalities.

### 6.5 Input Devices

### 6.5.1 Perceptual Considerations

Given the necessarily small size of buttons on hand-held devices, labeling these can be difficult, particularly when considering the reduced acuity of older users. High-contrast symbols are generally necessary as opposed to text, and these should be clearly defined in instructional materials and training programs. Tactile feedback should not be used as the primary feedback for input controls. Older adults are less sensitive than younger adults to tactile feedback (e.g., Thornberry and Mistretta, 1981).

Thus, when a button is pressed, visual or auditory feedback should be the primary means of feedback.

### 6.5.2 Motor Considerations

Hand-held devices necessarily have small controls—small jog dials, small buttons, and small input devices, such as styluses for touch screens. Reductions in force control and movement control are critical considerations in designing these devices.

*Jog Dials* Jog dials, typically used for rotating through options in small hand-held devices, should have sufficiently stiff, discrete stopping points when rotated, given older adults' force control deficiencies. The "teeth" on the dial should provide enough friction to account for older adults' more slippery skin (Cole, 1991). Rotary-type controllers are well suited as input devices for older adult users for certain controls such as sliders and scrolling (Rogers et al., 2005).

*Buttons* Buttons should be far enough apart to minimize accidental activations. Buttons should be firm, so that they are not depressed accidentally when older users rest their finger on them, which may be likely given reductions in force control. Tactile feedback of a button press should be provided as redundant feedback to visual and/or auditory feedback to inform the user that the control has been activated.

*Touch Screens* Touch screens are not optimal for older adults for small targets, due to high variability in movement control. For example, if selecting one of four $\frac{1}{4}$-in.-wide options on a hand-held system, a jog dial should be used to cycle through the options and make a selection, as opposed to requiring the older user to select the option with a touch pen or with a finger. If touch screens are used in small devices, selection areas should be maximized to increase accuracy. In general, touch screens should be used for ballistic movements (particularly when screen real estate is large), but for precise control, indirect pointing devices such as a rotary device or mouse should be used (Charness et al., 2004; Rogers et al., 2005). Older adults have difficulty making accurate, fine motor movements as well as making fast movements. The hypothetical system addresses this by providing navigation alternatives (use of the directional pad and buttons) that are more robust to tremor and motor control issues. If designing a non-hand-held system that includes a mouse, fine mouse movements should be minimized if possible, and the option to control the double-click speed and gain on the mouse should be available.

*Hardware Casing* Age-related changes in muscle strength (e.g., hand-grip strength and endurance), increased slipperiness, and higher likelihood of arthritis together have implications for designing the hardware casing of hand-held devices for older adults, especially gaming systems which may be used for extended periods of time. Nonslip casing materials are preferable and system weight should be minimized. User testing should be conducted to ensure usability and long-term comfort of the system.

### 6.5.3 Voice Command

Many hand-held devices, including game systems, feature voice command options. While this can serve as an alternative in some cases to overcome difficulties in motor control, it is not generally recommended as a primary input method. Even the best speech recognition software may frustrate users if recognition is imperfect, and there is reason to suspect older adults may experience greater errors compared to their younger counterparts. Speech recognition algorithms designed and evaluated using young adults will not be as accurate for older adults as a result of age-related declines in speech quality.

### 6.6 Training and Instructional Materials

Training can cover a multitude of design errors (although it should not be used as a crutch by designers). For example, people are entirely capable of learning the meaning of an obscure icon, provided that it is associated consistently with the same function and is not easily confused with other icons. Older adults may have unique training requirements. For example, older adults may be less familiar with computer and gaming technologies and as a result may require training for basic features of a system. For example, for PC-based gaming systems, mouse training, instruction on windowing, or search tool training may be required before other, higher level aspects of the system are trained. Older adults may also be less confident in their ability to interact successfully with novel technological devices such as PDAs and other hand-held devices (due in part to less experience).

Inexperienced older users may have an incorrect mental model of the system or no model at all, which is particularly likely for gaming devices. Often these models are constructed from repeated interaction with the system; hence, novice users should first be trained to form an appropriate model of the system. Older adults may be able to adopt new strategies that are optimal for the task (Rogers and Gilbert, 1997) and develop new mental models successfully (Gilbert and Rogers, 1999) although there are individual differences between older adults in this ability (Olson et al., 2009).

Training programs and instructional materials should be developed for the use of the hand-held game system and each game. Game and system tutorials should be clearly marked and easily accessible at any time during and after training. In addition, age-specific training might also have to be provided to enable older adults to capitalize on the functionality of the software (Hickman et al., 2007). In designing training programs and materials for the current hypothetical system, several considerations should be made. Many of these are relevant to training adults of all ages.

### 6.6.1 Duration of Training

Based on training research with simple and complex stimulus situations, older adults will require about one and a half to two times the amount of training required by younger adults (Fisk et al., 2004). Extended training (or *overtraining*) can help solidify the process being trained and improve retention (Jones, 1989). Older adults tend to benefit more from overtraining than

younger adults, who presumably reach a more stable area of the learning curve earlier (e.g., Sharit et al., 2003). Short breaks should be provided when training sessions extend for 30 min or more.

### 6.6.2 Format of Training

Video games are complex pieces of software. Appropriately constructed part-task training can be helpful in training complex tasks. Part-task training involves practice on some subset of a task before practice on the whole task (Kramer et al., 1995). Selecting the appropriate subset is, of course, critical. A thorough task analysis is required before a task is divided into parts, particularly in complex tasks. Artificial divisions of the task (especially in the simplest tasks) will be detrimental. For example, imagine a generic action game in which players must race their vehicle around a track and also use weapon systems against competing players. The control aspect of maneuvering around the track could first be trained independently of utilizing weapon systems. When proficiency is reached, the two can be combined and additional training provided. In the present system, a stylus and input device training application should be an optional training program for novice users, to be completed prior to using the system for games. Although part-task training is often beneficial, different aspects of a task will need to be closely integrated, such as related motor movements with different hands, or dividing the task will be detrimental to older adults' performance (Korteling, 1993). In addition to use of a game to provide training and instruction, training should also include clear, comprehensive written manuals for how to use the system and games. Older adults report a preference for written instructional materials when learning how to use new technology (Mitzner et al., 2008).

### 6.6.3 Flexibility of Training

A flexible training program is important for older users, as the variability in experience, skills, and knowledge can be high in an older population. The training application for hand-held gaming systems should assess older adults' system and gaming knowledge and be flexible enough to provide low-level training to novice users but to skip these aspects of the training program for users who demonstrate proficiency.

### 6.6.4 Active Learning

Active training is essential; passive observation leads to little, if any, learning (Schneider, 1985). Training programs and game tutorials should make use of the same interface on which users will be performing the actual tasks or as close as possible. Tutorials for using the gaming software can easily be presented using the same graphical user interface as the actual game. This allows the user to interact actively with the interface, as opposed to reading instructional text or viewing pictures of the interface.

### 6.6.5 Feedback in Training

Feedback should be provided for every interaction with the system (e.g., a button press should result in a corresponding change on the screen as well as an auditory cue), but specifically in training and tutorial environments, feedback is critical in making trainees aware of mistakes and in creating an appropriate mental model. Feedback is particularly critical for older adults (for a review, see Kausler, 1991). Given that they may experience a higher degree of anxiety at learning to interact with novel technology (Fisk et al., 2009), this feedback should be communicated as clearly as possible. In a training tutorial that teaches older adults basic system functions:

- *Feedback should be immediate*. If a user performs steps out of order, the training application should provide immediate feedback to prevent this incorrect order of operations from becoming a learned procedure.
- *Feedback should be specific*. Users should be informed of their incorrect action and shown the correct action.
- *Feedback should be succinct*. Removing the user from the training program for an extended period of time to explain a mistake will prevent the user from quickly learning the correct procedure.

### 6.6.6 Consistency

Learning will not occur for completely inconsistent information, but like younger adults, older adults can learn under partially consistent conditions (Meyer and Fisk, 1998). However, for older adults, consistent relationships between stimuli or aspects of a task or system should be identified explicitly. Because the hypothetical system will run multiple different pieces of game software, it would be to the advantage of designers to have consistent mappings between each system input and game action (e.g., the same buttons used to jump or fire weapons in one game would be used in other games requiring these actions).

### 6.6.7 Importance of Task Analysis

A device that seems simple to designers often is much more complicated and difficult to use for novice users. For example, several commercially available gaming systems require a number of steps before a game can even be started. By performing a comprehensive task analysis, the individual requirements for successful interaction with the system or device will be identified and accounted for in the training and instructional materials. Furthermore, if part-task training is plausible, a careful analysis of all aspects of the task is necessary to segment the task appropriately. Task analysis will result in an understanding of problems and errors that can occur. These issues should be anticipated in instructional manuals; for example, in a "frequently asked questions" section of a manual.

## 7 CONCLUSIONS

Older adults comprise a significant portion of users of technological products, thus demanding the attention of human factors professionals. We have described a wide

array of age-related factors that have functional significance for the performance of older adults and provided design implications and recommendations based on the existing literature. Human factors professionals will benefit by considering the age of their users and designing appropriately.

Several themes in the design guidelines follow from the review of age-related changes and from the case study. The importance of environmental support, or taking cognitively demanding requirements from the user and putting information in the task environment, is pervasive. Especially for older adults, this supportive information can direct attention to relevant stimuli; cue users' memory; support tasks such as reading, visual search, and even balance; and free up valuable cognitive resources that can be applied to other aspects of the task. Resources can also be allocated to other tasks if the stimulus itself is improved. Despite pervasive perceptual declines in the aging system, the perceptual stimulus can be greatly improved by increasing the size or intensity of a stimulus, increasing the lighting of an environment, or minimizing background clutter. The designer must understand the limitations of older users before even such simple design adjustments can be made.

For tasks that older adults continue to have difficulty with after these two guidelines have been followed, older adults may still be capable of attaining proficiency through appropriate training. Older adults are able to achieve skilled performance through training provided that the information to be learned is at least partially consistent. Older adults follow a power law of learning for consistent information similar to that of younger adults. Thus, older adults are certainly not limited in all aspects relative to their younger counterparts. In fact, designers should attempt to take advantage of those areas where older adults surpass the capabilities of younger adults, specifically in their semantic knowledge. However, none of these design guidelines are useful if older adults choose not to use the system or product. Fortunately, data suggest that older adults are willing, and it is critical that the benefits of new systems and products are communicated to potential older users to increase their motivation to learn to use these new technologies.

Designers should also be aware of tools that can simulate and predict older adult performance and, after a task analysis, can help designers choose between alternative designs. One such tool is the goals, operators, methods, and selection (GOMS) rules modeling technique. Originally modeled after the processing speeds and capacities of younger adults, parameters of the model are now available to simulate and predict older adults' interactions with technology (Jastrzembski and Charness, 2007). These updated parameters take into account age-related declines in memory, speed, and motor control. Designers should be cautious when using tools based on young adult data.

Age-related changes in capabilities of older adults have been well studied. An understanding of such differences provides constraints for the design space of new products and new instantiations of existing products. Clearly, iterative design and user testing will always be essential for good design, and older adults must be included in the usability test group. However, our goal in this chapter was to provide a summary of the literature on aging to enable designers to start from an informed position about how systems and products should be designed if they are to be used safely and effectively by older adults.

# CHAPTER 53

# DESIGNING FOR CHILDREN

**Valerie J. Berg Rice**
**General Ergonomics**
**Selma, Texas**

*There can be no keener revelation of a society's soul than the way in which it treats its children.*

  Nelson Mandela

## 1  INTRODUCTION: HOW DESIGNING FOR CHILDREN IS DIFFERENT FROM DESIGNING FOR ADULTS

Children are not merely diminutive adults. Their bodies and minds are still developing, and their physical and mental activities impact their development. The tools they use, the songs they sing, the games they play, and even the chairs they sit on can influence their growth. Those who design for children must consider how their designs will impact children's maturation, a consideration that is unnecessary when designing for adults.

Children lack the experience of an adult. They are less aware of dangers and are not fully conscious of the consequences of their own actions. They need to be protected by concerned, well-informed adults. The design of the products they use and the places where they work and play must incorporate protective measures, more so than typical when designing for adults.

Designing for children differs from designing for adults in context and content (Box 1). While safety is an important consideration during product design for adults, it receives greater emphasis when designing for children, as they are more vulnerable. Their vulnerability is a result of their cognitive abilities and understanding, their size and strength, and their being in the process of physical growth and development.

Annually worldwide nearly a million children die of injuries, while over 10 times that number receive care for nonfatal injuries [World Health Organization (WHO), 2008]. Many children are left with permanent disabilities. Younger children (under age 5) and boys are at greater risk (WHO, 2008). The most commonly occurring injuries result from traffic accidents, near drowning, burns, falls, and poisoning (WHO, 2008).

Children do not have to go far to encounter hazards, as the most frequently cited physical location at the time of injury is in or around their own homes (Brown and Beran, 2008). Most importantly, nearly all injuries are from accidents that could potentially be prevented through the thoughtful design of products, places, and processes and the design and implementation of educational, guidance, and supervisory programs. The responsibility for safe and useful designs falls not to any single group or profession but also to many, including families, local communities, and governments.

## 2  PRINCIPLES OF DESIGNING FOR CHILDREN

*You know the only people who are always sure about the proper way to raise children? Those who've never had any.*

  *Bill Cosby*

  Consider the Goal
  Consider the Target Audience

A similar sentiment may apply to those who design for children. While having children of one's own may not be necessary to design for children, certainly in-depth, first-hand knowledge and understanding of the target audience are requirements. Those who design for children must be intimately aware of how children think and act and possess a competent knowledge of children's capabilities and limitations at each age or stage of development. Having an expert in child development on the design team will enhance the application of design principles in accordance with the primary target audience—children (Lueder and Rice, 2008a).

Well-designed products, places, and processes fit the target audience who will use them and are effective, efficient, and safe (Kroemer and Grandjean, 2009).

**Figure 1** Two-year-old Maddie uses her mothers' decorative stickers in an unexpected way. (Photo courtesy of Carrie Vita.)

**Figure 2** Sophie explores a ''touch and feel'' book with her tongue, instead of her hands. Young children explore both with their mouths and their hands; both are rich in nerve endings, giving the child feedback as to the shape and consistency of the object. (Photo courtesy of Tim Vita.)

Yet, well-known principles of functional human factors design have slightly different implications and are applied differently when designing for children (Table 1). For example, when designing work processes for adults, the design process is often driven by the need to increase profits and decrease associated costs; thus the more effective and efficient the design, the better. The overriding management mission is to increase the company income. Safety, while important, historically has taken a "relative back seat," emerging when the cost of injuries and need for meeting standards are emphasized by management. This is not the case when designing for children. Product safety is considered paramount, especially by the secondary target audience and primary purchaser, the caregivers.

The parent or caregiver should have influence in designs for children. Their goals for the products, places, and processes their children use reflect their aspirations

**Table 1  Functional Design Principles and How They Differ When Designing for Children**

| Principle | How the Application Differs When Designing for Children |
|---|---|
| Fitting the Task to the Person | Not all strength measures are available for children of each age and gender.<br>Not all static and dynamic anthropometric measures are available for children of each age and gender.<br>Not all children develop at the same rate and change occurs rapidly.<br>Children of the same age and gender may vary significantly in their abilities.<br>Design for children:<br>• Focuses on more than the physical tasks and anthropometrics often considered for adult applications.<br>• Must take all types of development into account (physical, cognitive, emotional, social, speech/language, cultural, and the integration of each such as perceptual-motor, motor planning, etc.).<br>• Must simultaneously fit the current abilities of the child, while pulling them into the next phase of their development.<br>• Must ''fit''' a number of children at different ages and developmental stages.<br>• Must consider caregiver and parental concerns and goals for children, not just the child user. |
| Design for Efficacy | Finance: Effectiveness influences the financial ''bottom line'' in many designs for adults but does not similarly influence sales of products designed for children.<br>Importance: Effectiveness is essential in designs for adults but may be considered less important in designs for children.<br>Advocacy: Neither children nor caregivers may demand a product or process ''work'' exactly the way it should and when it should, while adults will actively advocate for effectiveness in products for adults.<br>Exploration: Some product design is purposely less than effective (less defined) to encourage imagination or multifunctional use by children.<br>Effectiveness assists with teaching children ''cause and effect.'' |
| Design for Efficiency | Finance: Efficiency influences the financial bottom line in many designs for adults but does not similarly influence sales of products designed for children.<br>Importance: Efficiency is extremely important when designing for adults but may be less so when designing for children.<br>Advocacy: Children are thought to have more available time and speed is less of an issue than exploration, problem solving, and imaginative use when designing for children.<br>Exploration: Some leeway in efficiency can lead children to explore alternate methods of use to discover effective, efficient, and fun techniques that are applicable in differing circumstances. This encourages creativity and problem solving. |
| Design for Safety | Safety is the priority focus in designing for children. This is especially the case if an injury link between product use and physical harm is readily apparent.<br>Safety can be ''down-played,'' if the injury link is less apparent. This is because adults may be unaware of injury potential or may believe symptoms among children are short-lived or will be outgrown. For example, many adults are not aware of the potential impact of overuse injuries among children.<br>Product safety is often taken for granted. Caregivers assume products for children are safe and have been safety tested before a product is offered for sale.<br>Parents tend to believe their own children are more mature and will make better decisions than other children of the same age (Harshman and Murphy, 2005). Thus, parents may not adhere to age-related recommendations for products or may encourage activities beyond their children's maturity level. |
| Intuitive Use and Ease-of-Use | Designs should be easy to use, but<br>• Children's physical size and attributes change rapidly.<br>• Children have little experience to draw upon.<br>• Children use items in unexpected ways.<br>• Cognitive development changes rapidly, for example, what is intuitive for an 8-year-old may not be intuitive for a 6-year-old or even for another 8-year-old with a different background or maturity level.<br>Young children explore a range of potential uses for an object.<br>A child's developmental skill levels differ in each type of development. For example, a child may be more physically developed than others their age yet less socially developed.<br>While a design should be easy to use, it is also necessary to offer supplemental challenges to help a child develop and hone their skills, especially with designing items such as playgrounds, toys, and learning products. |

for the children themselves. First and foremost, they want their children to be safe. They also want them to grow, develop, and mature, preferably at a rate similar to (or ahead of) their peers. They want their children to achieve, contribute, and have fun. Caregivers and parents want their children to "fit in," be happy, and at times simply to be entertained. They want the items their children interact with to:

- Be harmless
- Encourage and extend their developmental progress
- Permit their children to gain mastery over their environment
- Teach them important lessons necessary for their future
- Align with their own values and beliefs
- Bring them joy
- Keep them amused (Figure 3)

In addition, parents also recall their own childhood and these memories can influence their purchases. As noted by Walt Disney, "You are dead if you only aim for kids. Adults are grown up kids."

Just as caregiver's desires for designs[*] for children are multifaceted, the design process is also complex. Designing for children is not simple, as a design must be safe and fit children's current abilities, allowing them to experience success and accomplishment while simultaneously "pulling" them into the next stages

**Figure 3** Sometimes parents simply want their baby to be amused by the products (toys) they use. This baby plays happily while her mother shops for groceries. (Photo by Valerie Rice.)

---

[*] Design refers to the design of a product, place, or process.

of development. Designs must protect while encouraging a degree of risk. Designs for children should promote exploration even while they meet a child's expectations and "do what they are designed to do." The former fuels a child's thinking and investigation, while the latter helps a child learn about cause and effect.

A child's desires for designs of toys or products may be less complicated (compared with those of caretakers and business owners). Children want to have fun, for a design to reflect their taste in terms of color and preferred (often popular) images, and, in general, for an item to function as it should (Rice et al., 2008). They are less concerned with safety, learning, and their own development! For example, students in an elementary school noted their primary motives for selecting their backpack were the color and characters displayed on the pack (Rice et al., 2008).

Manufacturer's goals are aligned with the purpose and mission of their business, which is to show a financial profit. Therefore, they will often focus on making their design appealing to children, who then petition their caregiver (or another adult) to purchase the item (Box 2). Most also want their product to attract caregivers, who are the primary purchasers of children's products. Although the belief may not be in line with parental desires for their children, manufacturers often sell based on "age compression," that is, they believe the children of today mature at an earlier age than they did years ago. Therefore, the designs may try to capture the fun, but in a more sophisticated manner than years ago. Thus, the display of Barbie Dolls at FAO Swartz does not look much like a toy store; instead it has the appearance of a boutique (Fishel, 2001), and BRATZ Dolls wear clothing appropriate for an 18 year old but are popular with girls half that age.

Obviously, the principal user of children's products and environments are the children themselves. Other users are caregivers, family members, and friends. Caregivers can include parents, grandparents, nannies, baby-sitters, daycare providers, and teachers. Each of these individuals must keep the children in their care safe and must provide learning opportunities as well. The wise designer is aware of caregivers' goals and values. For example, toy designers may blend the old with the new in using toy designs that invoke nostalgia among caregivers (thus encouraging them to identify with and purchase a toy), while keeping the product fresh and in-line with children's current likes and dislikes.

### 2.0.1 What Does a Designer Need to Know?

While the item under design will dictate the core focus, in general designers should consider all aspects of child development. Without this broader consideration, oversights can easily ensue. For example, some playgrounds have signs describing them as accessible for children with disabilities. However, the single feature of accessibility may be a ramp with blocks a child can spin at the top platform. The designer did not seem to understand that a physical disability does not necessarily equate with a cognitive or social disability, nor does accessibility to children with disabilities merely mean being able to be "present" on a playground construed by the participant as being part of the "playing field." An accessible playground should have numerous ways for those who have disabilities, and those who do not have disabilities, to play together (Figures 4 and 5).

Another example demonstrating the importance of considering multiple perspectives of child development occurs with the design of clothing for toddlers. Many younger children cannot easily zip their jackets or button the small buttons on their shirts, as they are still developing their fine motor skills. Imagine the gains if a clothing manufacturer considered fine motor skills and psychosocial development, along with anthropometrics, in designing children's clothing. They could provide suitable clothing, offer early training to hone fine motor skills, and promote self-esteem through successful, independent dressing.

**Figure 4** Morgan's Wonderland contains playgrounds with a series of ramps as well as swings, cars, and a small train that can accommodate wheelchairs. On the playgrounds are games such as those shown here, where a child can move a person or car through a maze, learn Braille, make designs with sand or beads, or play music. (Photos by Valerie Rice.)

**Figure 5** At Morgan's Wonderland, children with disabilities can control water spouts, direct remote control boats, use water to shoot at targets, fish, and see themselves on a "weather channel." The entire park is accessible. (Photo by Valerie Rice.)

The provision of information on all aspects of child development is beyond the scope of this chapter (see Table 2). Entire books are dedicated to specific aspects of child development, such as motor skills (Liddle and Yorke, 2004) or language (Pinker, 1996). Other texts cover the full gamut of development, but may be limited to an age range (Brazelton and Sparrow, 2006; Berk, 2009). Frequently, texts contain developmental charts or tables listing and depicting milestones for skills and abilities of children. These describe the approximate time period during which the skills typically develop (Brown and Beran, 2008).[*]

Until recently, designers had to peruse a vast set of professional journals to obtain the most current information on designing for children. To address this issue, Lueder and Rice (2008a) compiled a unique, seminal text on designing for children. The text includes basic information on child development as well as specific chapters on product design, warnings, wayfinding, playgrounds, and designing for school and home environments, among others.

### 2.1 Does a Better Design Succeed in Preventing Injuries?

Protecting children through product, place, and process design can reduce injuries and even death. For example, the U.S. Consumer Product Safety Commission (CPSC) demonstrated that child-resistive packaging decreased prescription-related deaths by 45% (Rodgers, 1996), while a similar study on child-resistive packaging for aspirin reduced aspirin-related deaths by 34% (Rodgers, 1997, 2002). Numerous evidence-based studies have demonstrated other design-related success stories regarding injury and mortality prevention. Table 3

---

[*] Online developmental milestones are available in Lueder and Rice, (2008a) and at http://www.cdc.gov and http://www.dars .state.tx.us/ecis/resources/developmentmilestones.shtml

**Table 2 Child Development of Importance for Designers**

| Aspects of Development | Considerations |
|---|---|
| *Physical Development*<br>Body size (anthropometrics) and body composition; muscle, neuron, and skeletal growth; gross and fine motor skills; reflexes; vision, hearing, touch, taste and smell, complex skills such as visual–motor skills, etc. | Gender<br>Hormonal influences<br>Variations (heredity, environment, activities) |
| *Cognitive Development*<br>Neuropsychological, attention, concentration, planning, memory and memory retrieval, reasoning, problem solving, intelligence, etc. | Piaget's Cognitive Development Stages<br>Information processing perspectives<br>Brain-based learning<br>Metacognition |
| *Emotional Development*<br>Function, expressing, understanding, etc. | Interaction with cognition, health, and social behaviors<br>Self-regulation |
| *Social Development*<br>Self-awareness, self-concept, self-esteem, self-identify, relationships with others, moral development and reasoning, etc. | Vygotsky's Sociocultural Theories<br>Social problem solving<br>Coping skills, conflict resolution |
| *Speech and Language Development*<br>Phonics, semantics, grammar, sociolinguistics, etc. | Biological-Native Development<br>Behavioral learning<br>Interaction-based learning |
| *Cultural Understanding*<br>Social contexts — family, peers, teams, school, community, country, etc. | Gender<br>Context<br>Media<br>Groups |

**Table 3 Six Basic WHO Principles That Underlie Successful Child Injury Prevention Programs**

iterates basic WHO principles that underlie successful child injury prevention programs.

Even conveying risk and prevention information to caregivers and children can help, although it is not the sole answer to preventing injuries. In a literature review, Bass and colleagues (1993) found informing children and caregivers about potential injuries and injury prevention helped to reduce injuries. A high-quality, effective injury prevention program needs both a micro- and macroapproach and requires a variety of new and altered designs. Table 4 iterates WHO key strategies to reduce road traffic injuries and deaths among children, highlighting those that use or require design solutions.

Sweden has realized considerable success in reducing unintentional child injuries and deaths. Over the last 30 years, Sweden has reduced death rates due to injury from 24 to 5 (per 100,000) for boys and from 11 to 3 (per 100,000) for girls (WHO, 2008). Sweden has achieved these remarkable reductions using techniques such as (WHO, 2008):

- Environmental planning
  - Designing changes that divert traffic from residential areas and towns, permitting children to walk to school and play
  - Designing "safe communities"
- Home safety measures including home visits by health care professionals
- Product safety standards improvements
- School-based safety programs/measures
- Traffic safety measures including helmets and child restraint systems
- Water safety instruction

It also helps when success is expressed in terms of financial savings. For example, it is estimated that for every U.S. dollar spent on a child car seat, there is a savings of $29 in direct and indirect health care costs and other costs (WHO, 2008). Similar methods of reporting design and programmatic victories may assist with convincing governments to intervene on behalf of children.

Make safety a priority.

## 2.2 Special Design Considerations

### 2.2.1 Safety

Ensuring safety requires the designer to think about the probable results that may occur during reasonable,

**Table 4  WHO Key Strategies That Prevent Road Traffic Injuries among Children**

| Key Strategies | Effective | Insufficient Evidence | Ineffective | Harmful |
|---|---|---|---|---|
| Introducing and enforcing minimum legal drinking age laws | X | | | |
| *Setting (and enforcing) lower blood alcohol concentration limits for novice drivers and zero tolerance for offenders* | X | | | |
| ***Using appropriate child restraints and seatbelts*** | | | | |
| ***Wearing motorcycle and bicycle helmets*** | X | | | |
| *Forcing a reduction of speed around schools, residential areas, play areas* | X | | | |
| Separating different types of road user | X | | | |
| ***Introducing (and enforcing) daytime running lights for motorcycles*** | X | | | |
| Introducing graduated driver licensing systems | X | | | |
| *Implementing designated driver programs* | | X | | |
| ***Increasing the visibility of pedestrians*** | | X | | |
| *Introducing instruction in schools on the dangers of drunk driving* | | X | | |
| *Conducting school-based driver education* | | | X | |
| Putting babies or children on a seat with an air bag | | | | X |
| Licensing novice teenage drivers | | | | X |

*Source*: WHO, 2008.
NOTE: Bold italics designates obvious design needs, nonbold italics designates secondary design needs, such as newly designed signage, spaces, and programs/education.

normal use or misuse of a product. In the United States, the CPSC has detailed test methods to identify possible hazards, such as reasonably foreseeable misuse, damage, or abuse of the product, as well as established safety standards and guidelines [CPSC, 2010; 16 Code of Federal Regulations (CFR) §§ 1500.50–1500.53].

Determining what is "reasonable" for children as they explore their world using all of their senses of taste, touch, smell, hearing, and sight is not straightforward (Figure 6). It requires a thorough knowledge of child development, a "foreseeabilty conference" involving closely scrutinized observations of children using the product, and a team approach that involves both professionals and caregivers. In addition, there is no guarantee children will solely use those products designed for their age and maturity level. Parents can overestimate a child's maturity level and physical abilities (Schwebel and Bounds, 2003), younger siblings or playmates may pick up toys that do not belong to them, sales personnel may give out toys without checking for appropriate age ranges (such as fast food restaurants), and caregivers may fail to notice when a child is given a toy designed for an older child. Children also overestimate their own ability to perform physical tasks (Plumert, 1995; Schwebel and Bounds, 2003), and

Plumert (1995) found a relationship between six year olds overestimation of their abilities and their injuries.

It is important to consider safety when designing for children of all ages, not only younger children. Adolescents engage in risky behaviors (Steinberg, 2004; Vrendenburgh et al., 2010) and the highest unintentional injury rates occur among 15–18 year olds (Grossman, 2000). What is reasonable for an adolescent, may be less so for an adult and vice versa (Vrendenburgh et al., 2010). For example, the combined influence of wanting to look attractive and believing they are less vulnerable to injury may contribute to adolescent girls not using personal protective equipment (Vrendenburgh et al., 2010). Caregivers may warn their children about risk-taking behaviors, but they also underestimate the risk-taking behaviors of their children (Stanton et. al., 2000).

Removing a hazard through design is the best method of eliminating a hazard, thus removing the potential for human error (Kalsher and Wogalter, 2008; Rice and Lueder, 2008). The hierarchy for eliminating hazards includes (Table 5):

- Change the physical design so hazards are eliminated.

**Figure 6** Cole chooses ''pan play'' over play with his toys. Thus, he chooses the dull color of a pan over the primary colors of his playthings, the sound of a clanging pan over the melodies of his electronic toys or blocks, and the more-difficult-to-open cabinet over an easy-to-reach toy-basket. Such choices might seem counterintuitive, but children enjoy exploring and using objects in novel ways. (Photo by Jerry Duncan.)

- Add guards against hazards that cannot be eliminated through design.
- Provide warnings about hazards that cannot be eliminated through design and/or guarding.

### 2.2.2 Warnings

As noted above, warnings are necessary because not every hazard can be eliminated through design. Warnings for children's products target caregivers because caregivers purchase the majority of child products, supervise child activities, and guide and direct children's pursuits.

Caregivers are not likely to have access to the same information about a product that a manufacturer does, including the results of user testing, product construction (strength, component parts, etc.), and reports of misuse or breakage. Warnings assist manufacturers in alerting users about products, their proper use, breakage, and potential risks associated with improper or accidental misuse. Armed with such information, caregivers can make informed decisions about the products their children use, including the instructions they should

provide, how much supervision may be necessary, and whether personal protective equipment is needed and must be fit to the child.

The International Organization for Standardization (ISO) publishes safety label standards. The ISO standards deemphasize the use of text and encourage the use of pictorials as a means of broadening warning applications beyond the language of the text. The American National Standards Institute (ANSI) Z535.4 provides guidelines for warnings in the United States. The ANSI standards require testing before substituting a pictorial for text and testing must reveal less than 5% misunderstanding of the critical message and 85% comprehension.

One use of warnings is in poison control. In the United States, warnings must alert potential buyers if packaging does not include a child-resistant feature (or tampering with the product might have occurred) [Food and Drug Administration (FDA), 2005; Federal Register, 1998; Poison Prevention Packaging Act, 1970]. The warnings must be conspicuous and prominent (FDA 2005; Federal Register, 1998; Poison Prevention Packaging Act, 1970). Bix and colleagues (2009) found that adults (those with and without children in the home) spent little time attending to child-resistant warnings; instead the most time was spent attending to the brand name. Study results also revealed little recall of warning information and that child-resistant and tampering warnings were less legible than other gaze zones such as the brand name, facts about the drug, and claims (Bix et al., 2009). This is important because having non-child-resistant packaging for over-the-counter medications may contribute to unintentional poisonings (CPSC, 2005).

Table 6 gives both suggestions for constructing warnings and considerations important when designing warnings for children. For a detailed chapter on warnings for children, see Kalsher and Wogalter (2008).

Warnings are also constructed specifically for children, such as "Mr. Yuk." Mr. Yuk uses line drawings to depict a face with eyes closed and tongue protruding on a green background. The poison control design appears on stickers, typically with phone numbers of a local or national poison control center. The Mr. Yuk pictorial is trademarked and protected by copyright. The Pittsburgh Poison Center of Children's Hospital developed Mr. Yuk and tested its effectiveness with children at daycare centers, yet subsequent testing has not found conclusive evidence to substantiate the findings (Fergusson et al., 1982; Vernberg et al., 1984). Other picture-based warnings have been developed and tested for children, although they have not gained the notoriety of Mr. Yuk (Kalsher and Wolgalter, 2008; Wolgalter and Laughery, 2005).

Although warnings can be present, legible, and easily understood, if users do not read them, the effect is nil. In a recent survey, Vrendenburgh and colleagues (2010) investigated adolescent risk-taking behavior and use of instructions and warnings. They found 27% of participating adolescents rarely or never read instructions, and 35% rarely or never read warnings.

**Table 5  Hierarchy to Eliminate Hazards and Child Ergonomic Examples**

| Hierarchy | Example |
|---|---|
| Design to Eliminate hazards | **Crib Rails**<br>**Purpose:** Prevent strangulation (a child's body can slip an opening while their head cannot).<br>**Design Guidelines:** No more than a $2\frac{3}{8}$-in. space can exist between slats, spindles, corner posts, and rods at any point. A rectangular block $2\frac{1}{2}$ in. x $3\frac{1}{4}$ in. x $3\frac{1}{4}$ in. inserted in any position shall not be allowed to pass through any space between contoured or irregular slats or spindles. See CPSC (2001) for additional information. |
| Guard against hazards that cannot be eliminated through design | **Crib Rail Cover**<br>**Purpose**:<br>• Primary — Prevent injury hazard incurred by a child using a crib rail as "teething tool" or accidently bumping teeth or head on the crib rail.<br>• Secondary — May include attachment for teething toys, making them readily available for children.<br><br>**Design:** Crib rail guard/cover. Covered batting pads that cover wood crib railings, protecting the child, should he or she use the crib rail during teething (potential wood splinters or paint/varnish ingestion) or fall against the hardwood railing. |
| Warn about hazards that cannot be eliminated through design and/or guarding | **Crib and Bed Sheets**<br>**Purpose:** To prevent suffocation or strangulation of babies who may become entangled in crib or bed sheets.<br>**Future Design Guidelines/Requirements for Fitted Crib Sheets**<br><br>• Warning labels stressing the importance of a secure fit of sheets on crib mattresses. Anticipated Warning:<br><br>⚠ **WARNING**<br>Prevent suffocation or entanglement. Never use crib sheet unless it fits securely on crib mattress.<br>• Improvement in industry standards regarding the fit of crib sheets on mattresses.<br>• Current precautions offered to caregivers (CPSC Safety Alert, Crib Sheets, CPSC Document #5137): *To prevent tragedies, parents and caretakers can take the following precautions to ensure a safer sleeping environment for their young children.*<br>• *Make sure crib sheets fit snugly on a crib mattress and overlap the mattress so it cannot be dislodged by pulling on the corner of the sheet.*<br>• *Never use an adult sheet on a crib mattress; it can come loose and present an entanglement hazard to young children.*<br>• *Place a baby on his or her back on a firm, tight-fitting mattress in a crib meeting current safety standards.*<br>• *Remove pillows, quilts, comforters, and sheepskins from the crib.* |

## 3  CONCLUSIONS

Each new invention brings further design challenges for human factors engineers. Videogaming brings questions of exposure to violence and opportunities for producing games that will incorporate our culture and values, while children learn and still have fun. Social media (along with gaming) brings fears of a new generation of young adults who have difficulty interacting socially when in the physical presence of another person. They also bring us the chance to provide innovative ways to integrate learning in a virtual world with actions in the physical world. Extended computer use has us questioning the physical abilities of our youth and voicing concern over the detrimental effects of a sedentary lifestyle, including childhood obesity. Yet, it also introduces the prospects of shared exercise with friends who are miles away—at the click of a button. In short, there are vast opportunities to improve current designs for children, and new prospects are always on the horizon.

Designing for children is different than designing for adults. It requires additional knowledge of child development for a design to "pull" a child into a new developmental stage, while allowing them to succeed with their current skills. Toys, games, and playthings must be safe, even while providing an element of risk.

Most importantly, designing for children can serve to protect children from accidental injury and death. Each of the major causes of child injury and death (fire, drowning, falls, and traffic-related accidents) can be lessened through a multidisciplinary approach that

**Table 6 Suggestions for Constructing Warning Labels and How They May Differ for Children**

| Suggestions for Constructing Warnings (for Everyone) | Additional Considerations for Warnings for Children. |
|---|---|
| Warnings should be:<br><br>• Easy to understand<br>• Written in simple, uncomplicated language<br>• Uncluttered (easy to see and quickly comprehend)<br>• Placed where they are easily seen<br>• Durable | In addition, testing should include:<br><br>• Detection of the warning (did they see it?)<br>• Perception of the warning (did they read it?)<br>• Comprehension of the warning (did they understand it?)<br><br>Additional suggested testing includes whether the warning:<br><br>• Is recognized at a later date/time<br>• Is memorable<br>• Impacts decisions and/or actions<br><br>User testing should include children of the age and abilities expected to use the product and whether they find the warning (Steward and Martin, 1994; MacKinnon et al., 1993):<br><br>• Believable<br>• Important<br><br>Warnings should be specific, rather than general (Federal Trade Commission, 1981). |
| In compiling written warnings, designers should consider readers'<br><br>• Primary language(s)<br>• Reading ability<br>• Visual acuity in differing conditions (rain, low light, etc.)<br>• Visual field (so the warning is noticed) | In compiling written warnings, designers should consider child readers' abilities to:<br><br>• Understand the concept(s) being conveyed<br>• Problem solve<br>• Link warnings with their own behaviors and activities<br>• Understand the consequences of their own behaviors and deeds<br><br>In compiling written warnings, designers should consider caregivers' tendencies to overestimate their child's abilities.<br>An uncluttered visual field is less distracting. Adolescents demonstrate greater attention to and recall of warnings on generic (plain) packaging, than those containing brand imagery (Beede and Lawson, 1992) |
| If a picture is used, it should<br><br>• Provide a quick understanding of the issue<br>• Reinforce the textual message | If a picture is used:<br><br>• Pictures are better for very young children (Kalsher and Wogalter, 2008).<br>• Picture warnings may need an adult caregiver to explain them to children (DeLoache, 1991).<br>• The effectiveness of picture warnings differs according to the child's age. |

[a]*Note*: The same suggestions for constructing warnings "for everyone" (shown on the left of this table) apply to warnings for children (shown on the right of this table).

includes design modifications to products, places, and processes/procedures. Even the process of educating our youth and teaching injury prevention skills can be enhanced through informed design, such as brain-based learning, where knowledge of human abilities and limitations informs design.

It has been said that if one chooses not to pay for prevention, one will eventually pay in another way (medical costs). In terms of designing for children, particularly for injury prevention, the current needs include:

• More trained practitioners to identify needs, design improvements, implement interventions, and assess the effectiveness of such interventions
• Greater funding for design-related injury prevention programs and research
• Annotation of the cost effectiveness of design solutions
• Shared definitions of injuries and methods for collecting injury data

- Epidemiological injury data on risks, causes, and interventions
- Establishment of child injury prevention strategies based on injury data

There is much to do in meeting the needs to design for children. There is no shortage of opportunity. There is only the challenge to unite, to progress, and to care for our children, whatever their circumstance or background.

## 1  INTRODUCTION

The increased importance of user interface design methodologies, techniques, and tools in the context of the development and evolution of the information society has been widely recognized in the recent past in the light of the profound impact that interactive technologies are progressively acquiring on everybody's life and activities and of the difficulty in developing usable and attractive interactive services and products (e.g., Winograd, 2001). As the information society further develops, the issue of human–computer interaction (HCI) design becomes even more prominent when considering the notions of universal access (Stephanidis, 2001a) and universal usability (Shneiderman, 2000), aiming at the provision of access to anyone, from anywhere and at anytime, through a variety of computing platforms and devices to diverse products and services. Design for universal access in the information society has often been defined as design for diversity, based on the consideration of the several dimensions of diversity that emerge from the broad range of user characteristics, the changing nature of human activities, the variety of contexts of use, the increasing availability and diversification of information, the variety of knowledge sources and services, and the proliferation of diverse technological platforms that occur in the information society.

These issues imply an explicit design focus to systematically address diversity, as opposed to afterthoughts or ad hoc approaches, as well as an effort toward reconsidering and redefining the concept of design for all in the context of HCI (Stephanidis, 2001a). In the emerging information society, therefore, universal access becomes predominantly an issue of design, and the question arises of how it is possible to design systems that take into account diversity and satisfy the variety of implied requirements. Research work in the past two decades has highlighted a shift of perspective and reinterpretation of HCI design, in the context of universal access, from current artifact-oriented practices toward a deeper and multidisciplinary understanding of the diverse factors shaping interaction with technology, such as users' characteristics and requirements and contexts of use, and has proposed methods and techniques that enable to proactively take into account and appropriately address diversity in the design of interactive artifacts (Stephanidis, 2001a). In the framework of such efforts, the concept of design for all has been reinterpreted and redefined in the domain of HCI. One of the main concepts proposed in such a context as a solution for catering for the needs and requirements of a diverse user population in a variety of context of use is that of automatic user interface adaptation (Stephanidis, 2001b).

Despite the progress that has been made, however, the practice of designing for diversity remains difficult, due to intrinsic complexity of the task, the current limited expertise of designers and practitioners in designing interfaces capable of automatic adaptation, as well as the current limited availability of appropriate supporting tools.

The rationale behind this chapter is that the wider practice and adoption of an appropriate design method, supported through appropriate tools, have the potential to contribute to overcoming the above difficulties. Toward this end, this chapter, after highlighting the main issues involved in the effort of designing for diversity, briefly describes a design method, the unified user interface design method, which has been developed in recent years to facilitate the design of user interfaces with automatic adaptation behavior (Savidis and Stephanidis, 2009a). Subsequently, the chapter discusses a series of tools and components which have been developed and applied in various development projects. These tools are targeted to support the design and development of user interfaces capable of adaptation behavior and in particular the conduct and application of the unified user interface development approach. Over the years, these tools have demonstrated the technical feasibility of the approach and have contributed to reducing the practice gap between traditional user interface design and design for adaptation. They have been applied in a number of pilot applications and case studies.

## 2  DESIGN FOR ALL: OVERVIEW OF APPROACHES, METHODS, AND TECHNIQUES

Universal access implies the accessibility and usability of information society technologies by anyone, anywhere, anytime, with the aim to enable equitable access and active participation of potentially all citizens in existing and emerging computer-mediated human activities by developing universally accessible and usable products and services which are capable of accommodating individual user requirements in different contexts of use and independently of location, target machine, or run time environment. The origins of the concept of universal access are to be identified in early approaches to accessibility, mainly targeted toward providing access to computer-based applications by users with disabilities.

Subsequently, accessibility-related methods and techniques have been generalized and extended toward more generic and inclusive approaches. HCI design approaches targeted to support universal access are often grouped under the term *design for all*.

### 2.1  Reactive versus Proactive Strategies

Accessibility in the context of HCI refers to the access by people with disabilities to information and communication technologies (ICT). Interaction with ICT may be affected in various ways by the user's permanent, temporary, or contextual individual abilities or functional limitations. For example, someone with limited seeing functions will not be able to use an interactive system which only provides visual output, while someone with limited bone or joint mobility or movement functions which affect the upper limbs will encounter difficulties in using an interactive system which only accepts input through the standard keyboard and mouse. Accessibility in the context of HCI aims to overcome such barriers by making the interaction experience of people with diverse functional or contextual limitations as near as possible to that of people without such limitations.

In traditional efforts to improve accessibility, the main direction followed has been to enable disabled users to access interactive applications originally developed for able-bodied users through appropriate adaptations.

Two main technical approaches to adaptation have been followed. The first is to treat each application separately and take all the necessary implementation steps to arrive at an alternative accessible version—product-level adaptation. Product-level adaptation practically often implies redevelopment from scratch. Due to the high costs associated with this strategy, it is considered the least favorable option for providing alternative access. The second alternative is to "intervene" at the level of the particular interactive application environment (e.g., MS-Windows) in order to provide appropriate software and hardware technology so as to make that environment alternatively accessible (environment-level adaptation). The latter option extends the scope of accessibility to cover potentially all applications running under the same interactive environment, rather than a single application.

The above approaches have given rise to several methods for addressing accessibility, including techniques for the configuration of input/output at the level of the user interface and the provision of assistive technologies. Popular assistive technologies include screen readers and Braille displays for blind users, screen magnifiers for users with low vision, alternative input and output devices for motor-impaired users (e.g., adapted keyboards, mouse emulators, joystick, binary switches), specialized browsers, and text prediction systems.

Despite progress, prevailing practices aimed at providing alternative access systems, either at the product or environment level, have been criticized for their essentially reactive nature (Emiliani, 2009). Although the reactive approach to accessibility may be the only viable solution in certain cases, it suffers from some serious shortcomings, especially when considering the radically changing technological environment and, in particular, the emerging information society technologies. The critique is grounded in two lines of argumentation. The first is that reactive solutions typically provide limited and low-quality access.

The second line of critique concerns the economic feasibility of the reactive approach to accessibility. Reactive approaches, based on a posteriori adaptations, though important to partially solve some of the accessibility problems of people with disabilities, are not viable in sectors of the industry characterized by rapid technological change. By the time a particular access problem has been addressed, technology has advanced to a point where the same or a similar problem reoccurs. The typical example that illustrates this state of affairs is the case of blind people's access to computers. Each generation of technology (e.g., DOS environment, windowing systems, and multimedia) caused a new "generation" of accessibility problems to blind users, addressed through dedicated techniques, such as text-to-speech translation for the DOS environment, off-screen models, and filtering for the windowing systems.

In some cases, adaptations may not be possible without loss of functionality. For example, in the early versions of windowing systems, it was impossible for the programmer to obtain access to certain window functions, such as window management. In subsequent versions, this shortcoming was addressed by the vendors of such products allowing certain adaptations on interaction objects on the screen.

Finally, adaptations are programming intensive and, therefore, are expensive and difficult to implement and maintain. Minor changes in product configuration, or the user interface, may require substantial resources to rebuild the accessibility features.

From the above, it becomes evident that the reactive paradigm to accessible products and services does not suffice to cope with the rapid technological change and the evolving human requirements. At the same time, the proliferation of interactive products and services in the information society, as well as of technological platforms and access devices, brought about the need to reconsider the issue of access under a proactive perspective, resulting in more generic solutions. This entails an effort to build access features into a product starting from its conception throughout the entire development life cycle. In the context of the emerging information society, therefore, universal access becomes predominantly an issue of design, and the question arises of how it is possible to design systems that permit systematic and cost-effective approaches to accommodating all users. Toward this end, the concept of design for all has been revisited in the context of HCI (Stephanidis et al., 1998, 1999).

In the context of universal access, design for all in the information society has been defined as a general framework catering for conscious and systematic efforts to proactively apply principles, methods, and tools in order to develop information society technology (IST) products and services that are accessible and usable by all citizens, thus avoiding the need for a posteriori adaptations or specialized design. Design for all, or universal design, is well known in several engineering disciplines, such as, for example, civil engineering and architecture, with many applications in interior design, building, and road construction. In the context of universal access, design for all either subsumes or is a synonym for terms such as *accessible design*, *inclusive design*, *barrier-free design*, and *universal design*, each highlighting different aspects of the concept. Through the years, the concept of design for all has assumed various connotations:

- Design of interactive products, services, and applications which are suitable for most of the potential users without any modifications. Related efforts mainly aim to formulate accessibility guidelines and standards in the context of international collaborative initiatives (see Section 2.2).
- Design of products which have standardized interfaces capable of being accessed by specialized user interaction devices (Zimmermann et al., 2002).

- Design of products which are easily adaptable to different users by incorporating adaptable or customizable user interfaces (Stephanidis, 2001b). This entails an effort to build access features into a product starting from its conception throughout the entire development life cycle.

## 2.2 Accessibility Guidelines and De Facto Standards

Guidelines play a key role in the adoption of Web accessibility and usability by industries and society. In essence, they constitute a rapidly evolving medium for transferring established and de facto knowledge (know-how) to various interested parties.

Concerning accessibility, a number of guidelines have been developed (Vanderheiden et al., 1996; Pernice and Nielsen, 2001). In particular, the Web Content Accessibility Guidelines (WCAG) [World Wide Web Consortium (W3C), 1999] explains how to make Web content accessible to people with disabilities. Web "content" generally refers to the information on a Web page or Web application, including text, images, forms, and sounds. WCAG 1.0 provides 14 guidelines that are general principles of accessible design. Each guideline has one or more checkpoints that explain how the guideline applies in a specific area. WCAG foresees three levels of compliance, A, AA, and AAA. Each level requires a stricter set of conformance guidelines, such as different versions of Hypertext Markup Language (HTML) (transitional vs. strict) and other techniques that need to be incorporated into code before accomplishing validation. In addition to WCAG 1.0, in December 2008, the W3C announced a new version of the guidelines, targeted to help Web designers and developers create sites that better meet the needs of users with disabilities and older users. Drawing on extensive experience and community feedback, WCAG 2.0 (W3C, 2008) improves upon WCAG 1.0 and applies to more advanced technologies.

In general, for a website to comply with accessibility guidelines, it should have at least the following characteristics:

- (X)HTML Validation from the W3C for the page content
- Cascading style sheet (CSS) validation from the W3C for the page layout
- At least WAI-AA (preferably AAA) compliance with the Web Accessibility Initiative (WAI) WCAG
- Compliance with all guidelines from Section 508 of the U.S. Rehabilitation Act
- Access keys built into the HTML
- Semantic Web Markup
- A high-contrast version of the site for individuals with low vision
- Alternative media for any multimedia used on the site (video, flash, audio, etc.).

The usage of guidelines is today the most widely adopted process by Web authors for creating accessible Web content. This approach has proven valuable for bridging a number of barriers faced today by people with disabilities.

Additionally, guidelines constitute de facto standards as well as the basis for legislation and regulation related to accessibility in many countries (Kemppainen et al., 2009).

For example, U.S. government Section 508 of the U.S. Rehabilitation Act (Rehabilitation Act Amendments, 1998) provides a comprehensive set of rules designed to help Web designers make their sites accessible.

Unfortunately, however, many limitations arise in the use of guidelines due to a number of reasons, including the difficulty in interpreting and applying guidelines, which require extensive training. Additionally, the process of using, or testing conformance to, widely accepted accessibility guidelines is complex and time consuming. To address this issue, several tools have been developed enabling the semiautomatic checking of HTML documents. Such tools make easier the development of accessible Web content, especially due to the fact that the checking of conformance does not rely solely on the expertise of developers. Developers with limited experience in Web accessibility can use such tools for evaluating Web content without the need to go through a large number of checklists.

As a final consideration, guidelines provide a "one-size-fits-all" approach to accessibility, which, while ensuring a basic level of accessibility for users with various types of disabilities, does not support personalization and improved interaction experience.

## 2.3 Design for All as User Interface Adaptation Design

In the light of the above, it appears that single artifact-oriented design approaches offer limited possibilities of addressing the requirements posed by universal access. A critical property of interactive artifacts becomes, therefore, their capability for automatic adaptation and personalization (Stephanidis, 2001b).

Methods and techniques for user interface adaptation meet significant success in modern interfaces. Some popular examples are the desktop adaptations in Microsoft Windows XP, offering, for example, the ability to hide or delete unused desktop items. Microsoft Windows Vista and Seven (7) also offer various personalization features of the desktop based on personal preferences of the user, by adding helpful animations, transparent glass menu bars, and live thumbnail previews of open programs and desktop gadgets (clocks, calendars, weather forecast, etc.). Similarly, Microsoft Office applications offer several customizations, such as toolbars positioning and showing/hiding recently used options. However, adaptations integrated into commercial systems need to be set manually and mainly focus on aesthetic preferences. In terms of accessibility and usability, for instance to people with disability or older people, only a limited number of adaptations are available, such as keyboard shortcuts, size and zoom options, changing color and sound settings, and automated tasks.

On the other hand, research efforts in the past two decades have elaborated more comprehensive and

systematic approaches to user interface adaptations in the context of universal access and design for all. The unified user interface methodology was conceived and applied (Savidis and Stephanidis, 2009a) as a vehicle to efficiently and effectively ensure, through an adaptation-based approach, the accessibility and usability of user interfaces (UIs) to users with diverse characteristics, supporting also technological platform independence, metaphor independence, and user-profile independence. In such a context, automatic UI adaptation seeks to minimize the need for a posteriori adaptations and deliver products that can be adapted for use by the widest possible end-user population (adaptable user interfaces). This implies the provision of alternative interface manifestations depending on the abilities, requirements, and preferences of the target user groups as well as the characteristics of the context of use (e.g., technological platform, physical environment). The main objective is to ensure that each end user is provided with the most appropriate interactive experience at run time.

The scope of design for diversity is broad and complex, since it involves issues pertaining to context-oriented design, diverse user requirements, as well as adaptable and adaptive interactive behaviors. This complexity arises from the numerous dimensions that are involved and the multiplicity of aspects in each dimension. In this context, designers should be prepared to cope with large design spaces to accommodate design constraints posed by diversity in the target user population and the emerging contexts of use in the information society. Therefore, designers need accessibility knowledge and expertise. Moreover, user adaptation must be carefully planned, designed, and accommodated into the life cycle of an interactive system, from the early exploratory phases of design through evaluation, implementation, and deployment.

Therefore, a need arises of providing computational tools which can support the design of user interface adaptation. In the past, the availability of tools was an indication of maturity of a sector and a critical factor for technological diffusion. As an example, graphical user interfaces became popular once tools for constructing them became available, either as libraries of reusable elements (e.g., toolkits) or as higher level systems (e.g., user interface builders and user interface management systems). As design methods and techniques for addressing diversity are anticipated to involve complex design processes and have a higher entrance barrier with respect to more traditional artifact-oriented methods, it is believed that the provision of appropriate design tools can contribute overcoming some of the difficulties that hinder the wider adoption of design methods and techniques appropriate for universal access, in terms of both quality and cost, by making the complex design process less resource demanding. The main objective in this respect is to offer tools which reduce the difference in practice between conventional user interface development and development for adaptation.

Finally, another prominent challenge in the context of universal access has been identified as the need for developing large-scale case study applications providing instruments for further experimentation and ultimately improving the empirical basis of the field by collecting knowledge on how design for diversity may be concretely practiced. Such case studies should aim to not only demonstrate technical feasibility but also assess the benefits of the overall approach as well the applied methods and tools.

## 3 UNIFIED USER INTERFACES

The *unified user interface development* methodology provides a complete technological solution for supporting universal access of interactive applications and services through a principled and systematic approach toward coping with diversity in the target user requirements, tasks, and environments of use (Savidis and Stephanidis, 2009a). A unified user interface comprises a single (unified) interface specification that exhibits the following properties:

1. It embeds representation schemes for user and usage context parameters and accesses user and usage context information resources (e.g., repositories, servers) to extract or update such information.

2. It is equipped with alternative implemented dialogue artifacts appropriately associated with different combinations of values for user and usage context–related parameters. The need for such alternative dialogue patterns is identified during the design process, when, given a particular design context, for differing user and usage context attribute values, alternative design artifacts are deemed as necessary to accomplish optimal interaction.

3. It embeds design logic and decision-making capabilities that support activating, at run time, the most appropriate dialogue patterns according to particular instances of user and usage context parameters and is capable of interaction monitoring to detect changes in parameters.

As a consequence, a unified user interface realizes:

- User-adapted behavior (user awareness), that is, the interface is capable of automatically selecting interaction patterns appropriate to the particular user.

- Usage context–adapted behavior (usage context awareness), that is, the interface is capable of automatically selecting interaction patterns appropriate to the particular physical and technological environment.

From a user perspective, a unified user interface can be considered as an interface tailored to personal attributes and to the particular context of use, while from the designer perspective it can be seen as an interface design populated with alternative designs, each alternative addressing specific user and usage context parameter values. Finally, in an engineering perspective, a unified user interface is a repository of implemented

dialogue artifacts, from which the most appropriate according to the specific task context are selected at run time by means of an adaptation logic supporting decision making.

At run time, the adaptations may be of two types:

a) Adaptations driven from initial user and context information known prior to the initiation of interaction

b) Adaptations driven by information acquired through context and interaction monitoring

The former behavior is referred to as *adaptability* (i.e., initial automatic adaptation) reflecting the interface's capability to automatically tailor itself initially to each individual end user in a particular context. The latter behavior is referred to as *adaptivity* (i.e., continuous automatic adaptation) and characterizes the interface's capability to cope with the dynamically changing or evolving user and context characteristics.

The concept of unified user interface is supported by a specifically developed architecture (Savidis and Stephanidis, 2009b). This architecture consists of independent communicating components, possibly implemented with different software methods and tools (see Figure 1). Briefly, a user interface capable of adaptation behavior includes (i) information regarding user and context characteristics (user and context profile), (ii) a decision-making logic, and (iii) alternative interaction widgets and dialogues.

The storage location, origin, and format of user-oriented information may vary. For example, information may be stored in profiles indexed by unique user identifiers, may be extracted from user-owned cards, may be entered by the user in an initial interaction session, or may be inferred by the system through continuous interaction monitoring and analysis. Additionally,

usage context information, for example, user location, environment noise, and network bandwidth, is normally provided by special-purpose equipment, such as sensors, or system-level software. In order to support optimal interface delivery for individual user and usage context attributes, it is required that for any given user task or group of user activities the implementations of the alternative best-fit interface components are appropriately encapsulated.

At design time, the design space is captured through a task hierarchy representation which allows for explicitly assigning alternative designs to node elements, called polymorphic task hierarchy (see Figure 2). Alternatives designs, call styles, can affect the syntactic level (i.e., alternative task decompositions) or the lexical level (i.e., alternative (i.e., alternative physical designs, such as layout appearances and widgets). Adaptation relations are established among alternative design styles for each node in the hierarchy. These relations define the run time adaptation behavior of the user interface, thus providing the adaptation decision-making logic. They include exclusion (two styles are never active at the same time), compatibility (two styles may be active at the same time), substitution (one style is deactivated and the second one is activated), and augmentation (the second style is activated, keeping the first active).

Upon start-up and during run time, the software interface relies on the particular user and context profiles to assemble the user interface on the fly, collecting and gluing together the constituent interface components required for the particular end user and usage context. In this context, run time adaptation-oriented decision making is engaged, so as to select the most appropriate interface components for the particular user and context profiles, for each distinct part of the user interface. The role of the decision making in UI adaptation is to effectively drive the interface assembly process

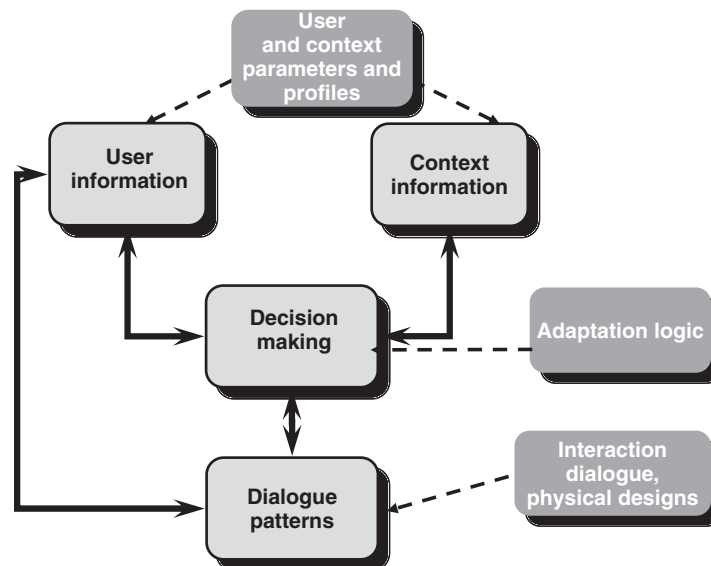

**Figure 1**   Unified user interface architecture.
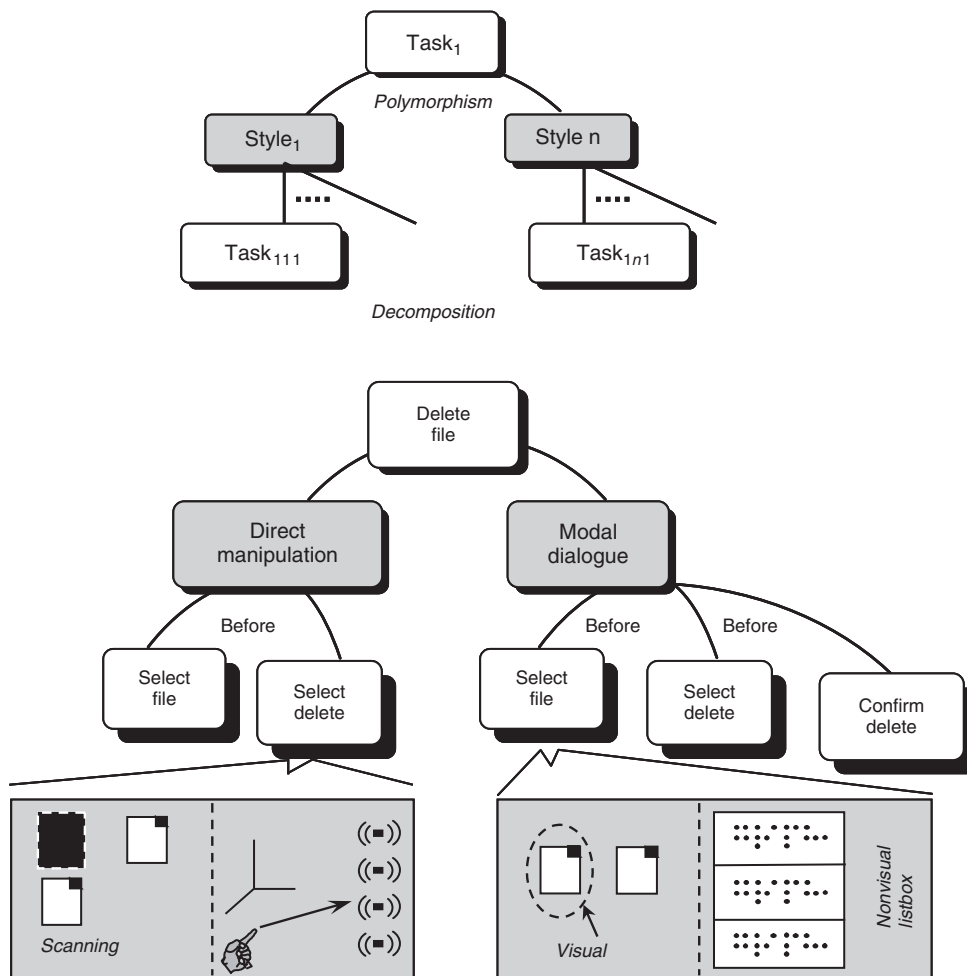

**Figure 2**  Example of polymorphic task hierarchy.

by deciding which interface components need to be selectively activated. The interface assembly process has inherent software engineering implications on the software organization model of interface components. For any component (i.e., part of the interface to support a user activity or task) alternative implemented incarnations may need to coexist, conditionally activated during run time due to decision making. In other words, there is a need to organize interface components around their particular task contexts, enabling them to be supported in different ways depending on user and context parameters. This contrasts with traditional nonadapted interfaces in which all components have singular implementations.

The unified user interface development method is not prescriptive regarding how each component is to be implemented (Savidis and Stephanidis, 2009c). For example, the alternative ways of representing user-oriented information and decision-making mechanisms may be employed. Also, the method does not affect the way designers will create the necessary alternative artifacts (e.g., through prototyping).

Since its beginning, the unified user interface development methodology has been accompanied by tools targeted to facilitate its employment. Early tools developed in this context are discussed in detail elsewhere (Stephanidis, 2001a). The next sections of this chapter focus on more recent tools which have been applied in a variety of case studies and have proved to contribute to a more effective and efficient application of the unified user interface concept, with particular focus on design.

## 4   TOOLS FOR DESIGN OF USER INTERFACE ADAPTATIONS

Tools developed in recent years to support user interface adaptation design include facilities for specifying

decision-making rules, adaptation design tools, adaptable widget toolkits for various interaction platforms, and user interface prototyping facilities.

## 4.1 Decision-Making Specification Language

The role of decision making in user interface adaptation is to effectively drive the interface assembly process by deciding which interface components need to be selectively activated. The Decision Making Specification Language (DMSL) (Savidis et al., 2005) is a rule-based language specifically designed and implemented for supporting the specification of adaptations. DMSL supports the effective implementation of decision making and has been purposefully elaborated to be easier for designers to directly assimilate and deploy, in comparison to programming-based approaches using logic-based or imperative-oriented programming languages.

In DMSL, the decision-making logic is defined in independent decision "if–then–else" blocks, each uniquely associated to a particular dialogue context. The individual end-user and usage context profiles are represented in the condition part of DMSL rules using an attribute values notation. Three types of design parameters values are allowed: (i) enumerated, that is, values belong to a list of (more than two) strings specified by the designer; (ii) boolean, that is, values True or False; and (iii) integer, which are specified by supplying minimum and maximum bounds of an integer range allowed as a value. Value ranges define the space of legal values for a given attribute. The language is equipped with three primitive statements: (a) dialogue, which initiates evaluation for the rule block corresponding to dialogue context value supplied; (b) activate, which triggers the activation of the specified component(s); and (c) cancel, which, similar to activate, triggers the cancellation of the specified component(s). These rules are compiled in a tabular representation that is executed at run time. Figure 3 provides an example DMSL rule. The representation engages simple expression evaluation trees for the conditional expressions.

The decision-making process is performed in independent sequential decision sessions, and each session is initiated by a request of the interface assembly module for execution of a particular initial decision block. In such a decision session, the evaluation of an arbitrary decision block may be performed, while the session completes once the computation exits from the initial decision block. The outcome of a decision session is a sequence of activation and cancellation commands, all of which are directly associated with the task context of the initial decision block. Those commands are posted back to the interface assembly module as the product of the performed decision-making session.

## 4.2 MENTOR Tool for User Interface Adaptation

The unified user interface design is recognized to require a higher initial effort and investment than traditional HCI design approaches, as it involves the identification of relevant design parameters, the design of alternative interface instances, and the delivery of an interface adaptation logic. MENTOR (Antona et al., 2006) is a support tool for the process of unified user interface design, which has been developed in order to address the following objectives:

- Provision of practical integrated support for all phases of unified user interface design by appropriately guiding the process and structuring the outcomes of creative design steps through appropriate editing facilities.
- Provision of practical support for a "smooth transition" from design to development of unified user interfaces through availability of automated verification mechanisms for the designed adaptation logic as well as the automated generation of "ready-to-implement" interface specifications, including the adaptation logic.
- Provision of support for reusing and extending (parts of) past design cases.

MENTOR targets the community of interface designers and do not assume deep knowledge of the unified user interface design method or particular HCI modeling techniques while, on the other hand, also supporting designers more experienced in adaptation design in effectively performing their work.

Figure 4 depicts the overall interactive environment of MENTOR, comprising four main editing environments:

- *Design Parameters Editor* (1 in Figure 4). The design parameters editor supports the encoding of design parameter attributes and related value spaces. These constitute the "vocabulary" for

---

| 1 | If | [Elderly user's age = 1 or 2 or 3] or [Elderly user 's life situation = 2 or 3] or [Elderly user's computer literacy level = 0] or [ Vision impairment = 1 or 2 or 3] |
| | Then | Resolution 640*480 pixels |

| 2 | If | [Elderly user's life situation = 1] or [Elderly user's computer literacy level = 1] |
| | Then | Resolution 800*600 pixels |

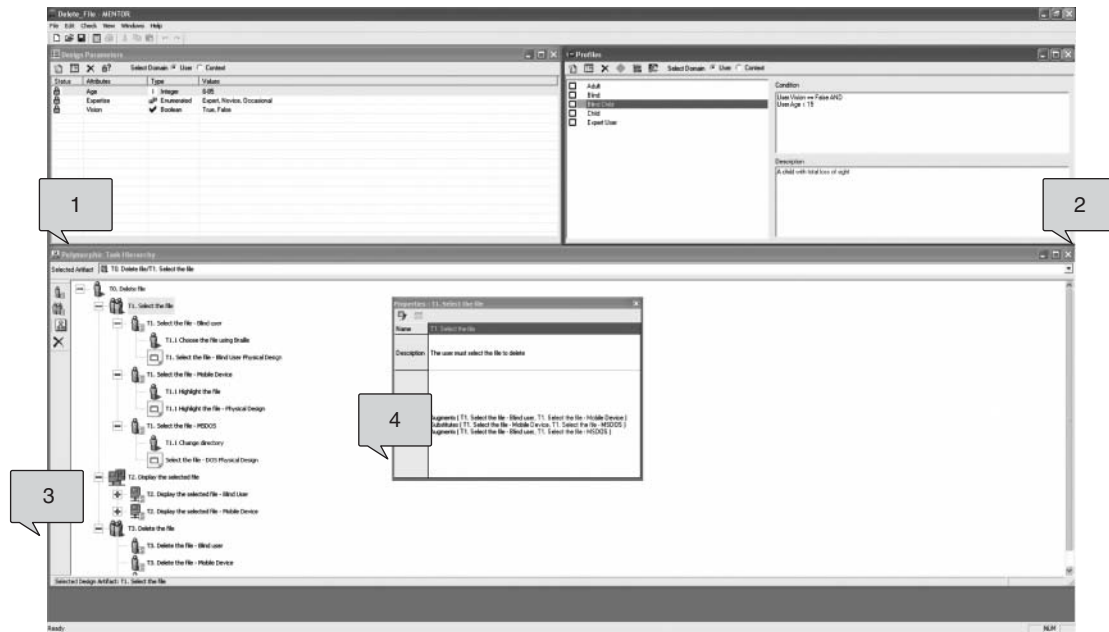
**Figure 3**  Example DMSL rule.


**Figure 4**  Overall MENTOR interactive environment: (1) design parameters editor; (2) profile editor; (3) polymorphic task hierarchy editor; (4) properties editor.

defining the "adaptation space" of the user interface under design. Parameters can belong to the user domain (i.e., user characteristics) or to the context domain (i.e., characteristics of the context of use and of the interactive platform). The editor also supports importing existing design parameters, applying the necessary consistency checking.

- *Profile Editor* (2 in Figure 4). User and context profiles can be defined by setting design parameter values in the profile editor. Existing profiles can be imported if consistent with the current design case.

- *Polymorphic Task Hierarchy Editor* (3 in Figure 4). The polymorphic task hierarchy editor allows designers to perform polymorphic task decomposition and encode the results in a hierarchy. The editor guides the decomposition process through decomposition steps.

- *Properties Editor* (4 in Figure 4). This editor allows assigning specific properties to the artifacts in the polymorphic hierarchy. Different categories of artifacts involve different properties. The most important piece of information to be attached to styles concerns the user and context parameter instantiations that define the style appropriateness at run time. Style conditions in MENTOR are formulated in the condition fragment of DMSL. For polymorphic artifacts, adaptation relations between children styles also need to be specified (selecting among incompatibility, compatibility, augmentation, and substitution).

Automated verification facilities for DMSL conditions are also included in MENTOR. These include the verification of the lexical and syntactic correctness as well as the verifiability of each DMSL expression separately. Additionally, hierarchical relations among styles in the polymorphic task hierarchy are also checked. MENTOR also supports verifying that the conditions on two styles related through a particular relation are compatible with the type of the relation. For example, if two styles are defined as incompatible, their conditions must not be consistent. These verification facilities ensure that the resulting run time adaptation logic is semantically sound and does not contain ambiguities which could cause problems when applying adaptations.

MENTOR also produces textual documentation of designs which can be used for several purposes, such as reviewing and evaluation, interface documentation, and, most importantly, implementation. The design report contains the project's design parameters and defined profiles, a textual representation of the polymorphic task hierarchy, the properties of each designed artifact, and the designed adaptation logic in the form of DMSL rules automatically produced by the tool. The DMSL rules produced by MENTOR can be directly embedded in the decision-making component of the designed user interface.

MENTOR has been validated in a number of design case studies, including the design of a unified user interface in the context of a health telematics scenario as well as the design of a shopping cart (Antona et al., 2006). These case studies have confirmed its overall usefulness and its advantages compared to "paper-based" adaptation design. The designers involved in

the case studies were able to rapidly acquire familiarity with the unified user interface design method and with the tool itself and expressed the opinion that the tool appropriately reflects and complements the method and significantly simplifies the conduct of polymorphic task decomposition. The verification facilities have also been found particularly effective in helping the designer to detect and correct inconsistencies or inaccuracies in the style conditions. Furthermore, the tool has been considered as particularly useful in providing the automatic generation of the DMSL adaptation logic, which, in the case of the shopping cart case study, has been directly integrated in the prototype implementation of the component.

### 4.3 Interaction Toolkits

User interface adaptation necessitates alternative versions of interaction artifacts to be created and coexist in the eventual design space. At the lexical level of interaction this can be achieved through software toolkits capable of dynamically delivering an interface instance that is lexically adapted to a specific user in a specific context of use. Such toolkits are essentially software libraries encompassing alternative versions of interaction elements and common dialogues, each version designed in order to address particular values of the user and usage context parameters. The run time adaptation-oriented selection of the most appropriate version, according to the end-user and usage context profiles, is the key element in supporting a wide range of alternative interactive incarnations. It should be noted that the presence and management of the alternative versions is fully transparent to toolkit clients. The latter provides the behavior of a smart toolkit capable of adaptively delivering its interaction elements so as to fit the current usage profile.

#### 4.3.1 EAGER

In order to support unified Web user interfaces, the combination of user-centered design, user interface prototyping, and design guidelines is applied together with unified user interface design. The proposed methodology (Partarakis et al., 2010a) is derived from the unified user interface software architecture and is instantiated in the EAGER software toolkit. In particular, EAGER integrates a design repository of:

- Alternative primitive UI elements with enriched attributes (e.g., buttons, links, radios)
- Alternative structural page elements (e.g., page templates, headers, footers, containers)
- Fundamental abstract interaction dialogues in multiple alternative styles (e.g., navigation, file uploaders, paging styles, text entry)

The EAGER Designs Repository is an extensible collection of implemented and ready-to-use alternative interaction elements which are organized around a polymorphic task hierarchy (Savidis and Stephanidis, 2009a). Each alternative element version, called a style following the terminology of Savidis and Stephanidis

(2009a), is purposefully designed to address the requirements of specific user and context parameter values. Alternative styles have been designed following typical user-centered design, user interface prototyping, and adoption of design guidelines. Additionally, EAGER design alternatives not only integrate current accessibility guidelines but also provide a suitable approach to personalized accessibility. In this respect, the EAGER Designs Repository can be viewed as encompassing consolidated adaptation design knowledge, thus greatly facilitating designers in the choice of suitable adaptations according to user-related or context-related parameters.

The Designs Repository component of EAGER provides the designs of alternative dialogue controls in the form of abstract interaction objects and task-level polymorphism. For each alternative version, the respective adaptation rationale is also recorded, including the profile parameters which are adaptively addressed.

An example is provided by images. Blind or low-vision users are interested not in viewing images but in reading the alternative text that describes the image. In order to facilitate blind and low-vision users, two design alternatives were produced, which are presented in Figure 5.

The text representation of the image presents not the image but only a label with the prefix "Image:" followed by the alternative text of the image. The second representation, targeted to users with visual impairments, is same as the first with the difference that, instead of a label, a link is included that leads to the specific image giving the ability of saving the image. In particular, a blind user may not wish to view an image but may wish to save it to a disk and use it properly. In addition to the above, another design was produced that can be selected as a preference by Web portal users in which the images are represented as a thumbnail bounding the size that holds on the Web page. A user who wishes to view the image in normal size may click on it. In Table 1, the design rationale of the alternative images design is presented, including its adaptation logic.

EAGER allows Microsoft® .NET developers to create interfaces that conform to the W3C accessibility guidelines (W3C, 1999) and which are able to adapt to the interaction modalities, metaphors, and user interface elements most appropriate to each individual user, according to profile information (user and context). The process of employing EAGER is significantly less demanding in terms of time, experience, and skills required from the developer than the typical process of developing Web interfaces for the "average" user. The benefits gained by using the EAGER toolkit lie on a number of dimensions, including:

- The time required for designing a Web application and the detail of design information needed
- The time required for designing the front end of the application to be used by end users
- The developer effort for setting up the application

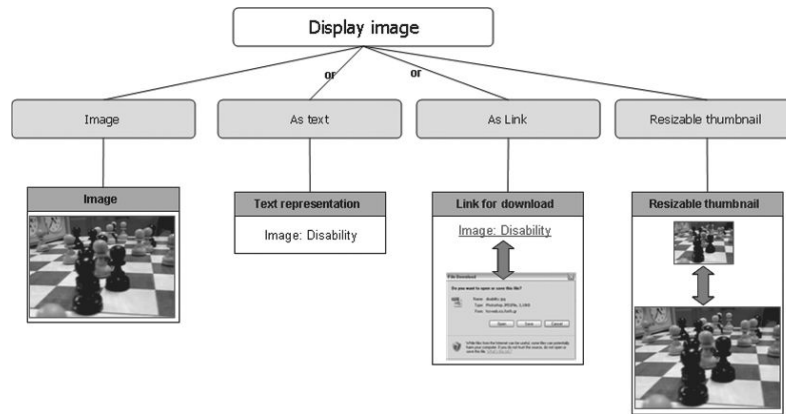
Through EAGER, the complexity of the UI design effort is radically reduced due to the flexibility provided


**Figure 5**   Alternative image hierarchy in EAGER. (From Partarakis et al., 2010a.)

**Table 1  Design Rationale of Alternative Image Styles (from 0)**

| | | Task: Display Image | | |
|---|---|---|---|---|
| Style | Image | As Text | As Link | Resizable Thumbnail |
| Targets | — | Facilitate screen reader and low-vision users in order not to be in difficulties with image viewing | Facilitate screen reader and low-vision users in order not to be in difficulties with image viewing but with the capability to save or view an image | Viewing images in small size in order not to hold large size on the Web page with the capability to enlarge the image to normal size when it is necessitated |
| Parameters | User (default) | User (blind or low vision) | User (blind or low vision) and user preference | User (preference) |
| Properties | View image | Read image alternative text | Read image alternative text and/or select link named as the image alternative text to save or view the image | View image thumbnail and select it to view it in normal size |
| Relationships | Exclusive | Exclusive | Exclusive | Exclusive |

by the toolkit for designing interfaces at an abstract task-oriented level. Therefore, designers are not required to be aware of the low-level details introduced in representing interaction elements; rather they should be aware of only the high-level structural representation of a task and its appropriate decomposition into subtasks, each of which represents a basic UI and system function.

On the other hand, the process of designing the actual front end of the application using a mark-up language is radically decreased in terms of time, due to the fact that developers initially have to select among a number of interface components each of which represents a far more complex facility. Additionally, developers do not have to spend time editing the presentation characteristics of the high-level interaction element due to the internal styling behavior.

The actual process of transforming the initial design into the final Web application using traditional UI controls introduces a lot of coding. However, when using EAGER, the amount of code required is significantly reduced due to the fact that the developer has the option to use a number of plug-and-play controls each of which

represents a complex user task. These controls are contained in the advance UI library of EAGER consisting of a total number of 55K pure code lines. Furthermore, the incorporation of EAGER's higher level elements make the code more usable, more readable, and especially safe due to the fact that each interaction component introduced is designed separately and developed and tested introducing a high level of code reuse, efficiency, and safety.

### 4.3.2   JMorph

The JMorph adaptable widget library (Leonidis et al., in press) is another example of a toolkit that inherently supports the adaptation of user interface components. It contains a set of adaptation-aware widgets designed to satisfy the needs of various target devices—Swing-based components for PC and Adaptive Window Toolkit- (AWT-) based components for Windows Mobile devices. Adaptation is completely transparent to developers, who can use the widgets as typical UI building blocks.

JMorph instantiates a common look and feel across the applications developed using it. The implemented

adaptations are meant to address the interaction needs of older users (Leuteritz et al., 2009) and follow specific guidelines which have been encoded into DMSL rules (Savidis et al., 2005). This approach is targeted to novice developers of adaptable user interfaces, as it relieves developers from the task of reimplementing or modifying their applications to integrate adaptation-related functionality.

The developed widgets are built in a modular way that facilitates their further evolution by offering the necessary mechanism to support new feature additions and modifications. Therefore, more experienced developers can use their own adaptation rules to modify the adaptation behavior of the interactive widgets.

The library's implementation using the Java programming language ensures the development of portable UIs that can run unmodified with the same look regardless of the underlying operating system (OS). Apart from OS independence, the proposed framework offers a solution that targets mobile devices running Windows Mobile.

The JMorph library provides the necessary mechanisms to support the alternative look and feel of either the entire environment (i.e., skins) or individual applications.

For that to be achieved, every widget initially follows the general rules to ensure that the common look and feel invariant will be met and then applies any additional presentation directives declared as "custom" look and feel rules. A custom rule could affect either an individual widget (e.g., the OK button that appears in the confirmation dialog of a specific application) or a group of widgets; therefore, entire applications can be fully skinned since their widgets inherently belong to a group defined by the application itself (e.g., all the buttons that belong to a specific application). The look-and-feel implementation of JMorph is based on the Synth technology (Sun Microsystems, 2010a).

Every adaptable widget in JMorph extends the relevant primitive Java component (i.e., AdaptableButton extends Java's Swing JButton) to provide its typical functionality, while the adaptation-related functionality is exposed via a straightforward application programming interface (API), the AdaptableWidget API. The API declares one main and two auxiliary methods: the adapt and the get/set function methods. Application developers can apply adaptation by simply calling the adapt method. The notion of the adapt method and the augmented set/get attribute methods has been originally proposed and implemented in the context of the PIM language-based generator of multiplatform adaptable toolkits (Savidis et al., 1997). This zero-argument method is the key method of the whole API, as it encapsulates the essential adaptation functionality and every adaptation-aware widget implements it accordingly. The global adaptation process includes first the evaluation of the respective DMSL rules that define the appropriate style and size and then their application through Synth's region matching mechanism.

For a local look and feel to be applied, the adapt method additionally utilizes the function getter method. The function attribute can be set manually by the designer/developer and is used on the one hand to decide whether and which transformations should be applied and on the other hand to define the group (i.e., all the buttons appear in the main navigation bar) or the exact widget (i.e., the OK button in a specific application) where they should be applied utilizing Synth's name-matching mechanism.

The adaptable widgets currently implemented in JMorph include label, button, check box, list, scrollbar, textbox, text area, drop-down menu, radio button, hyperlink, slider, spinner, progress bar, tabbed pane, menu bar, menu, menu item, and tooltip. Complex widgets such as date and time entry have also been developed. Adaptable widget attributes include background color/image, widget appearance and dimensions, text appearance, cursor's appearance on mouse over, highlighting of currently selected items or options, orientation options (vertical or horizontal), and explanatory tooltips.

Figure 6 shows some of the available widgets. Adaptable attributes for each widget are summarized in Table 2. All widgets in the library also include a text description which allows easy interoperation with speech-based interfaces, thus offering also the possibility to deploy a nonvisual instance of the developed interfaces.

## 4.4 Adaptive User Interface Prototyping

Popular user interface builders provide graphical environments for user interface prototyping, usually following a WYSIWYG ("what you see is what you get")

**Figure 6** Examples of adaptable widgets.

design paradigm. Available WYSIWYG editors offer graphical editing facilities that allow designers to perform rapid prototyping visually. Such editors may be stand alone or embedded in integrated environments (IDEs), that is, programming environments which allow developing application functionality for the created prototypes directly. Commonly used IDEs are Microsoft Visual Studio, NetBeans, and Eclipse. IDEs are very popular in application development because they greatly simplify the transition from design to implementation, thus speeding up considerably the entire process. However, currently available tools do not integrate adaptable widgets or provide any support for developing user interface adaptations. Therefore, prototyping alternative design solutions for different needs and requirements using prevalent prototyping tools may become a complex and difficult task if the number of alternatives to be produced is large and no specific support is provided for structuring and managing the design space. In order to facilitate the employment of the JMorph adaptable widget library described in the previous section toward rapid development of adaptable UIs, it has been integrated into the NetBeans graphical user interface (GUI) Builder (version 8.0, see Figure 7). The result is claimed to be the first and so far unique tool which supports rapid prototyping of adaptable user interfaces, with the possibility of immediately previewing adaptation results.

The choice of NetBeans was based on a thorough survey to identify the most suitable available IDE candidates to incorporate the adaptable widget library into their GUI Builder. NetBeans was preferred to Eclipse, which offers almost equivalent facilities, because it is better supported and more extensible, as its GUI Builder offers the essential mechanisms that facilitate the integration of custom widgets. The library's integration into the NetBeans built-in tool offers prototyping functionalities such as live "UI" preview as well as automatic application of specific sizing directives according to the OASIS styleguide. Moreover, NetBeans facilitates the implementation of the application's logic associated with the UI, thus offering not only a prototyping tool but

also a complete framework supporting the entire application development life cycle (design, development, and maintenance).

The NetBeans GUI Builder contains a palette that displays all the available widgets, initially only Java's built-in widgets, while the designers/developers, experienced or not, are familiar with its straightforward drag-and-drop functionality to add widgets on a "screen." The palette can only contain widgets that adhere to the JavaBean specification (Sun Microsystems, 2010b). JavaBeans are reusable software components for Java that can be manipulated visually in a builder tool. Practically, they are classes written in the Java programming language conforming to a particular convention.

They are used to encapsulate many objects into a single object (the bean), so that they can be passed around as a single bean object instead of as multiple individual objects. The integration of JMorph into NetBeans was achieved by implementing every AWT widget as a JavaBean.

To prototype a user interface, the designer will create the application's main window and will add the common containers (e.g., menu panels, status bar, header) by placing AdaptivePanels where appropriate. The necessary widgets (e.g., menu buttons, labels, text fields) will then be dragged from the palette and dropped into the design area of the builder.

To customize widgets, the typical process is to manually set the relevant attributes for each widget using the designer's "property sheets." To apply the same adjustment to other widgets, one can either copy/paste them or iteratively set them manually. In the adaptation-enabled process, using the function attribute, the process is slightly different. First, one needs to set the function attribute, then define the required style (e.g., colors, images, fonts), and finally define the rule (in a separate rule file) that maps the newly added style to the specific function. Whenever the same style should be applied, it is sufficient to simply set the function attribute respectively (CSS-like).

In some cases, more radical adaptations are required with respect to widget customization, as the same physical UI design cannot be applied as is.

In these cases, alternative dialogues can be designed by creating a container to host the different screens. The JMorph library offers the means to dynamically load different UI elements on demand, providing the functionality through adaptation rules and utilizing Java's reflection (introspection) capabilities.

The drag-and-drop selection and placement of widgets follow a conventional WYSIWYG approach. However, in the specific case, what you see is one instance of what you get, as all adaptation alternatives can be produced in the preview mode of the builder by simply setting some user-related variables (e.g., selecting a profile). During preview, a set of sizing rules are automatically applied to ease the design process. The obtained prototypes can easily be used for testing and evaluation purposes.

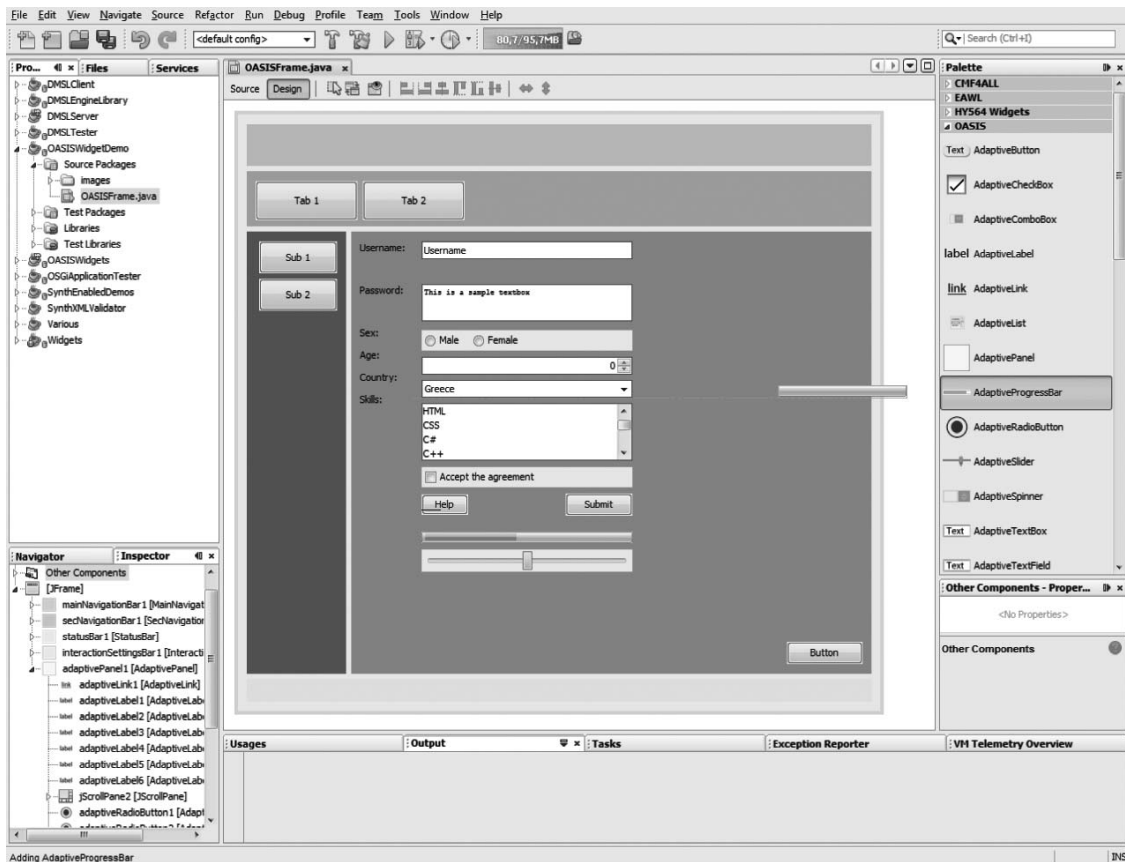
The result is a tool which offers the possibility of prototyping adaptable interfaces following standard practices without the need of designing customized


**Figure 7** Using the adaptable widget library integrated in the NetBeans IDE.

widget alternatives, which are included in the adaptable widgets, or to specify adaptation rules (which are predefined). Through the prototyping tool, it is also possible to preview how adaptations are applied for the defined user profiles. However, more expert designers can easily modify the DMSL adaptation rules, which are stored in a separate editable file, and experiment with new adaptations and varying look and feels. Finally, besides appearance adaptations, the overall approach allows to implement more complex forms of adaptation (e.g., dialogue adaptation) by prototyping alternative dialogues and introducing the respective adaptation logic.

## 5 PROTOTYPE APPLICATIONS AND CASE STUDIES

The methods and tools described in the previous sections have been employed over the years in the development of several prototype applications and services in various domains. These efforts demonstrate both the technical feasibility of the adaptation-based approach and the

progress achieved toward simplifying and improving development practices of user interface adaptation.

### 5.1 AVANTI and PALIO

The AVANTI universally accessible Web browser[*] and the PALIO tourist information system[†] (Stephanidis et al., 2011) constitute the first large applications applying the concepts and methods of unified user interfaces (see Section 3) as well as the first applications of the DMSL language for the implementation of the decision-making component in their architectures (see Section 4.1). While AVANTI constituted an adaptable and adaptive content-viewing application that can view any type of content, adapted or not, PALIO supported the creation of adaptable and adaptive content that can be viewed with any kind of browser. Thus, the two complemented each other.

---

[*] The AVANTI Web browser has been developed in the context of the ACTS AC042—AVANTI project (see Acknowledgments).

[†] The PALIO tourist information system has been developed in the context of the IST-1999-20656—PALIO project (see Acknowledgments).

The AVANTI browser provides an accessible and usable interface to a range of user categories, irrespective of physical abilities or technology expertise. Moreover, it supports various differing situations of use. The end-user groups targeted in AVANTI, in terms of physical abilities, include (i) "able-bodied" people, assumed to have full use of all their sensory and motor communication "channels"; (ii) blind people; and (iii) motor-impaired people, with different forms of impairments in their upper limbs, causing different degrees of difficulty in employing traditional computer input devices, such as a keyboard and/or a mouse. In particular, in the case of motor-impaired people, two coarse levels of impairment were taken into account: "light" motor impairments (i.e., users have limited use of their upper limps but can operate traditional input devices or equivalents with adequate support) and "severe" motor impairments (i.e., users cannot operate traditional input devices at all). Furthermore, since the AVANTI system was intended to be used both by professionals (e.g., travel agents) and by the general public (e.g., citizens, tourists), the users' experience in the use of, and interaction with, technology was another major parameter that was taken into account in the design of the user interface. Thus, in addition to the conventional requirement of supporting novice and experienced users of the system, two new requirements were put forward: (a) supporting users with any level of computer expertise and (b) supporting users with or without previous experience in the use of Web-based software.

In terms of usage context, the system was intended to be used both by individuals in their personal settings (e.g., home, office) and by the population at large through public information terminals (e.g., information kiosks at a railway station, airport). Furthermore, in the case of private use, the front end of AVANTI was intended to be appropriate for general Web browsing, allowing users to make use of the accessibility facilities beyond the context of a particular information system.

Users were also continuously supported as their communication and interaction requirements changed over time due to personal or environmental reasons (e.g., stress, tiredness, or system configuration). This entailed the capability, on the part of the system, to detect dynamic changes in the characteristics of the user and the context of use (either of temporary or of permanent nature) and cater for these changes by appropriately modifying itself.

The above requirements dictated the development of a new experimental front end which would not be based on existing Web browser technology or designed following traditional techniques oriented to the "typical user." In fact, the accessibility requirements posed by the user categories addressed in AVANTI could not be met either by existing customizability features supported by commercial Web browsers or through the use of third-party assistive products.

The unified user interface development approach was adopted to address the above requirements, as it provides appropriate methodologies and tools to facilitate the design and implementation of user interfaces that cater for the requirements of multiple, diverse end-user categories and usage contexts.

Following the unified user interface design method, the design of the user interface followed three main stages: (a) identification of different design alternatives to cater for the particular requirements of the users and the context of use; (b) integration of the designed alternatives into a polymorphic task hierarchy; and (c) development and documentation of the adaptation logic that drives the run time selection between the available alternatives.

AVANTI also constituted the first application of the DMLS language. Figure 7 shows an example adaptation decision block in the context of AVANTI. Such a decision block is targeted to selecting the best alternative interface components for the "link" task context. The interface design relating to this adaptation decision logic is provided in Figure 8.

Building on the results and findings of AVANTI, PALIO set out to address the issue of access to communitywide services by anyone, from anywhere, by proposing a hypermedia development framework supporting the creation of adaptive hypermedia systems. PALIO supported the provision of tourist services in an integrated, open structure while it constituted an extension of previous efforts, as it accommodated a broader perspective on adaptation and covered a wider range of interactive encounters beyond desktop access and advanced the current state of affairs by considering novel types of adaptation based on context and situation awareness. The PALIO framework was based on the concurrent adoption of the following concepts: (a) integration of different wireless and wired telecommunication technologies to offer services through both fixed terminals in public places and mobile personal terminals [e.g., mobile phones, personal digital assistants (PDAs), laptops]; (b) location awareness to allow the dynamic modification of information presented (according to user position); (c) adaptation of the contents to automatically provide different presentations depending on user requirements, needs, and preferences; (d) scalability of the information to different communication technologies and terminals; and (e) interoperability between different service providers in both the envisaged wireless network and the World Wide Web.

In the context of PALIO, DMSL has been effectively employed not only for user interface adaptation but also for adaptable information delivery over mobile devices to tourist users. The decision-making process was based on parameters such as nationality, age, location, interests or hobbies, time of day, visit history, and group information (i.e., family, friends, couple, colleagues, etc.). The information model reflected a typical relational database structure while content retrieval was carried out using Extensible Markup Language (XML)–based Structured Query Language (SQL) queries. In this context, in order to enable adapted information delivery, instead of implementing hard-coded SQL queries, query patterns have been designed, with specific polymorphic placeholders filled in by dynamically decided concrete subquery patterns. For instance, as seen in Figure 10, particular data categories or even query operations may be left

```
taskcontext link [
    evaluate linktargeting;
    evaluate linkselection;
    evaluate loadconfirmation;
]
taskcontext linktargeting [
    if (user.abilities.pointing == accurate) then
            activate "manual pointing";
    else
            activate "gravity pointing";
]
taskcontext linkselection [
    if (user.webknowledge in {good, nornal}) then
            activate "underlined text";
    else
            activate "push button";
]
taskcontext loadconfirmation [
    if (user.webknowledge in {low, none} or context..net==low) then
            activate "confirm dialogue";
    else
            activate "empty";
]
```

**Figure 8** DMSL decision block for adaptation of links in the AVANTI browser. (From Savidis et al., 2005.)

**S1**: Requires load confirmation. It is designed for:
1. Users with limited web experience;
2. Users that get tired and show high error rates during interaction;
3. Low-bandwidth networks.

**S2**: Link selection is done as far as the mouse cursor is inside the rectangular area of the link and the left mouse button is pressed. Designed for frequent and/or web-expert users.

**S3**: Link selection is done via typical GUI button press (i.e., press while cursor inside, release while cursor inside). In comparison to S2, it allows cancellation in the middle of the action (by releasing mouse button while cursor is outside).

**S4**: Gravity support for link targeting. If mouse cursor is inside gravity zone of the link, it is automatically positioned at the center of the link. Designed for users that cannot perform accurate mouse positioning.

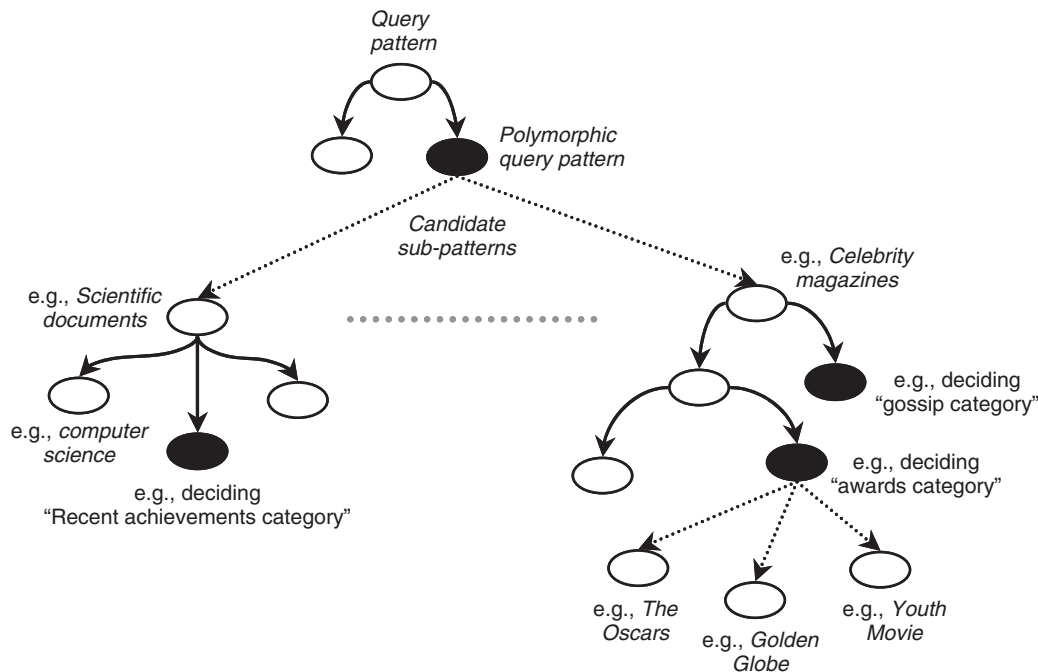
**Figure 9** Link adaptation design in AVANTI. (From Savidis et al., 2005.)


**Figure 10** Query adaptation using DMSL in PALIO. (From Savidis et al., 2005.)

"open," with multiple alternatives, depending on run time content adaptation decision making.

The experience gained in the development of AVANTI and PALIO has demonstrated the effectiveness of the use of adaptation-based methodologies, techniques, and tools toward the achievement of access to the World Wide Web by a wide range of user categories, irrespective of physical abilities or technology expertise, in a variety of contexts of use and through a variety of access devices, going far beyond previous approaches that rely on assistive or dedicated technologies.

Both AVANTI and PALIO make it possible to adopt a stepwise introduction of adaptation at different stages of development, thus enabling the progressive introduction of complex accessibility features and facilitating the incorporation of new user groups with distinct requirements in terms of accessibility.

### 5.2  EDeAN Web Portal

The portal of the European Design for All e-Accessibility Network (EDeAN)[*] (Partarakis et al., 2010b) was developed as a proof of concept by means of the EAGER toolkit (see Section 4.3.). As this was the redevelopment of an existing portal, it provided the opportunity to identify and compare the advantages of using EAGER, both at the developer's site, in terms of developer's performance, and at the end-user site, in terms of user experience improvement.

The new EDeAN portal disseminates information about the scope, objectives, and outcomes of the EDeAN networking activities. Through the portal public area (Figure 11) a number of facilities can be accessed, such as information about EDeAN, resources from a dedicated resource center, news and announcements, frequently asked questions, statistics regarding the networking activities, and surveys for collecting user feedback. The portal area for subscribed users is intended to support the actual networking activities and therefore provides a number of communication and collaboration facilities.

The users of the portal have the option to access the portal settings and alter them in order to match their personal characteristics and the characteristics of the context of use. A number of parameters can be set, such as language, device and display resolution, assistive technology, input device, disability, and Web familiarity. Additionally, to allow users to quickly alter their settings, the quick-settings option can be used, offering a number of predefined user profiles.

Adaptations can also take place based in interaction preferences. More specifically, interaction preferences settings can alter the interaction elements used for performing fundamental operations, such as browsing content and images or uploading files. The changes made to these settings are propagated to all portal modules. By manually altering these settings, the default adaptation logic that occurs based on the user basic setting is enriched.

Finally, adaptations can take place based on accessibility preferences. Custom accessibility includes all the

(silver-black)

(crystal-blue)

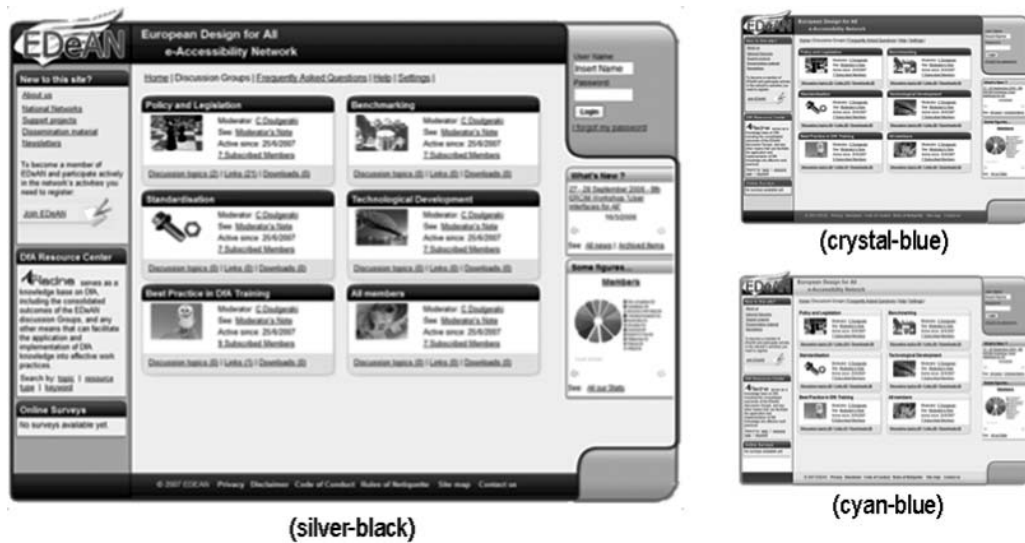
(cyan-blue)


**Figure 11**   Main page of the EDeAN Web portal.

**Figure 12**   Example of widget adaptation in the ASK-IT Home Automation Application.

settings that can be altered to enhance the accessibility characteristics of the final user interface. Although each user interface is already compliant with the W3C accessibility guidelines, theses settings can further enhance the actual system accessibility and the perceived quality of interaction.

### 5.3   Applications of the JMorph Library

The JMorph adaptable widget library (see Section 4.3.2) has been used in the context of a number of development projects through which it is continuously refined and enhanced.

The first such example was the ASK-IT Home Automation Application,[*] which facilitates remote overview and control of home devices through the use of a

portable device. The user interface of the application has the ability to adapt itself according to user needs (vision and motor impairments), context of use (alternative display types and display devices), and presence of assistive technologies (alternative input devices).

Figure 12 presents an example of adaptation in the screen of the application which supports room selection on a PDA device. In the left part of the figure, the interface displays a color combination, while in the right part a grey scale is used for enhanced contrast.

The version of JMorph used to develop this application included simple graphics and adaptation rules and the widgets needed to be used programmatically.

Subsequently, the library has been enriched with more simple and complex widgets specifically designed for older users (Leuteritz et al., 2009). Currently, JMorph is being used in the development of the OASIS service suite (Bekiaris and Bonfiglio, 2009), comprising

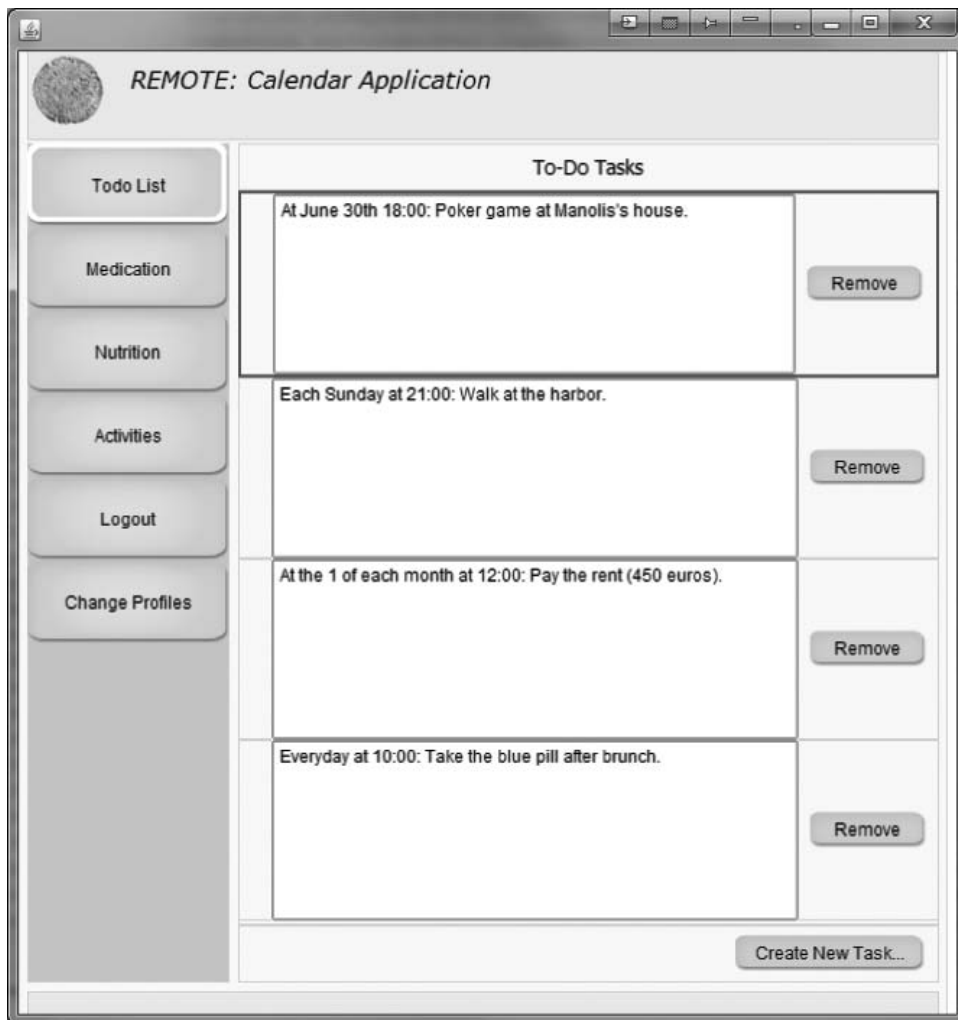
---


**Figure 13**   To-do list in the REMOTE calendar application.

12 services in three main domains addressing the quality of life of the elderly, namely Independent Living Applications, Autonomous Mobility, and Smart Workplaces Applications.[*] These applications are intended to be available through three different technological platforms, namely tablet PC, PDA, and mobile phone. One such application is a five-card poker game for older users which can be adapted to three different age and visual acuity profiles as well as to different levels of expertise in poker playing. In this context, the JMorph library has been distributed to a pool of universities, research institutions, and companies that are in charge of developing the applications.

Another application currently under development is the REMOTE calendar for older users,[†] offering functionalities such as to-do list, medication reminder, nutrition suggestions, daily activities schedule, and other notifications. Figure 13 presents a preliminary prototype of the calendar to-do list developed using JMorph in the NetBeans IDE.

## 6   CONCLUSIONS

Recent progress in the field of universal access and design for all, that is, access by anyone, anywhere, and

anytime to interactive products and services in the information society, has highlighted a shift of perspective and reinterpretation of HCI design, from current artifact-oriented practices toward a deeper and multidisciplinary understanding of the diverse factors shaping interaction with technology, such as users' characteristics and requirements and contexts of use, and has proposed solutions for methods, techniques, and codes of practice that enable to proactively take into account and appropriately address diversity in the design of interactive artifacts.

As a consequence, user interface design methodologies, techniques, and tools acquire increased importance in the context of universal access and strive toward approaches that support design for diversity based on the consideration of the several dimensions of diversity that emerge from the broad range of user characteristics, the changing nature of human activities, the variety of contexts of use, the increasing availability and diversification of information, the variety of knowledge sources and services, and the proliferation of diverse technological platforms that occur in the information society. Two main dimensions of such a perspective are its user-oriented focus, targeted toward capturing and collecting the requirements of a diversity of users in a diversity of usage context, and its adoption of intelligent interface adaptation as a technological basis, viewing design as the organization and structure of an entire design space of alternatives to cater for diverse requirements. In a universal access perspective, adaptation needs to be "designed into" the system rather than decided upon and implemented a posteriori.

Unified user interface design has been proposed in recent years as a method to support the design of user interfaces which automatically adapt to factors that impact on their accessibility and usability, such as the abilities and characteristics of different user groups, but also factors related to the context of use and the access technological platforms. Despite progress, however, the practice of designing for diversity remains difficult, due to the intrinsic complexity of the task and the current limited expertise of designers and practitioners. To overcome such a difficulty, tool support is required for supporting and facilitating adaptation design.

This chapter has discussed a series of tools and components developed over a period of more than a decade to support and facilitate the conduct of user interface adaptation design. These include:

- A language for the specification of adaptation decision making (DMSL, see Section 4.1)
- An interactive design environment for user interface adaptation (MENTOR, see Section 4.2)
- A toolkit supporting the development of adaptable Web-based user interfaces for the .NET platform (EAGER, see Section 4.3.1)
- A toolkit of platform-adaptable interaction widgets, implemented in Java, supporting the development of applications for PCs and mobile devices (JMorph, see Section 4.3.2)

- A prototyping solution for adaptable user interfaces within the NetBeans IDE (see Section 4.4)

Such tools are claimed to have a significant role in widening and improving the practice of design for all and ensuring a more effective transition from the design to the implementation phase. They have been used in practice in a series of case studies involving different types of applications for different purposes, contexts, and interaction platforms. These extensive case studies have demonstrated the technical feasibility of the overall adaptation-based approach to universal access. Additionally, these developments have provided hands-on experience toward improving the usefulness and effectiveness of the developed tools in different phases of the user interface development life cycle, in particular design. During these developments, it has progressively become clear that user interface adaptation can be adopted in practice as a result of reducing the gap with mainstream design practices. Ultimately, this amounts to providing transparent solutions which do not require specific adaptation knowledge and support prototyping. Therefore, more recent solutions have gone into the direction of providing ready-to-use widget toolkits that integrate all the required adaptation knowledge and logic as well as supporting the view of alternative designs in mainstream development environments. Obviously, however, such solutions, while achieving the objective of simplifying the design of adaptation as far as alternative widget instances are concerned, still require specialized knowledge and mastery of user interface adaptation mechanisms for designing dialogue adaptation at a syntactic or semantic level as well as for creating new or modifying existing adaptable widgets.

The tools discussed in this chapter have also proved their usefulness for educational purposes. In particular, DMSL, MENTOR, and, more recently, the JMorph library with its accompanying prototyping solution have been used in the context of an advanced HCI course at the University of Crete, with the objective of introducing postgraduate students to the basics of developing self-adapting user interfaces.

As the information society further develops, the issue of efficiently designing user interfaces capable of automatic adaptation behavior becomes even more prominent in the context of the next anticipated technological generation, that of ambient intelligence environments (see Chapter 49 xx). Ambient intelligence provides a vision of the information society where humans are surrounded by intelligent intuitive interfaces that are embedded in all kinds of objects and an environment that is capable of recognizing and responding to the presence of different individuals in a seamless, unobtrusive, and often invisible manner. Clearly, ambient intelligence environments are intrinsically based on adaptation, and user and context awareness, as well as adaptation decision making, become fundamental. Therefore, current research efforts are targeted toward providing tools and facilities to support user interface adaptation design in ambient intelligence environments.

## 1 INTRODUCTION

According to the International Organization for Standardization/International Electrochemical Commission (ISO/IEC) guide 2 (2004), a standard is a document established by consensus and approved by a recognized body that provides, for common and repeated use, rules, guidelines, or characteristics for activities or their results aimed at the achievement of the optimum degree of order in a given context (ISO/IEC, 2004). Additionally, the guide states that standards should be based on the consolidated results of science, technology, and experience and be aimed at the promotion of optimum community benefits. Geographically the standardization process can be distinguished into three main levels: national, regional, and international (see Figure 1). At the highest and broadest level of applicability are the international standards. The basis for worldwide standardization in all areas is provided primarily by three organizations: the ISO, IEC, and International Telecommunications Union (ITU). Standards related to human factors and ergonomics are developed by the ISO.

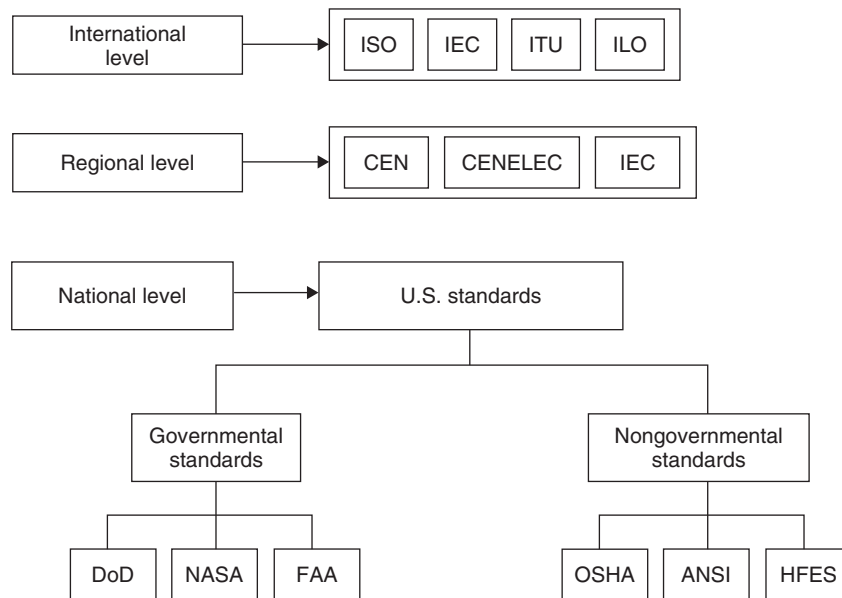
Following the international level, standards are being developed regionally. For example, in Europe, there are three standardization bodies: the European Committee for Standardization (CEN), European Committee for Electrotechnical Standardization (CENELEC), and European Telecommunications Standards Institute (ETSI). Their mission is to develop and achieve a coherent set of voluntary standards as a basis for a single


**Figure 1** Hierarchy of standards levels.

European market/European economic area (Wetting, 2002). At the national level almost every nation has its own national body for standards development. Examples of the national standardization organizations are the American National Standards Institute (ANSI), British Standards Institution (BSI), Deutsches Institut fur Normung (DIN), and Association Francaise de Normalisation (AFNOR). Standards can also be prepared by technical societies, labor organizations, consumer organizations, trade associations, and governmental agencies.

International, regional, and national standards are distinguished by documented standards development procedures. These procedures have been designed to ensure that all interested parties that can be affected by a particular standard will have an opportunity to represent their interest and participate in the standards development process. For example, ISO standards are developed by technical committees which consist of experts from the industrial, technical, and business sectors that are in need of standards. Many ISO national members apply public review procedures in order to consult draft standards with the interested parties, including representatives of government agencies, industrial and commercial organizations, professional and consumer associations, and the general public. The ISO national bodies are expected to take into account any feedback they receive and to present a consensus position to appropriate technical committees.

Standards are necessary to provide quality control and to support legislation and regulations to ensure an equal-opportunity and fairly operating international market. The main purpose of standardization is to achieve uniformity and interchangeability. Standardization limits the diversity of sizes, shapes, or component designs and prevents the generation of unneeded variation of products which do not provide unique services. Standardization is also the means by which society gathers and disseminates technical information (Spivak and Brenner, 2001). Harmonization of standards reduces trade barriers; promotes safety; allows interoperability of products, systems, and services; and promotes common technical understanding (Wetting, 2002).

The need for standardization from the human factors and ergonomics viewpoints can be illustrated by many "horror stories" following World War II. The war required that pilots fly on different types of aircraft which had no standard control arrangement in the cockpits (McDaniel, 1996). Many planes crashed because the pilots used wrong controls based on erroneously applied behavioral patterns. The human factors solutions included standardization of a single arrangement for engine controls and development of distinct shapes for the control handles (McDaniel, 1996). In this chapter we provide an overview of the human factors and ergonomics (HFE) standardization efforts around the world. Standards that cover any area of human factors and ergonomics at the international, regional, and national levels have been listed in this chapter. These areas include physical and cognitive ergonomics, human–computer interaction, human–system integration, and occupational health and safety. Unlike other fields, standards and the standardization process in human factors and ergonomics are relatively new. The pioneering landmark of publication on human factors and ergonomics standards by Karwowski (2006) comprehensively reviewed selected international and national standards and guidelines. The handbook was intended to disseminate knowledge about those standards and guidelines to professionals from a great variety of interrelated fields.

## 2 ISO STANDARDS FOR ERGONOMICS

The ISO was created in 1947 to coordinate the development of international standards. The ISO is a worldwide federation of national standards bodies from 163 countries. The mission of the ISO is to promote the development of standardization and related activities in the world in order to facilitate the international exchange of goods and services and to develop cooperation in the spheres of intellectual, scientific, technological, and economic activity (ISO/IEC, 2004). The International Electrotechnical Commission (IEC) is a nonprofit international standards organization that in collaboration with ISO prepares and publishes international standards related to electrical, electronics, and related technologies. In general, The ISO standards are developed based on three principles: (1) consensus—the views of all interests are taken into account: manufacturers, vendors and users, consumer groups, testing laboratories, governments, engineering professions, and research organizations; (2) industrywide—global solutions to satisfy global industries and consumers; and (3) voluntary—international standardization is market driven and therefore based on voluntary involvement of all interests in the marketplace. A standardization effort in the ISO goes through three phases:

1. An industry sector expresses the need for a standard by communicating to a national member body, which in turn proposes the new work item to the ISO. In this phase, definitions of the technical scope of the future standard are established following which the need for the standard is recognized and formally agreed upon by working groups comprising technical experts from the countries interested in the subject matter.

2. In the second phase, the consensus-building phase, the interested countries negotiate the detailed specifications within the standard.

3. The final phase comprises the formal approval of the resulting draft international standard (the acceptance criteria stipulate approval by two thirds of the ISO members that have participated actively in the standards development process and approval by 75% of all members that vote), following which the agreed-upon text is published as an ISO international standard.

In general, the standardization process of the ISO undergoes several stages from proposal for a new standard (stage code 00.00) to withdrawal of the standard (stage code 95.99). The distinct various stages, substages, and decision substages are presented in Table 1.

In 1974, the ISO formed technical committee TC 159 to develop standards in the field of ergonomics. The scope of ISO TC 159 activity has been described as standardization in the field of ergonomics, including terminology, methodology, and human factors data. According to the agreed-upon scope, ISO TC 159 (through standardization and coordination of related activities) promotes the adaptation of working and living conditions to human anatomical, psychological, and physiological characteristics in relation to the physical, sociological, and technological environment. Among the main objectives of such efforts are safety, health, well-being, and effectiveness (Parsons, 1995c). It should be noted that because of historical and organizational factors, many standards in the field of ergonomics are not developed by ISO TC 159.

At present, the ISO TC 159 organizational structure is administered by the DIN. The ergonomics standardization group consists of five subcommittees: SC 1, SC 3, SC 4, and SC 5. Through these subcommittees and various working groups (WG), TC 159 has published 108 standards. The subject areas of subcommittees and their organizational structure are presented in the Table 2.

### 2.1 Ergonomics Guiding Principles

The standards concerned with the ergonomics basic principles are elaborated by the TC 159/SC I subcommittee. The list of published standards and standards in development for the ergonomics guiding principles are provided in Table 3. ISO 6385:2004 is a basic standard that states the objectives of the ergonomics system design and provides definitions of basic terms and concepts in ergonomics (HFE). This standard establishes ergonomics principles of the work system design as basic guidelines. Such guidelines should be applied for the design of optimal working conditions with regard to human well-being, safety, and health, with consideration of technological and economic efficiency (Parsons, 1995a). Cullen (2007) examined the effectiveness of ISO 6385 while integrating between the designers and end users. In another study Andreas et al. (2009) utilized ISO 6385 in designing a verification and validation method (CRIOP) for an industrial setting.

The ISO 10075 standard dealing with mental workload is comprised of three parts. The first part presents terminology and main concepts. Part 2 covers guidelines on the design of work systems, including task, equipment, workspace, and work conditions with reference to the mental workload. Part 3 provides guidelines on measurement and assessment of mental workload. The third part specifies the requirements for the measurement instruments to be met at different levels of precision in measuring mental workload. In these standards it was stated that any human activity, even those that are considered primarily as physical activities, includes a mental workload (Nachreiner, 1995). Therefore, the described standards on mental workload are relevant to all kinds of work design. All of the abovementioned standards published standards in the review stage. Recent research efforts encompass examining the effectiveness of the standard (Schutte et al., 2007, 2009; Helvi et al., 2009) and the use of the standard to define and measure mental strain in noisy environments (Sandrock et al., 2009). ISO/DIS 268000 is currently a draft international standard (DIS).

### 2.2 Anthropometry and Biomechanics

The standards related to anthropometry and biomechanics are developed by the TC 159/SC 3 subcommittee. Currently, this subcommittee consists of two working

**Table 1 Stages of ISO Standardization Process**[a]

| Stage | Substage 00 Registration | Substage 20 State of main action | Substage 60 Completion of main action | Substage 90 Decision Substages — 92 Repeat an Earlier phase | 93 Repeat Current phase | 98 Abandon | 99 Proceed |
|---|---|---|---|---|---|---|---|
| 00 Preliminary stage | 00.00 Proposal for new project received | 00.20 Proposal for new project under review | 00.60 Close of review | | | 00.98 Proposal for new project abandoned | 00.99 Approval to ballot proposal for new project |

provided in the ISO 7250 standards (parts 1 and 2). In addition to the lists of the basic anthropometric measurements, part 2 contains body measurements from ISO populations for comparison purposes. Recent research utilized ISO 7250 to obtain anthropometric data for workstation design (Deros et al., 2009), parametric human body modeling (Mustafa and Nadia, 2007), and estimation of anthropometric proportions (Gerd et al., 2009).

The three-part standards for the safety of machinery (ISO 15534) provide guidelines for determining the dimensions required for openings for access for machinery. The first part of this standard (ISO 15534-1:2000) presents principles for determining the dimensions for opening for whole-body access to machinery; the second part (ISO 15534-2:2000) specifies dimensions for the access openings. The third part of the safety of machinery standards (ISO 155343:2000) provides the requirements for the human body measurements (anthropometric data) that are needed for the calculation of access opening dimensions for machinery specified in the two previous parts of this standard (Parsons, 1995c). The anthropometric data are based on static measurements on nude people and representative of the European population of men and women.

ISO 14738:2002 describes principles for deriving dimensions from anthropometric measurements and applying them to the design of workstations at nonmobile machinery. This standard also specifies the body space requirements for equipment during normal operation in sitting and standing positions. ISO 15535:2006 specifies general requirements for anthropometric databases and their associated reports that contain measurements taken in accordance with ISO 7250. This standard presents such information as characteristics of the user population, sampling methods, and measurement items and statistics to make international comparison possible among various population segments.

groups: anthropometry (WG 1) and human physical strength; manual handling and force limits (WG 4). The list of the published standards and standards in development for anthropometry and biomechanics are presented in Table 4. The description of anthropometric measurements, which can be used as a basis for definition and comparison of population groups, are

| ISO 20685:2010 | Three-dimensional scanning methodologies for internationally compatible anthropometric databases |

ISO 11228-1:2003 describes limits for manual lifting and carrying with consideration, respectively, of the intensity, frequency, and duration of the task. The limits recommended can be used in the assessment of several task variables and the health risk evaluation of the working population (Dickinson, 1995). This standard does not include holding of objects (without walking), pushing or pulling of objects, lifting with one hand, manual handling while seated, and lifting by two or more people. Holding, pushing, and pulling objects are included in parts 2 and 3 of ISO 11228, which are currently at the review stage. In conjunction with the ISO 11228 series, an application document (ISO/NP TR 12296) is under development. ISO/TS 20646-1:2004 present guidelines for application of various ergonomics standards related to local muscular workload (LMWL) and specify activities to reduce LMWL in workplaces. As part of development of new standards, in 2010, the ISO published a new standard, ISO 20685:2010, that addresses protocols for the use of three-dimensional (3D) surface-scanning systems in the acquisition of human body shape data and measurements defined in ISO 7250-1 that can be extracted from 3D scans.

## 2.3  Ergonomics of Human–System Interaction

The TC 159/SC 4 subcommittee develops the standards related to ergonomics of human–system interaction. The subcommittees are divided into 11 working groups, each dealing with a specific topic (see Table 2).

### 2.3.1  Controls and Signaling Methods

ISO 9355, *Ergonomic Requirements for the Design of Displays and Control Actuators*, provides guidelines for the design of displays and control actuators on work equipment, especially machines (see Table 5). A list of all parts of ISO 9355 is presented in Table 5. Part 1 describes general principles of human interactions with displays and controls. The other two parts provide recommendations on the selection, design, and location of information displays (part 2) and control actuators (part 3). Part 4 covers general principles for the location and arrangement of displays and actuators. No changes were made to these standards in the last five years. Currently these standards are in the review stages.

**Table 5  ISO Standards for Controls and Signaling Methods**

| Reference Number | Title |

| ISO 9355-1:1999 | Ergonomic requirements for the design of displays and control actuators, Part 1: Human interactions with displays and control actuators |
| ISO 9355-2:1999 | Ergonomic requirements for the design of displays and control actuators, Part 2: Displays |
| ISO 9355-3:2006 | Ergonomic requirements for the design of signals and control actuators, Part 3: Control actuators |

### 2.3.2  Visual Display Requirements

The multipart standard ISO 9241, *Ergonomics of Human System Interaction,* is believed to be the most important and known standard for ergonomic design (Stewart, 1995; Eibl, 2005). This standard presents general guidance and specific principles that need to be considered in the design of equipment, software, and tasks for office work with visual display terminals (VDTs). All parts of ISO 9241 are presented in Table 6. Major revisions were made to the parts of the standard. Along with its original parts, the standard includes the following series of standards:

- 100 series: Software ergonomics
- 200 series: Human–system interaction processes
- 300 series: Displays and display–related hardware
- 400 series: Physical input devices—ergonomics principles
- 500 series: Workplace ergonomics
- 600 series: Environment ergonomics
- 700 series: Application domains—Control rooms
- 900 series: Tactile and haptic interactions

Part 1 of ISO 9241, which described the basic underlining principles of the user performance approach, has been withdrawn along with parts 3 (visual display requirements), 7 (requirements for display with reflections), 8 (color displays), and 10 (dialogue principles). Part 2 describes how task requirements may be identified and specified in organizations and how task requirements can be incorporated into the system design and implementation process. Parts 4, 5, 6, and 9 provide assistance in the procurement and specification of the hardware and environmental components. Part 4 provides criteria for the keyboard and part 9 for no-keyboard input devices. Parts 5 and 6 establish ergonomic principles for the appropriate design and procurement of workstation, workstation equipment, and work environment for office work with VDTs (Eibl, 2005). Those two parts include such issues as technical

design of furniture and equipment for the workplace, space organization and workplace layout, physical characteristics of office work environment: lighting, noise, and vibrations. Part 10 has been replaced by part 110 (dialogue principles). Part 11 defines usability and specifies the usability evaluation in terms of the user performance and satisfaction measures (Dzida, 1995). Part 12 provides ergonomic recommendations for information presentation on the text-based displays and graphical user interfaces. Part 13 presents recommendations for different types of user guidance attributes of software interfaces, such as feedback, status, help, and error handling. Parts 14–17 deal with particular kinds of dialogue styles: menus, commands, direct manipulation, and form filling. In 2008, a new standard was included in the 9241 series, part 20, which deals with accessibility guidelines for information/communication technology (ICT) equipment and services.

The ISO 13406 standard provides recommendations additional to those of ISO 9241 in respect to visual displays based on flat panels. Two parts of this standard cover image quality requirements for the ergonomic design and evaluation of flat-panel displays. ISO 14915 provides additional recommendations to ISO 9241 concerning multimedia presentations. These standards are being developed by WGs 2, 3, 5, 6, and 9.

There is significant research effort examining the ISO 9241 standards to investigate their effectiveness and design and evaluation of products using an appropriate standard(s). Very recently, for example, ISO 9241-9 has been widely used to design and evaluate various pointing devices (input controllers) mainly due to the explosion of the gaming industry (Natapov et al., 2009), haptic feedback (Teather et al., 2010), gesture interface (Silva et al., 2003), and interface design (Ludger and Daniel, 2009).

### 2.3.3 Software Ergonomics

ISO 14915, *Software Ergonomics for Multimedia User Interfaces*, specifies recommendations and principles for the design of interactive multimedia user interfaces that integrate various media, such as static text, graphics, and images, and dynamic media such as audio, animation, and video. This standard focuses on issues related to integration of different media; hardware issues and multimodal input are not considered. The standard consist of three parts (see Table 7), which address general design principles and framework (part 1), multimedia navigation and control (Part 2), and media selection and combination (part 3). The committee draft ISO/CD 23973 considers ergonomics design principles for World Wide Web user interfaces. The standards are developed by WG 5. The effectiveness of ISO 14915 has been examined in the design of user interface (Luis et al., 2008; Bernsen and Dybkjær, 2009; Sgro et al., 2009). The standard has also been used to design multimedia user interface (Sutcliffe, 2009), evaluation of websites (Tobar et al., 2008), and PDA interface design (Blum and Khakzar, 2007).

**Table 7  ISO Standards for Software Ergonomics**

### 2.3.4  Ergonomic Design of Control Centers

ISO 11064, *Ergonomic Design of Control Centers,* specifies requirements and presents principles for the ergonomic design of control centers. The list of all parts of ISO 11064 is provided in Table 8. The seven parts of this standard are concerned with the following issues: principles for the design of control centers, principles of control suite arrangements, control room and workstation layout and dimensions, displays and controls, environmental requirements, evaluation of control rooms, and ergonomic requirements for specific applications. WG 8 is responsible for development of these standards. ISO/CD 11064-4, Part 4: Layout and Dimensions of Workstations, is currently under development. In recent studies the standard has been used to design control rooms (Jamil et al., 2007; Isaac et al., 2008).

### 2.3.5  Human–System Interaction

The guidelines on the human-centered design process throughout the life cycle of computer-based interactive systems are described in ISO ISO/TR 18529:2000.

**Table 8  ISO 11064: Ergonomic Design of Control Centers**

| Reference Number | Title |
|---|---|
| ISO 11064-1:2000 | Part 1: Principles for the design of control centers |
| ISO 11064-2:2000 | Part 2: Principles for the arrangement of control suites |
| ISO 11064-3:1999 | Part 3: Control room layout |
| ISO 11064-4:2004 | Part 4: Layout and dimensions of workstations |
| ISO 11064-5:2008 | Part 5: Displays and controls |
| ISO 11064-6:2005 | Part 6: Environmental requirements for control centers |
| ISO 11064-7:2006 | Part 7: Principles for the evaluation of control centers |
| ISO/CD 11064-4 | Ergonomic design of control centres, Part 4: Layout and dimensions of workstations |

Usability methods supporting human-centered design are described in ISO/TR 16982:2002. Further standards concerned with human–system interaction address such issues as development and design of icons (ISO 11581), design of typical controls for multimedia functions (ISO 18035), icons for typical WWW browsers (ISO 18036), and definitions and metrics concerning software quality (ISO 9126). Table 9 shows the list of published ISO standards and standards in development for human–system interaction.

### 2.3.6  Ease of Operation and Accessibility

Recently TC 159 introduced standards related to ease of operation of everyday products, divided into four parts. Part 1 deals with design requirements, parts 2, 3, and 4 deal with test methods, and ISO/NP TS 20282-3 is currently under development. These standards are developed under WG 11. In 2010, through WG 10, the ISO introduced a new draft standard, ISO/FDIS 24503, Accessible Design, that deals with tactile dots and bars on consumer products. These standards are given in Table 10.

## 2.4  Ergonomics of the Physical Environment

The ISO TC159 SC5 document contains an international standard in the area of the ergonomics of the physical environment. The subcommittee is divided into seven working groups (see Table 2).

### 2.4.1  Ergonomics of the Thermal Environment

The standards on the ergonomics of thermal environments are concerned with heat stress, cold stress, and thermal comfort as well as with the thermal properties of clothing and metabolic heat production due to activity (Olesen, 1995). Physiological measures, skin reaction to contact with hot, moderate, and cold surfaces, and thermal comfort requirements for people with special requirements are also considered. The list of all standards and standards in development on thermal environment ergonomics are presented in Tables 11 and 12, respectively.

**Table 9  Published ISO Standards for Human-System Interaction**

| Reference Number | Title |

| ISO/TR 18529:2000 | Ergonomics of human-system interaction: Human-centered lifecycle process descriptions |

**Table 10  Ease of Operation of Everyday Products and Accessibility**

| Reference Number | Title |
| --- | --- |
| *Published* | |
| ISO 20282-1:2006 | Ease of operation of everyday products, Part 1: Design requirements for context of use and user characteristics |
| ISO/TS 20282-2:2006 | Ease of operation of everyday products, Part 2: Test method for walk-up-and-use products |
| ISO/PAS 20282-3:2007 | Ease of operation of everyday products, Part 3: Test method for consumer products |
| ISO/PAS 20282-4:2007 | Ease of operation of everyday products, Part 4: Test method for the installation of consumer products |
| *Under Development* | |
| ISO/NP TS 20282-3 | Ease of operation of everyday products, Part 3: Test method for consumer products |
| ISO/FDIS 24503 | Ergonomics : Accessible design: Tactile dots and bars on consumer products |

The main thermal comfort standard. ISO 7730, provides a method for predicting the thermal sensation and the degree of discomfort, which can also be used to specify acceptable environmental conditions for comfort. This method is based on the predicted mean vote (PMV) and predicted percentage of dissatisfied (PPD) thermal comfort indices (Olesen and Parsons, 2002). It also provides methods for the assessment of local discomfort caused by draughts, asymmetric radiation, and temperature gradients. Other thermal environment standards address such issues as thermal comfort for people with special requirements (ISO/TS 14415:2005), responses on contact with surfaces at moderate temperature (ISO 13732-2:2001), and thermal comfort in vehicles (ISO 14505, parts 1–3). Standards concerned with thermal comfort assessment specify measuring instruments (ISO 7726:1998), methods for estimation of metabolic heat production (ISO 8996:2004), estimation of clothing properties (ISO 9920:2007), and subjective assessment methods (ISO 10551:1995). ISO 11399:1995 provides information needed for the correct and effective application of international standards concerned with the ergonomics of the thermal environment. The standards that are under development deal with assessment of physical quantities, perceived indoor air quality, and mathematical models for human physiological responses.

### 2.4.2  Communication in Noisy Environments

The standard for communication in noisy environments includes warnings, danger signals, and speech. The list

**Table 12 ISO Standards under Development for Ergonomics of the Thermal Environment**

| Reference Number | Title |
|---|---|
| ISO/AWI 7726 | Ergonomics of the thermal environment: Instruments for measuring physical quantities |
| ISO/NP 16077 | Ergonomic of the physical environment: A method for assessing perceived indoor air quality using human subject panels |
| ISO/NP 16418 | Ergonomics of the thermal environment: Mathematical model for predicting and evaluating the dynamic human physiological responses to the thermal environments |
| ISO/AWI 16594 | Guide for working practices for moderate thermal environments |
| ISO/DIS 28802 | Ergonomics of the physical environment: Assessment by means of an environmental survey involving physical measurement of the environment and subjective responses of people |
| ISO/DIS 28803 | Ergonomics of the physical environment: Application of international standards to people with special requirements |

of related standards is provided in Table 13. The ISO 7731:2003 document specifies the requirements and test methods for auditory danger signals and gives guidelines for the design of the signals in the public and in workplaces. This document also provides definitions to guide in the use of the standards concerned with noisy environments. Criteria for the perception of the visual danger signals are provided in ISO 11428:1996. This international standard specifies the safety and ergonomic requirements and the corresponding physical measurements.

ISO 11429:1996 specifies a system of danger and information signals in reference to various degrees of urgency. This standard applies to all danger signals that have to be clearly perceived and differentiated, from extreme urgency to "all clear." Guidance on delectability is provided in terms of luminance, Illuminance, and contrast, considering both surface and point sources. ISO 9921:2003 describes a method for prediction of the effectiveness of speech communication in the presence of noise generated by machinery as well as in any other noisy environment. The following parameters are taken into account in this standard: the ambient noise at the speaker's position, the ambient noise at the listener's position, the distance between the communication partners, and a variety of physical and personal conditions (Parsons, 1995b). ISO/TR 19358:2002 deals with the testing and assessment of speech-related products and services. The standards that are under development are ISO/AWI 16613 (sound pressure levels for products and PA systems), ISO/FDIS 24501 (consumer products), and ISO/FDIS 24502 (specification of age-related luminance contrast for colored light), where AWI refers to approved new work item and FDIS refers to final draft international standard.

### 2.4.3 Lighting of Workplaces

ISO 8995 (Part 1: 2002 and Part 3: 2006) was developed by the ISO 159 SC5 WG 2 "Lighting" group in collaboration with the International Commission on Illumination (CIE). This standard describes the

**Table 13 ISO Standards for Danger Signals and Communication in Noisy Environments**

principles of the visual ergonomics, identifies factors that influence visual performance, and presents criteria for the achievement of an acceptable visual environment (Parsons, 1995b).

## 3 CEN STANDARDS FOR ERGONOMICS

In Europe, there are three standardization organizations: CEN, CENELEC, and ETSI. Their aim is development and achievement of a coherent set of voluntary standards that can provide a basis for a single European market/European economic area without internal frontiers for goods and services inside Europe. Their work is carried out in conjunction with worldwide bodies and the national standards bodies in Europe (Wetting, 2002). Members of the European Union (EU) and the European Fair Trade Association (EFTA) have agreed to implement CEN standards in their national system and to withdraw conflicting national standards.

In 1987, the CEN established CEN/TC 122, "Ergonomics," which is responsible for development of the European ergonomic standards (Dul et al., 1996). The scope of CEN/TC 122 is standardization in the field of ergonomics, in order to meet the requirements for ergonomic and efficient products under the conditions

of free trade so that enhanced health, safety, and well-being of the consumers and users as well as the overall performance are ensured. These ergonomics standards are aimed to be applied in work systems as well as in private use, for new technologies, and changes in the population (CEN, 2008). The organizational structure of the CEN/TC 122 is presented in Table 14.

The ISO and CEN have signed a formal agreement, *Agreement on Technical Cooperation between ISO and CEN* (the Vienna Agreement), that established close cooperation between these standardization bodies. The ISO and CEN decided to harmonize the development of their standards and to cooperate regarding exchange of information and standards drafting. According to this agreement, the ISO standards are adopted by the CEN, and vice versa. Table 15 presents published CEN ergonomics standards. Most of the ergonomic standards published by CEN/TC 122 are adoption, or adaptation, of ISO standards. In the last five years, the CEN ergonomic standards in development have been published as formal standards.

### 3.1 Other International Standards Related to Ergonomics

For historical and organizational factors, many ISO and CEN standards in the field of ergonomics have not been developed by the technical committees ISO TC 159 and CEN and TC 122. Some ergonomics areas covered by other ISO and CEN technical committees are presented in Table 16. The lists of published ISO standards related to the ergonomics area, but developed by groups other than the TC 159 committee, are provided in Table 17.

## 4 ILO GUIDELINES FOR OCCUPATIONAL SAFETY AND HEALTH MANAGEMENT SYSTEMS

The popularity and success of a systematic and standardized approach to the management systems introduced by the ISO led to the view that this type of approach can also improve the management of occupational safety and health. Following this idea, the International Labour Organization (ILO) developed voluntary guidelines on OSH management systems which reflect ILO values and ensure protection of workers' safety and health (ILO-OSH; ILO, 2001).

The ILO was founded at the Versailles Congress in 1919 and became a specialized agency of the United Nations (UN) in 1946. The aims of the ILO are to promote rights at work, encourage decent employment opportunities, enhance social protection, and strengthen dialogue in handling work-related issues through its four principal strategic objectives: (1) to promote and realize standards and fundamental principles and rights at work, (2) to create greater opportunities for women and men to secure decent employment, (3) to enhance the coverage and effectiveness of social protection for all, and (4) to strengthen tripartisan and social dialogue

(ILO, 2010). The ILO represents the interests of three parties treated equally: employers, employee organizations, and government agencies.

The ILO (2001) guidelines provide recommendations concerning design and implementation of occupational safety and health management systems (OSHMS) that allow for integration of OSH with the general enterprise management system. The ILO guidelines state that these recommendations are addressed to all who are responsible for the occupational safety and health management. These guidelines are nonmandatory and are not intended to replace national laws and regulations. The ILO (2001) document distinguished two levels of guideline application: national and organizational. At the national level ILO-OSH (ILO, 2001) provides recommendations for the establishment of a national framework for OSHMS. The guidelines suggest that this process should be supported by the provision of the relevant national laws and regulations.

Establishment of a national framework for OSHMS included the following actions (ILO, 2001): (1) nomination of competent institution(s) for OSHMS, (2) formulation of a coherent national policy, and (3) development

of national and tailored guidelines. The process of establishment of a national framework for OSHMS and its components is presented in Figure 2.

At the organizational level ILO (2001), guidelines establish employer responsibilities regarding occupational safety and health management and emphasize the importance of compliance with national laws and regulations. ILO (2001) suggests that OSH management system elements be integrated into overall organizational policy and management strategies actions (ILO, 2001).

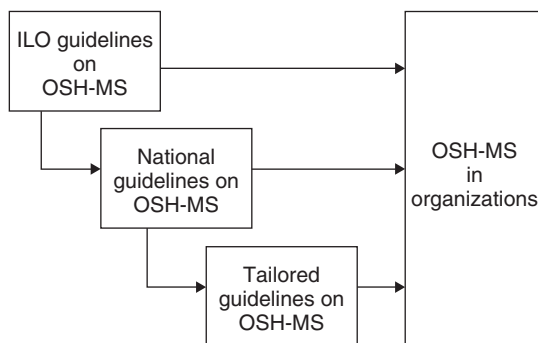

**Figure 2**  Establishment of a national framework for the OSHMS. (From ILO, 2001.)

The OSH management systems in the organization consist of five main sections: policy, organizing, planning and implementation, evaluation, and action for improvement. These elements correspond to the Demming cycle of plan–do–check–act, internationally accepted as the basis for the systems approach to management. The OSHMS main sections and their elements are listed in Table 18.

ILO (2001) guidelines require establishment by the employer of the OSH policy in consultation with workers and their representatives and define the content of such policy. The ILO-OSH (ILO, 2001) guidelines also indicate the importance of OSH policy integration and compatibility with other management systems in the organization. These guidelines emphasize the necessity of worker participation in the OSH management system in the organization. Therefore, workers should be consulted regarding OSH activities and should be encouraged to participate in OSHMS, including a safety and health committee. The organizing section of the guidelines underlines the need for allocation of responsibility and accountability for the implementation and performance of the OSH management system to the senior management. This section also includes requirements related to competence and training in the OSH field and defines the necessary documentation and communications activities. The planning and implementation section includes the elements of initial review, system planning, development and implementation, OSH objectives, and hazard prevention. The initial review identifies the actual states of the organization with regard to the OSH and creates the baseline for OSH policy implementation. The evaluation section consists of performance monitoring and measurement, investigation of work-related diseases and incidents, audit, and management review. The guidelines require carrying out internal audits of the OSHMS according to the policies established. Action for improvement includes the elements of preventive and corrective action and continual improvement. The final section underlines the need for continual improvement of OSH performance through the development of policies, systems, and techniques to prevent and control work-related injuries and diseases.

## 5  U.S. STANDARDS FOR HUMAN FACTORS AND ERGONOMICS

### 5.1  U.S. Government Standards

Among the HFE U.S. government standards, two documents are usually mentioned as basic: a military standard providing human engineering design criteria (MIL-STD-1472) and a human–system integration standard (NASA-STD-300) (Chapanis. 1996; McDaniel, 1996). In addition, there are more specific standards that have been developed by such departments as the Department of Defense (DOD), Department of Transportation (DOT), Department of Energy (DOE), and U.S. Nuclear Regulatory Commission (NRC). Additionally, a large number of handbooks that contain more detailed and descriptive information concerning human factor and

ergonomics guidelines, preferred practices, methodology, and reference data that may be needed during the design of equipment and systems have also been developed. The handbooks provide assistance in the use and application of relevant government standards during the design process.

### 5.1.1 Military Standards

The set of consensus military standards was developed by human factors engineers from the U.S. military's three services (Army, Navy, and Air Force), industry, and technical societies (McDaniel, 1996). As a result of standardization reform in the late 1990s, most of the single-service standards were canceled and were integrated into a few DOD standards and handbooks. However, the distinction between two main categories of human factors military standards—general (MIL-STD-1472 and related handbooks) and aircraft QSSG 2010 and related handbooks)—remains unchanged, which reflects the criticality of aircraft design. The list of the main military standards and handbooks are presented in Table 19.

The basic human engineering principles, design criteria, and practices required for integration of humans with systems and facilities are established in MIL-STD-1472F, *Human Engineering Design Criteria for Military*

*Systems, Equipment and Facilities.* This standard document can be applied to the design of all systems, subsystems, equipment, and facilities, not only military but commercial as well. MIL-STD-1472F includes requirements for displays, controls, control–display integration, anthropometry, ground workspace design, environment, design for maintainability, design of equipment for remote handling, small systems and equipment, operational and maintenance ground/shipboard vehicles, hazards and safety, aerospace vehicle compartment design requirements, and human–computer interface. MILSTD-1472 also includes nongovernmental standards ANSI/Human Factors Society (HFS) 100 on VDT workstations. After standardization reform the design data and information part of MIL-STD-1472F were removed and inserted into MIL-HDBK-759.

Another important military standard document is MIL-HDBK-46855, *Human Engineering Requirements for Military Systems Equipment and Facilities.* This handbook presents human engineering program tasks, procedures, and preferred practices. MIL-HDBK-46855 covers such topics as analysis functions, including human performance parameters, equipment capabilities, and task environments design; test and evaluation: workload analysis; dynamic simulation; and data requirements. This handbook also adopted materials from DOD-HDBK-763, *Human Engineering Procedures Guide,* concerned with human engineering methods and tools, which remained stable over time. The newest rapidly evolving automated human engineering tools are not described in MIL-HDBK-46855 but can be found at Directory of Design Support Methods (DSSM) at http://www.dtic.mil/dticasd/ddsm/index.html.

Other military standards cover such topics as standard practice for conducting system safety (MIL-STD-882D); acoustical noise limits, testing requirements, and measurement techniques (MIL-STD-1474D); physical characteristics of symbols for army system displays (MIL-STD-1477C); and symbology requirements for aircraft displays (MILSTD-1787C). The definitions for all human factors standard documents are provided in MIL-HDBK-1908B, *Department of Defense Handbook: Definitions of Human Factors Terms.*

### 5.1.2 Other Government Standards

The lists of other government standards are provided in Table 20. National Aeronautics and Space Administration (NASA) STD-3000 provides generic requirements for space facilities and related equipment important for proper human–system integration. This document is integrated with the website, which also offers video images from space missions that illustrate human factors design issues. This standard document is not limited to any specific NASA, military, or commercial program and can be applied to almost any type of equipment. NASA-STD-3000 consists of two volumes: Volume 1, *Man–Systems Integration Standards,* presents all of the design standards and requirements, and Volume II, *Appendices,* contains the background information related to standards. NASA-STD-3000 covers the following areas of human factors: anthropometry

and biomechanics, human performance capabilities, natural and induced environments, health management, workstations, activity centers, hardware and equipment, design for maintainability, and facility management.

Standards of the Federal Aviation Administration (FAA) are concerned with the following topics: human factors design criteria oriented to the FAA mission and systems (HF-STD-001); design and evaluation of air traffic control systems (DOT-VNTSC-FAA-95-3); elements of the human engineering program (FAA-HF-001); evaluation of human factors criteria conformance of equipment that interface with the operator (FAA-HF-002) and with the maintainer (FAA-HF-003).

In their standard DOE-HDBK-1140-2001, the DOE provides the system maintainability design criteria for DOE systems, equipment, and facilities. The Federal Highway Administration (FHA) establishes standards concerning the development and operation of traffic management centers (FHWA-JPO-99-042). The FHA also describes human factors guidelines and recommendations for design of advanced traveler information systems (ATISs), commercial vehicle operations (CVOs), and accommodation of older drivers and pedestrians. The NRC provides guidelines of HFE conformance evaluation of the interface design of nuclear power plant systems (NUREG—0700 and NUREG—0711). FED-STD-795, which has been developed for use in federal

and federally funded facilities, establishes standards for facility accessibility by physically handicapped persons.

## 5.2  OSHA Standards

Development of occupational safety and health standards in the United States is mandated by the general duty clause, Section 5(a)(1), of the *Occupational Safety and Health Act of 1970,* which states: "Each employer shall furnish to each of his employees, employment and a place of employment which is free from recognized hazards that are causing or are likely to cause death or serious harm to his employees." In general, penalties related to deficient and unsafe working conditions have been issued under this general duty clause. The general duty clause has also been supplemented by the *Americans with Disabilites Act* (ADA, Public Law 101-336, 1990). The disabilities act has an important bearing on ergonomics design of workplaces. The ADA prohibits disability-based discrimination in hiring practices and requires that all employers make reasonable accommodations to working conditions to allow qualified disabled workers to perform their job functions.

In 1990, the Occupational Safety and Health Administration (OSHA) issued a set of voluntary guidelines entitled *Ergonomics Program Management Guidelines for Meatpacking Plants* (OSHA 3123), which have been used successfully by many types of industries, including those from outside the food production business.

In 2000, the U.S. government proposed the *Ergonomics Program Rule (Federal Register,* November 14, 2000, Vol. 65, No. 220). The main elements of the standard included (1) training in basic ergonomics awareness, (2) providing medical management of work-related musculoskeletal disorders, (3) implementing a quick fix or going to a full program, and (4) implementing a full ergonomic program when indicated, including such elements as management leadership, employee participation, job hazard analysis, hazard reduction and control, training, and program evaluation. However, the regulation was repealed in March 2001.

Recently, OSHA has developed a four-pronged comprehensive approach to ergonomics designed to address musculoskeletal disorders (MSDs) in the workplace. The four segments of the OSHA's strategy were stated as follows:

1. *Guidelines:* to develop industry- or task-specific guidelines for industries based on current incidence rates and available information about effective and feasible solutions

2. *Enforcement:* to conduct inspections for ergonomic hazards and issue citations under the general duty clause and to issue ergonomic hazard alert letters where appropriate

3. *Outreach and assistance:* to provide assistance to businesses, particularly small businesses, and

help them proactively address ergonomic issues in the workplace

4. *National advisory committee:* to charter an advisory committee that will be authorized to, among other things, identify gaps in research to the application of ergonomics and ergonomic principles in the workplace

Recently, OSHA has also published three voluntary guidelines to assist employers of the specific type of industries in recognizing and controlling hazards: (1) *Nursing Home Guideline* (2003), (2) *Draft Guideline for Poultry Processing* (2003), and (3) *Guideline for the Retail Grocery Industry* (2004). The objective of this protocol is to establish a fair and transparent process for developing industry- and task-specific guidelines that will assist employers and employees in recognizing and controlling potential ergonomic hazards. By using this protocol, each set of guidelines will address a particular industry or task. It is intended that the industry- and task-specific guidelines will generally be presented in three major parts:

1. Program management recommendations for management practices addressing ergonomic hazards in the industry or task

2. Work site analysis recommendations for work site/workstation analysis techniques geared to the specific operations that are present in the industry or task

3. Hazard control recommendations that contain descriptions of specific jobs and that detail the hazards associated with the operation, possible approaches to controlling the hazard, and the effectiveness of each control approach

Since there are many different types of work-related hazards and injuries, and controls vary from industry to industry and task to task, OSHA expects that the scope and content of the guidelines will vary. Thus, OSHA enforces a general industry-related regulation [29 Code of Federal Regualtions (CFR) 1910] and two industry specific regulations: (1) construction (29 CFR 1926) and (2) maritime (29 CFR 1915, 1917, and 1918). Through the directorate of enforcement programs, OSHA ensures the implementation of these regulations.

### 5.3   Other Standards for Occupational Safety and Health

In 2000, the National Safety Council (NSC), acting on behalf of the Accredited Standards Committee (ASC), has issued a draft document (known as Z-365) entitled *Management of Work-Related Musculoskeletal Disorders* (*MSD*). The draft defines the following areas of importance to preventing work-related injuries: (1) management responsibility, (2) employee involvement, (3) training, (4) surveillance, (5) evaluation and management of work-related MSD cases, (6) job analysis and design, and (7) follow-up.

Independent of the efforts noted above, in 2001 another ANSI committee, *ASC Z-10, Occupational*

*Health Safety Systems,* was formed under the auspices of the American Industrial Hygiene Association (AIHA). The main objective of ASC Z-10 is to develop a standard of management principles and systems for improving the occupational safety and health in companies.

### 5.4   ANSI Standards

The following HFE-relevant standards have been developed by the ANSI.

#### 5.4.1   Human Factors Engineering of VDTs

ANSI/HFS 100-1988 presents ergonomics principles related to visual display terminals. The standard has been updated as ANSI/Human Factors and Ergonomics Society (HFES) 100-2007 and is available at http://www. hfes.org/publications/ProductDetail.aspx?ProductId=69.

#### 5.4.2   Human Factors Engineering of Computer Workstations

As stated in the trial use, the BSR/HFES 100 (currently ANSI/HFES 100-2007) Human Factors Engineering of Computer Workstations (HFES 100) is *a specification of the recommended human factors and ergonomic principles related to the design of the computer workstation, and is intended for fixed, office-type computer workstations for individuals who are moderate to intensive computer users* (Albin, 2006). This standard is organized into four major chapters: (1) installed systems, (2) input devices, (3) visual displays, and (4) furniture. The installed systems chapter specifies how to arrange all the workstation system components to match the capabilities of the intended user. The input devices chapter focuses on the design of input devices (including the issues of physical size, operation force, handedness, etc). The visual displays chapter discusses the human factors in the design of monochrome and color CRT and flat-panel displays. The furniture chapter provides design specifications for workstation components, including chairs and desks. The major topics described in each of these chapters are listed in Table 21.

#### 5.4.3   Ergonomic Requirements for Software User Interfaces

The HFES/HCI 200 Committee, which operates under the auspices of the HFES Technical Standards Committee, has been working on development of a proposed U.S. national standard for software user interfaces. This standard, updated in 2005, provides requirements and recommendations for software interfaces, with a primary focus on business and personal computing applications. The standard is related to the ISO 9241 series of user interface standards. The topics described in each section of the HFES 200 standard are listed in the Table 22.

#### 5.4.4   Ergonomic Guidelines for the Design, Installation, and Use of Machine Tools

ANSI B 11, *Technical Report: Ergonomic Guidelines for the Design, Installation and Use of Machine Tools,* is a consensual ergonomic guidelines developed by the Machine Tool Safety Standards Committee (B 11) of the

**Table 21  Main Chapters and Topics of the Human Factors Engineering of Computer Workstations: ANSI/HFES 100-2007 Standard**

| Chapter | Topics |
| --- | --- |
| Installed systems | Hardware components, noise, thermal comfort, and lighting |
| Input devices | Keyboards, mouse and puck devices, trackballs, joysticks, styluses and light pens, tablets and overlays, touch-sensitive panels |
| Visual displays | Monochrome and color cathode ray tube (CRT) and flat-panel displays (viewing characteristics, contrast, legibility, etc.) |
| Furniture | Specifications for workstation components (chairs, desks, etc.); postures (reference postures, reclined sitting, upright sitting, declined sitting and standing); anthropometry |

**Table 22  Topics Addressed in the Ergonomic Requirements for Software User Interfaces: HFES 200-2005**

| Chapter | Topics |
| --- | --- |
| Accessibility | Keyboard input; multiple keystrokes |
| | Customization; repeat rates; acceptance delays |
| | Pointer alternative; accelerators; remapping; navigation |
| | *Display fonts:* size, legibility, styles, colors |
| | *Audio output:* volume and frequencies, customization, content and alerts, graphics |
| | *Color:* palettes, background–foreground, customization, coding |
| | *Errors and persistence:* online documentation and help |
| | *Customization:* cursor, button presses, click interval, pointer speed, chording |
| | *Window appearance and behavior:* navigation and location, window focus, titles |
| | *Input focus:* navigation, behavior, order, location |
| Color | Color *selection:* chromostereopsis, blending and depth effects, use of blue and red, identification and contrast |
| | *Color assignments:* conventions, uniqueness and reuse, naming, cultural assignments |
| | *General use consideration:* number of colors, highlighting, positioning and separation |
| | *Special uses:* warnings, coding, state indications, pointers, area identification |
| Voice and telephony | *Speech recognition (input):* commands, vocabularies, prompts, consistency, feedback, error handling, dictation |
| | *Speech output:* vocabularies message format, speech characteristics, dialogue techniques, physical properties, alerting tones, stereophonic presentation |
| | *Nonspeech auditory output:* consistency, tone format, critical messages, frequency, amplitude |
| | Interactive voice response |
| Technical sections | Presentation of information, user guidance, menu dialogues, command dialogues, direct manipulation, dialogue boxes, and form-filling dialogue windows |

ANSI. The subcommittee responsible for the preparation of these guidelines consisted of representatives from manufacturing, higher education, safety, design, and ergonomics. The document specifies ergonomic guidelines to assist in the design, installation, and use of individual and integrated machine tools and auxiliary components in manufacturing systems.

The guidelines document underlines the importance of three basic ideas for achievement of effective and safe design, installation, and use of machine tools: (1) communication among all persons involved with the machine tools (users, installers, manufacturers, and designers), (2) dissemination of knowledge concerning ergonomics concepts and principles among all persons, and (3) the ability to apply ergonomics concepts and principles effectively to machine tools and auxiliary components. The guidelines document states that the provision of worker safety, work efficiency, and optimization of the entire production system requires consideration of the following ergonomics issues:

- The variation in employee physiological and psychological characteristics such as strength and capacity
- Incorporation of ergonomics concepts and principles into all new project, tool, machine, and work processes at the beginning of the process
- The goal that routine tasks that are to be done precisely, rapidly, and continuously, especially tasks in hazardous environments, should be performed by machines
- The goal that tasks that require judgment and integration of information (i.e., the tasks that humans do best) should be assigned to workers
- The knowledge that a system that does not consider human limits such as information handling,

perception, reach, clearance, posture, or strength exertion can predispose to accident or injury

The documents also recommend matching the design of the tool or process with the physical characteristics and capabilities of workers, to ensure accommodation, compatibility, operability, and maintainability of the machine tools and/or auxiliary components. A complete list of standards included in B11 is shown in Table 23.

**Table 23 ANSI B11 Parts**

| Standard | Title |
| --- | --- |
| ANSI B11-2008 | General safety requirements common to ANSI B11 machines |
| ANSI B11.1 | Mechanical power presses |
| ANSI B11.2 | Hydraulic power presses |
| ANSI B11.3 | Mechanical power press brakes |
| ANSI B11.4 | Shears |
| ANSI B11.5 | Ironworkers |
| ANSI B11.6 | Lathes |
| ANSI B11.7 | Cold headers and cold formers |
| ANSI B11.8 | Drilling, milling, and boring machines |
| ANSI B11.9 | Grinding machines |
| ANSI B11.10 | Metal sawing machines |
| ANSI B11.11 | Gear and spline cutting machines |
| ANSI B11.12 | Roll forming and roll bending machines |
| ANSI B11.13 | Automatic screw/bar and chucking machines |
| ANSI B11.14 | Withdrawn (now see B11.18) |
| ANSI B11.15 | Pipe, tube, and shape bending machines |
| ANSI B11.16 | Metal powder compacting presses |
| ANSI B11.17 | Horizontal hydraulic extrusion presses |
| ANSI B11.18 | Coil processing systems |
| ANSI B11.19 | Performance criteria for safeguarding |
| ANSI B11.20 | Integrated manufacturing systems |
| ANSI B11.21 | Machine tools using lasers for processing materials |
| ANSI B11.22 | Turning centers and CNC turning machines |
| ANSI B11.23 | Machining centers and CNC milling, drilling, and boring machines |
| ANSI B11.24 | Transfer machines |
| ANSI B11.TR1-2004 | Ergonomic guidelines |
| ANSI B11.TR2-1997 | Mist control considerations |
| ANSI B11.TR3-2000 | Risk assessment and risk reduction |
| ANSI B11.TR4-2004 | Selection of programmable electronic systems (PES/PLC) for machine tools |
| ANSI B11.TR5-2006 | Sound level measurement guidelines |
| ANSI B11.TR6-20XX (not an approved document; in development) | Control reliable circuits and servo drive technology |
| ANSI B11.TR7-2007 | Design for safety and lean manufacturing |

## 5.5 State-Mandated Occupational Safety and Health Standards

Section 18 of the Occupational Safety and Health Act (1970) encourages states to develop and operate their own job safety and health programs. In general, states with OSHA-approved occupational safety and health programs may follow OSHA's approach to ergonomics: to adopt ergonomic standards, include ergonomics in standards establishing safety and health program requirements, and utilize the general duty authority for enforcement purposes (Seabrook. 2001; Stuart-Buttle, 2005). To date, 22 stes and jurisdictions are operating complete state plans that cover both the private sector and state and local government employees and five states, that is, Connecticut, Illinois, New Jersey, New York, and the Virgin Islands cover public employees only. Of the states and jurisdictions, seven (California, Michigan, New Mexico, Oregon, Puerto Rico, Vermont, and Washington) have the operational status agreement, that is, the state is independently capable of enforcing its own standard. Out of those seven, only Oregon has received the final approval of OSHA in 2005. However, this final approval does not include temporary labor camps in agriculture, general industry, construction, and logging. Nine states that previously had final approval of an independent state program withdrew their programs and currently use OSHA funded on-site consultation programs. Details of state-mandated occupational safety and health programs can be found at http://www.osha.gov/dcsp/osp/index.html.

## 5.6 Other Standardization Efforts

The American Conference of Governmental Industrial Hygienists (ACGIH) (www.aegih.org) established threshold limit values (TLVs) for the following physical categories of work: (1) hand–arm and whole-body vibration, (2) thermal stress, (3) hand activity level ("monotask" jobs, performed for 4 h or more), and (4) lifting tasks (load limits based on lift frequency, task duration, horizontal distance, and height at the start of the lift). Other organizations that develop HFE-related standards include the American Society of Mechanical Engineers (ASME), American Society for Testing and Materials (ASTM), Institute of Electrical and Electronics Engineers (IEEE), Society of Automotive Engineers (SAE), and National Institute of Standards and Technology (NIST, www.nist.gov).

A notable use of standards is the SAE HFE standards widely used in the US automotive industry. Table 24 shows the various standards and guidelines that are in use currently by the various automotive manufacturing companies in the United States.

## 6 ISO 9000-2005: QUALITY MANAGEMENT STANDARDS

Quality standards can also play an important role in assuring safety and health at the workplace. The ISO stipulates that if a quality management system is implemented appropriately utilizing the eight quality management principles (see below) and in accordance with

**Table 24  SAE Technical Automotive Standards for Human Factors and Ergonomics**

ISO 9004, all of an organization's interested parties should benefit. For example, people in the organization will benefit from (1) improved working conditions, (2) increased job satisfaction, (3) improved health and safety, (4) improved morale, and (5) improved stability of employment, and the society at large will benefit from (1) fulfillment of legal and regulatory requirements, (2) improved health and safety, (3) reduced environmental impact, and (4) increased security.

As discussed by Hoyle (2009), the term ISO 9000 refers to a set of quality management standards. ISO 9000 currently includes three quality standards: ISO 9000:2005, ISO 9001:2008, and ISO 9004:2009. ISO 9001:2008 presents requirements; ISO 9000:2005

and ISO 9004:2009 present guidelines. The ISO first published its quality standards in 1987, revised them in 1994 and 2000, and then republished an updated version in 2005. These new standards are referred to as the ISO 9000:2005 standards.

ISO 9000:2005 describes fundamentals of quality management systems, which form the subject of the ISO 9000 family, and defines related terms. It is applicable to the following: (a) organizations seeking advantage through the implementation of a quality management system; (b) organizations seeking confidence from their suppliers that their product requirements will be satisfied; (c) users of the products; (d) those concerned with a mutual understanding of the terminology used in quality management (e.g., suppliers, customers, regulators); (e) those internal or external to the organization who assess the quality management system or audit it for conformity with the requirements of ISO 9001 (e.g., auditors, regulators, certification/registration bodies); (f) those internal or external to the organization who give advice or training on the quality management system appropriate to that organization; and (g) developers of related standards. The standard recognizes that the word *product* applies to services, processed material, and hardware and software intended for, or required by, the customer (Hoyle, 2001).

The ISO 9000:2005 standards apply to all types of organizations, including manufacturing, service, government, and education. The standards are based on eight *quality management principles* (Hoyle, 2006):

- *Principle* 1: customer focus
- *Principle* 2: leadership
- *Principle* 3: involvement of people
- *Principle* 4: process approach
- *Principle* 5: system approach to management
- *Principle* 6: continual improvement
- *Principle* 7: factual approach to decision making
- *Principle* 8: mutually beneficial supplier relationships

As part of ISO 9000, requirements for a quality management system are met by implementing ISO 9001: 2008. ISO 9001:2008 specifies requirements for a quality management system where an organization (1) needs to demonstrate its ability to consistently provide product that meets customer and applicable statutory and regulatory requirements and (2) aims to enhance customer satisfaction through the effective application of the system, including processes for continual improvement of the system and the assurance of conformity to customer and applicable statutory and regulatory requirements. All requirements of ISO 9001:2008 are generic and are intended to be applicable to all organizations, regardless of type, size, and product provided. Where any requirement(s) of ISO 9001:2008 cannot be applied due to the nature of an organization and its product, this can be considered for exclusion. Where exclusions are made,

claims of conformity to ISO 9001:2008 are not acceptable unless these exclusions are limited to requirements within Clause 7, and such exclusions do not affect the organization's ability, or responsibility, to provide product that meets customer and applicable statutory and regulatory requirements.

ISO 9004:2009 can be used to extend the benefits obtained from ISO 9001:2008 to employees, owners, suppliers, and society in general. This standard provides guidance to organizations to support the achievement of sustained success by a quality management approach. It is applicable to any organization, regardless of size, type, and activity.

ISO 9001:2008 and ISO 9004:2009 are harmonized in structure and terminology to assist an organization to move smoothly from one to the other. Both standards apply a process approach. Processes are recognized as consisting of one or more linked activities that require resources and must be managed to achieve predetermined output. The output of one process may form directly the input to the next process, and the final product is often the result of a network or system of processes. The eight quality management principles stated in ISO 9000:2005 and ISO 9004:2009 provide the basis for the performance improvement outlined in ISO 9004:2009. The ISO 9000 standards cluster also includes other 10000 series standards. Table 25 shows a list of the relevant standards and their purposes.

ISO requires that the organization determine what it needs to do to satisfy its customers, establish a system to accomplish its objectives, and measure, review, and continually improve its performance. More specifically, the ISO 9001 and 9004 requirements stipulate that an organization must:

1. Determine the needs and expectations of customers and other interested parties

2. Establish policies, objectives, and a work environment necessary to motivate the organization to satisfy these needs

3. Design, resource, and manage a system of interconnected processes necessary to implement the policy and attain the objectives

4. Measure and analyze the adequacy, efficiency, and effectiveness of each process in fulfilling its purpose and objectives

5. Pursue the continual improvement of the system from an objective evaluation of its performance

The ISO identified several potential benefits of using the quality management standards. These benefits may include the connection of quality management systems to organizational processes, encouragement of a natural progression toward improved organizational performance, and consideration of the needs of all interested parties. Along with the main quality management standards, the ISO also published standards that deal with quality management of specific products (e.g., medical devices), specific industry (e.g., ships and marine,

**Table 25  ISO 9000:2005 Quality Management Standards and Guidelines**

| Standard or Guideline | Purpose |
| --- | --- |
| ISO 9000:2005, Quality management systems: Fundamentals and vocabulary | Establishes a starting point for understanding the standards and defines the fundamental terms and definitions used in the ISO 9000 family to avoid misunderstandings in their use |
| ISO 9001:2008, Quality management systems: Requirements | Requirement standard to be used to assess the organization's ability to meet customer and applicable regulatory requirements and thereby address customer satisfaction: now the only standard in the ISO 9000 family against which third-party certification can be carried |
| ISO 9004:2009, Managing for the sustained success of an organization: A quality management approach | Provides guidance for continual improvement of an organization's quality management system to benefit all parties through sustained customer satisfaction |
| ISO 19011:2002, Guidelines on quality and/or environmental management systems auditing | Provides an organization with guidelines for verifying the system's ability to achieve defined quality objectives (use internally or for auditing suppliers) |
| ISO 10005:2005, Quality management: Guidelines for quality plans | Provides guidelines to assist in the preparation, review, acceptance, and revision of quality plans |
| ISO 10006:2003, Quality management: Guidelines to quality management in projects | Guidelines to help the organization to ensure the quality of both project processes and project products |
| ISO 10007:2003, Quality management: Guidelines for configuration management | Gives an organization guidelines to ensure that a complex product continues to function when components are changed individually |
| ISO 10012:2003, Measurement management systems: Requirements for measurement processes and measuring equipment | Specifies generic requirements and provides guidance for the management of measurement processes and metrological confirmation of measuring equipment used to support and demonstrate compliance with metrological requirements |
| ISO/TR 10013:2001, Guidelines for quality management system documentation | Provides guidelines for the development and maintenance of quality manuals tailored to specific needs |
| ISO 10014:2006, Guidelines for realizing financial and economic benefits | Provides guidance on how to achieve economic benefits from the application of quality management |
| ISO 10015:1999, Quality management: Guidelines for training | Provides guidance on the development, implementation, maintenance, and improvement of strategies and systems for training that affects the quality of products |
| ISO/TS 16949:2009, Quality management systems: Particular requirements for the application of ISO 9001:2008 for automotive production and relevant service part organizations | Provides sector-specific guidance to the application of ISO 9001 in the automotive industry |

petroleum, software engineering, information technology, systems engineering, intelligent transport systems), environment, and customer satisfaction. Those standards are listed in Table 26.

## 7  CONCLUSIONS

Although human factor and ergonomics standards cannot guarantee appropriate workplace design, they can provide clear and well-defined requirements and guidelines and therefore the basis for good ergonomics design. Standards for workstation design and the work environment can ensure the safety and comfort of working people through establishing requirements for optimal working conditions. By providing consistency in the human–system interface and improving ergonomics quality of the interface components, ergonomics

standards can also contribute to the enhanced systems usability and overall system performance. This benefit is based on the general requirement of harmonization across different tools and systems to support user performance and avoid unnecessary human errors.

One of the most important benefits from standardization efforts is a formal recognition of the significance of ergonomics requirements and guidelines for system design on the national and international levels (Harker, 1995). The consensus procedure applied to standards development demands consultation with a wide range of commercial, professional, and industrial organizations. Therefore, the decision to develop standards and a consensus of diverse organizations concerning the need for standards reflects the formal recognition that there are important human factors and ergonomics issues that need to be taken into account during the design and development of workplaces and systems. In the last few

**Table 26 Other Quality Management Standards and Guidelines**

| Standard Reference | Title |
| --- | --- |
| ISO 10001:2007 | Quality management: Customer satisfaction: Guidelines for codes of conduct for organizations |
| ISO 10002:2004 | Quality management: Customer satisfaction: Guidelines for complaints handling in organizations |
| ISO 10003:2007 | Quality management: Customer satisfaction: Guidelines for dispute resolution external to organizations |
| ISO 10019:2005 | Guidelines for the selection of quality management system consultants and use of their services |
| ISO 13485:2003 | Medical devices: Quality management systems: Requirements for regulatory purposes |
| ISO 14001:2004 | Environmental management systems: Requirements with guidance for use |
| ISO 14004:2004 | Environmental management systems: General guidelines on principles, systems and support techniques |
| ISO 14050:2009 | Environmental management: Vocabulary |
| ISO 14063:2006 | Environmental management: Environmental communication: Guidelines and examples |
| ISO 15189:2007 | Medical laboratories: Particular requirements for quality and competence |
| ISO 15225:2010 | Medical devices: Quality management: Medical device nomenclature data structure |

years, we have seen a greater effort on the part of the ISO and CEN in publishing the underdeveloped standards into full standards. At the same time, the ISO is making every effort to outreach, in particular to developing and underdeveloped countries. Despite these efforts, there is a lack of research endeavor examining or investigating the effectiveness of these standards. There is also the question of whether organizations will feel implementing a large number of standards a burden, specially the small business entrepreneurs.

Nevertheless, standards represent the essence of the best available knowledge and practice extracted from a variety of academic sources, presented in the way that is easy to use by professional designers, and to include this knowledge in the design process. The consensus procedure makes the standards under development known and available to interested parties and the general public. Such a procedure also facilitates dissemination and promotion of human factors and ergonomics knowledge across the world of nonexperts.

## 1  CONCEPTUAL OVERVIEW

### 1.1  Introduction

The purpose of this chapter is to present an overview of ergonomic issues in the office workplace. However, in determining the scope of this material, it is necessary to consider a fundamental question: What is an office? In the modern electronic workplace, the answer is not straightforward. A traditional (*Compact Edition of the Oxford English Dictionary*, 1971) definition states that an office is "a place for the transaction of private or public business." With the profusion of portable computers and hand-held devices currently available, almost any location can fit that definition: an airport waiting room, a kitchen table, an automobile, even a park bench. Nevertheless, this chapter must focus on evidence-based findings, and the bulk of such research has been conducted in traditional offices. Therefore, we will focus on workplaces whose primary purpose is some aspect of information processing and transformation, where some sort of computer equipment is employed, and whose occupants are expected to remain in place for extended periods of time (i.e., several hours). On the other hand, the general principles discussed here can be usefully applied to more temporary venues (e.g., setting up a temporary workspace with a laptop and modem in a hotel room). Of particular interest is the increasingly frequent case of telework in which individual employees are—either voluntarily or involuntarily—expected to set up their primary workplace at home.

The chapter cannot hope to be comprehensive. A search of the terms "office ergonomics" in Google Scholar resulted in 72,000 hits. Even allowing for overlap, a comprehensive literature review would likely result in all of the allocated space for this chapter being composed of citations. Nevertheless, it is the intent of the authors that at least the major issues will be introduced and discussed with sufficient citations to enable the reader to explore these issues in depth.

The contribution of individual authors can be specifically identified. In Section 2, Johan Andersen presents a systematic review of the epidemiological literature linking carpel tunnel syndrome and upper extremity disorders among computer users. In Sections 3 through 7 Wayne Maynard relies on consensus standards [Business and Institutional Furniture Manufacturers Association (BIFMA), 2002; Human Factors and Ergonomics Society (HFES), 2007], the draft report of the Z365 committee of the National Safety Council (Accredited Standards Committee, 2002), and many years of practical experience to summarize ergonomic recommendations for office design from a practitioner's perspective. In Section 8, Michelle Robertson considers the evidence for effective interventions. Finally, Marvin Dainoff provides a conceptual framework (Sections 1 and 9) and is responsible for overall organization and integration. The authors do not speak with one voice and disagreements will appear. We regard this as a strength of the chapter. As Root-Bernstein (1989) argues, "it is not consensus for which we must strive, but the elaboration of as many adequate descriptions of nature as we can imagine—in short the sort of complementarist view espoused by Bohr" (p. 375).

### 1.2  An Ecological Approach to Ergonomics

This overview is based on previous work (Dainoff and Mark, 2001; Dainoff, 2005, 2008).

Galison (1997) has provided an intriguing study of the development of the field of microphysics, from the nineteenth century cloud chamber to the factorylike laboratories of the present day at places like the European Organization for Nuclear Research (CERN), Stanford, and Berkeley. His particular focus is on the way in which the development of laboratory apparatus transformed the *social/organizational* structure of microphysics from individual investigators working alone or in small groups with total control and understanding of their apparatus to industrial-style organizations requiring collaboration among many professionals. In order for this collaboration to have occurred, Galison invokes the concept of "trading zones" (1997, p.46). Derived from the field of linguistics, trading zones refer to simplified languages (creoles, pidgins) that arise when adjacent cultures require a mutually understandable means of communication in order to transact business. Galison's insight has important implications for the field of ergonomics.

Just in the area of ergonomics of chairs and furniture, the applicable research involves individuals from a number of academic specialties, including biomechanics, epidemiology, economics, industrial engineering, industrial medicine, industrial design, muscle physiology, multivariate statistics, psychology of human performance, psychophysics, organizational design, orthopedics, and optometry. What is required is a trading zone, a conceptual framework within which specialists in one area can communicate with specialists in another.

### 1.3  Foundations

Two books were written at the end of the 1940s, which together should have changed the face of psychology. Both of these books offered naturalistic approaches to basic psychological processes which, prior to that time, had been treated in highly abstract ways, torn out of their functional contexts (Reed and Bril, 1996, p. 242).

The first of these books was J. J. Gibson's *Perception of the Visual World* (Gibson, 1950); the second, which was suppressed for political reasons, was Bernstein's *On Dexterity and Its Development*. The volume was finally published (Bernstein, 1996), and it remained for those who followed and elaborated the Gibsonian position to incorporate Bernstein's insights into the ecological position. See, for example, Turvey et al. (1978).

Gibson's ecological approach to psychology, as outlined in his last book (Gibson, 1979), provides part of the foundational basis for ecological ergonomics. Gibson rejected the prevailing view of psychology as the study of an individual organism, in which environmental context is simplified or ignored. Instead, he argued that the individual and environment are so tightly and reciprocally coupled that they cannot be studied independently of one another. Thus, to understand the simple case of a person walking across a field, a detailed physical analysis of the terrain is required—including characterization of the projected optical flow patterns across the retina

associated with movement in a given direction. Because this approach takes into account the interacting aspects of both person and environment, Gibson called it an "ecological" approach. Gibson's arguments are similar to the *systems*-versus-*psychological* distinction made by Meister (1989) and, in fact, Gibson himself saw similarities between his view and systems theory (Vicente, 1999).

While Gibson argued for the importance of viewing perception within the functional context of behavior in the environment, Bernstein presented a parallel argument for viewing actions within their functional/adaptive contexts. What he called "dexterity" is a capacity of solving motor control problems under dynamically changing parameters (Reed and Bril, 1996). Hence, movement science cannot study movements as abstract patterns without taking into account functional demands of task constraints, environmental constraints, and (changing) constraints within the individuals themselves (Newell, 1996).

## 1.4 Elements of an Ecological Framework for Ergonomics

The core of this approach rests on the parallelism between basic concepts of ergonomics and ecological psychology. Ergonomics can be characterized as the *fit* between the human being and those things (tools, workplaces, environments) with which he or she interacts (Dainoff and Dainoff, 1986). At the same time, ecological psychology provides a theoretical foundation which allows us to relate the physical attributes of people and their environments with behavioral acts required to function in that environment (Gibson, 1979). Therefore, the fact that both ecological psychology and ergonomics focus on the mutual relationship between person and environments leads us to propose an ecological framework for ergonomics.

The starting point for analysis is a single individual (or "actor") interacting with his or her environment. Two conceptual building blocks form the core of this analysis: *affordances* and *perception–action cycles*.

The first component of the ecological framework is the concept of *affordance*. Affordances are attributes of the environment of an individual (or "actor") defined with respect to the action capabilities of that individual (Dainoff and Mark, 2001; Gibson, 1979). Insofar as the fundamental definition of ergonomics can be construed in terms of the fit between individual and environment (Dainoff and Dainoff, 1986; see above), the concept of affordance, as developed within the theoretical framework of ecological psychology, provides a systematic approach to understanding and critical analysis of person–environment complementarity. Thus, components of an ergonomic chair are affordances for alternating between different seated work postures, but only for a particular set of users. The chair is not usable as designed for a two-year-old child who is too small, an extremely obese adult who is too large, or a person with muscle impairment who is unable to adjust the controls. The chair is not functionally usable by the person who does fall in the above categories but does not understand either how to adjust the controls or why such adjustments might be useful.

The concept of affordance is particularly relevant to ergonomic aspects of design, since it requires the designer to explicitly take into account how physical objects relate to the action capabilities of users. Action capabilities, in turn, are determined by certain classes of *constraints*: personal, environmental, and task (Newell, 1996). Personal constraints refer to individual variability, including body dimensions (anthropometry), biodynamics (body strength, mass, flexibility), and relevant psychological factors (perceptual, cognitive, motivational). Environmental constraints include both size and shape of objects and surfaces as well as their physical properties relevant to the action.

The second component of the ecological framework for ergonomics is the *perception–action cycle*. Any integrated behavior pattern (task) can be decomposed into a series of steps in which perceived information about the possibility of action is followed by the action itself, which, in turn, reveals new information about potential actions, and so on. For example, information is extracted from the home page of a website indicating the presence of a clickable button. Hand and finger muscles move the mouse to the location of the button and click. The effect of the click is to act on the environment—a new Web page appears. The new page has additional information, some of which is extracted (perceived) and the cycle continues. (See Figure 1.)

Perception–action cycles are defined by certain classes of constraints, which can be classified into four groups. Task constraints reflect the functional requirements of a task. This includes individual task demands. A second class of constraints consists of surrounding social and organizational factors. Workspace constraints reflect the layout of components within the workspace (e.g., display, input/out device, furniture) as well as relevant environmental constraints (lighting, air quality, temperature and humidity, gravity). Individual constraints reflect both physical (anthropometric and physiological) and psychological (cognitive, motivational, emotional) attributes of the actor.

The action components of perception–action cycles take place within a three-dimensional postural envelope. Within the postural envelope, the operator must reach, lift, and manipulate, while parts of his or her body are or are not supported.

The perception–action cycle is the theoretical conception which links Gibson's concept of affordance with Bernstein's concept of skill as the coordination of multiple degrees of freedom. It is the information about affordances which, when perceived, initiates the perception–action cycle by revealing the capabilities for action within the environment. At the same time, the existence of multiple affordances within the system requires a degree of coordination through selection and timing of appropriate task-relevant actions associated with appropriate affordances. When this coordination can be achieved under changing environmental constraints, the user has achieved what Bernstein called "dexterity" (Bernstein, 1996). *Consequently, we argue that the perception–action cycle should be the fundamental unit of analysis of work systems and, therefore, a basic tool for ergonomics.*
**Figure 1**  Perception–action cycle defined by constraints.

### 1.4.1  Application of the Framework

The preceding conceptual framework can be used as a practical tool, a kind of lens with which the remaining information in this chapter may be viewed.

Let us consider in detail the example of a user seated at a fully adjustable computer workstation while writing an article for a book chapter. The adjustability of the height and angle of the seat, angle of the backrest, height and angle of the keyboard support, height and angle of the monitor, as well as the scalable font size of the word-processing program are all affordances which allow this particular person to achieve a comfortable working posture. Each of these affordances refer to physical properties of the workstation defined in terms of corresponding attributes (action capabilities) of the actor's anthropometry, motor control ability, and understanding of operation and coordination of the control mechanisms. These affordances are defined in explicit detail in Section 4. Thus, in a real sense, the products of design are affordances.

A critical point here, and one that is often misunderstood, is that the physical attributes described above are only considered affordances if they are perceived as such by the actor. That is, a chair may have a height adjustment lever, but if the actor does not know that it exists, knows that it exists but does not know its location, knows its location but not how it operates, or knows how it operates but does not have the physical capability to operate it, the chair *does not* have an affordance for height adjustability.

If, on the other hand, the actor is fully aware of the functionality of each of the components above, they become affordances enabling the individual to adapt to the complexity of the workstation in that he or she can achieve comfortable/efficient working posture. More precisely, this awareness can allow the execution of multiple nested perception–action cycles.

Consider the detailed task requirements involved in creating text in the process of composing a book chapter. This involves periods of rapid keyboard operation interspersed with periods of reflection and pondering. Therefore, one set of perception–action cycles involves the linkage between actions of the fingers on the keys and corresponding reading of the text on the screen. Here the fingers and eyes are playing a primary role whereas the remaining bodily structures (head, neck, arms, shoulders, trunk) are in a more passive supporting role. What we call efficient/comfortable working posture is a set of perception–action cycles which adjust the relative locations of these limbs into orientations which allow the primary keying–reading cycle to be easily performed. [*Note*: The term "comfort" here is a convenient label for a hypothetical underlying physiological principle of efficiency or least effort. (See, e.g., Nubar and Contini, 1961.) ]

In a well-designed office environment, efficient/comfortable posture is afforded by the adjustability mechanisms in that the seat and backrest can be adjusted so that the trunk can be inclined backward with the feet flat on the floor and the lower back supported. The keyboard support is adjusted so that the hands are flat and forearms parallel to the floor. The head is erect and the monitor is within a field of view 30° below the horizontal. The backward-inclined working posture places the eyes over 100 cm from the display screen, but this is compensated for by increasing the font size of the displayed characters. These criteria for comfortable posture are contained in many standards and guidelines [e.g., American National Standards Institute (ANSI)–HFES 100-2007: U.S National Standard for Human Factors Engineering of Computer Workstations (HFES, 2007)] and are reviewed later in Section 4.

It is useful to examine in the detail the perception–action cycle for just one of these adjustments—seat height. It is assumed that the actor is fully informed about the functionality of the particular chair he or she is using which has a height adjustment lever (HAL) below the seat surface on the right side. Table 1 depicts the four stages of the perception–action cycle required to operate this lever and raise the level of the seat to the desired height. This entails locating the lever, pulling it upward while at the same time elevating the buttocks, and allowing the seat surface to move upward to a desired height. In this case, both the HAL and seat surface can be considered affordances.

**Table 1 Perception–Action Cycle for Height Adjustment of Ergonomic Chair**

| Information | Perception | Activation | Action |
|---|---|---|---|
| Height adjustment lever (HAL) right side below seat | Tactile/visual pickup of HAL location | Arm extension plus grasp | Hand moves to HAL |
| HAL is in operating position (graspable) | Tactile pickup that HAL is graspable | Grasp and pull HAL: rotate thighs and buttocks upward | Seat surface moves upward to new position of buttocks |
| Elbow height lower than work surface | Tactile/visual pickup: seat height not yet correct | Continue | |

What is the desired height? In this case, the goal is to raise the trunk so that the elbows are approximately level with the keyboard. At the same time, the legs should be straight and feet flat on the floor. Depending on the individual anthropometry of the actor, this goal may not be achievable without additional perception–action cycles, such as adjusting the height of the keyboard support surface.

A completely different set of perception–action cycles is brought into play if the task requirements change. Assume that a section of the chapter has been finished and printed on paper copy. The actor's preference is to place the paper document on a copy holder adjacent to the display screen for further editing. Hence a new adaptation in working posture to these changed demands is necessary. Because the small font size on the paper document is no longer visible while the seat back is inclined rearward, the seat back must be adjusted to a more upright position.

In Bernstein's terms, a certain degree of dexterity (coordination of multiple degrees of freedom) is required to utilize the adaptive potential of a modern ergonomic office to achieve the desired goal of efficient/comfortable working posture for multiple task demands. These degrees of freedom are manifest as individual furniture adjustment mechanisms and major joints of the body. Depending on the particular equipment supplied, adjustment mechanisms can include seatpan angle, seatpan height, backrest angle, backrest height, backrest tension, work surface height, monitor height, and monitor angle. Major joints include wrist, elbow, shoulder, neck, thigh, knee, and ankle.

While the motor control mechanisms for coordinating postural degrees of freedom is the subject of considerable research activity within the ecological psychology community (see, e.g., Latash and Turvey, 1996), for the purposes of this chapter, it is sufficient to reiterate the point made earlier that the actor must understand both how to adjust the controls and why such adjustments might be useful. Simply put, user training must be an essential component of office ergonomics.

Therefore, to return to where we started, fit (Dainoff and Dainoff, 1986) is achieved when the appropriate constraints and affordances are available so as to allow adaptive perception–action cycles to move the actor into a three-dimensional postural envelope (comfort zone) within which task activities can be carried out with a minimum of physical effort (see, e.g., Newell, 1996).

## 2 EPIDEMIOLOGICAL EVIDENCE FOR CARPAL TUNNEL SYNDROME AND UPPER EXTREMITY MUSCULOSKELETAL DISORDERS AMONG COMPUTER USERS

### 2.1 Introduction

Musculoskeletal disorders of the neck and upper limb (UEMSDs) and carpal tunnel syndrome (CTS) have been linked to keyboard and visual display terminal (VDT) use since the beginning of the 1970s. Early reports on occupational cramps and muscle pain appeared in Australia (Ferguson, 1971) and Japan (Maeda, 1977) after use of electric keyboards or among accounting machine operators. Later, an apparent epidemic occurred in Australia in the mid-1980s, where so-called repetition strain injuries (RSIs) were frequently reported among computer users. The epidemic disappeared, and the background and causes of the epidemic have been discussed ever since. Historically, there have been similar examples of outbreaks of pain and cramps—for example, writer's cramp or telegraphers' cramp (Dembe, 1996)—often coinciding with the introduction of new technology into the society. Arguments on causes to explain the outbreaks have ranged from specific physical exposures at the workplace to cultural beliefs and societal expectations (Lucire, 2003). In Europe and the United States, the first concerns on health effects of VDTs were potential adverse effects on reproduction, which has been refuted by large epidemiological studies.

The majority of UEMSDs are characterized by recurrent episodes of pain and consequent disability, varying in severity and impact. Most of the episodes are self-limiting and subside within days or weeks, while

some end up with long-lasting chronic problems. Risk factors from physical, psychological, and social domains have been identified, but the relative contribution of the various risk factors to the onset and aggravation of UEMSDs is less known. As a result, controversies still exist regarding the degree of work-relatedness of UEMSDs (Silverstein et al., 1996).

The last decades, since the anecdotal stories in the 1970s and the early reviews, have been characterized by a steady increase in the number of published studies on computer work and UEMSDs, The studies generally fall into one of two categories: either experimental studies trying to identify a possible pathophysiology of computer-related disorders or intervention studies and epidemiological studies focusing on the association between workplace risk factors and musculoskeletal outcomes.

The pathophysiological studies have produced a large number of hypothetical injury mechanisms ranging from a systematic overload of low-threshold motor units (the "Cinderella" hypothesis) to intracellular $Ca^{2+}$ accumulation, impaired blood flow, reperfusion injury, blood vessel nociceptor interaction, myofascial force transmission, intramuscular shear forces, trigger points, and aggravated heat shock response. There is a certain degree of overlap between the hypotheses, but in spite of intensive research the empirical data to support a unifying hypothesis or identify a specific injury mechanism has been limited. It is assumed that pain results from muscle tissue damage due to prolonged low-force muscle activity with few breaks and little variation. However, muscle activity measured by electromyography seems to be slightly higher during rest breaks and noncomputer office work than during computer work. In a study by Richter et al. (2009), the division between computer activity and noncomputer activity was based on electronic activity registration with different cut-offs. These observations may be seen as support for few, if any, biologically plausible effects of mouse work on UEMSDs.

The pathophysiological or mechanistic studies are not included in this chapter. Instead, the scope is to summarize the knowledge and synthesize the evidence gained from the large number of risk factor studies, including prospective studies, which have been published since 2000. Although several systematic reviews on computer work and UEMSDs and CTS have been published in recent years in an attempt to provide this kind of information, the conclusions in the reviews are often in discord and the heterogeneity has created a situation of confusion rather than of clarity.

## 2.2 Carpal Tunnel Syndrome

Carpal tunnel syndrome is a compression neuropathy of the median nerve as it passes through the carpal tunnel. It is regarded as the most frequent compression neuropathy. Based on both clinical symptoms and nerve conduction tests (NCTs), overall prevalences of 3.0–5.8% among women and 0.6–2.1% among men have been found in general population samples (Atroshi et al., 1999). CTS is generally believed to be caused by increased pressure in the carpal tunnel. It is widely accepted that exposure to hand–arm vibrations and exposure to a combination of repetitive hand use and hand force may be causally related to CTS. In recent years, with the expanding use of computers, it has been a matter of concern if computer use could be a risk factor for the development of CTS. Three recent reviews of high quality concluded that there is insufficient epidemiological evidence that computer work causes CTS (Palmer et al., 2007; Thomsen et al., 2008; Van Rijn et al., 2009). Table 2 summarizes the aims and main conclusions from the three reviews.

## 2.3 Upper Extremity Musculoskeletal Disorders

Upper extremity musculoskeletal disorders cover a wide range of complaints from the neck, shoulder, elbow, forearm, and wrist/hand. Umbrella terms such as repetition strain injuries (RSIs), occupational cervicobrachial disorders (OCDs), and cumulative trauma disorders (CTDs) have often been used in the literature, but terms like these assume that the proposed mechanisms or exposure must be avoided. It is fairly consistent from the literature that distal arm pain and, to a lesser extent, neck–shoulder pain are associated with intensive use of the keyboard and the mouse, and the conclusions from several reviews (Gerr et al., 2004, 2006; Griffiths et al., 2007; IJmker et al., 2007; Village et al., 2005; Waersted et al., 2010; Wahlström, 2005) are shown in Table 2. The reviews are based on a total of 80 original studies.

The association is much more uncertain when it comes to computer use and more prolonged or chronic pain and clinical entities such as shoulder tendonitis, lateral and medial epicondylitis, forearm disorders, or wrist tendonitis. Researchers recently performed a critical review of the epidemiological evidence for a possible causal relationship between different aspects of computer work, including keyboard and mouse use, and neck and upper extremity musculoskeletal disorders diagnosed with a physical examination (Wahlström, 2005). As can be seen in Table 2, they found limited epidemiological evidence for an association between aspects of computer work and the clinical diagnoses. There is a tendency for recent reviews to be more critical than earlier reviews, even though newer and prospective studies have been included in the reviews. In epidemiological studies it is usually found that more and better studies provide stronger evidence for a causal relation if such exists in the real world. The current level of findings is in contradiction with a causal relation between aspects of computer use and clinical verified UEMSDs. Nevertheless, this should be carefully interpreted. With the very widespread use of computers in professional work life and in leisure activities, even a small increase in risk could have profound importance and, based on our current knowledge, we cannot discount such small risks. Over the last 25 years we have witnessed some big changes in the office environment. The physical work environment has changed and, maybe of more importance, the psychosocial and work organizational circumstances have changed toward increase in office worker flexibility, more precarious work, and incessant organizational changes. Loss of worker autonomy, lack of predictability and meaning, and appreciation by supervisors or peers are probably of more importance in today's office work than biomechanical loads.

**Table 2  Aims and Main Conclusions from Reviews on Risk Factors for CTS and UEMSDs among Computer Users**

| | **Carpal Tunnel Syndrome** |
|---|---|
| Palmer et al., 2007 | *Aim*: To assess occupational risk factors for CTS<br>*Conclusion*: The balance of evidence on keyboard and computer work does not indicate an important association with CTS. |
| Thomsen et al., 2008 | *Aim*: To examine evidence for an association between computer work and CTS<br>*Conclusion*: There is insufficient epidemiological evidence that computer work causes CTS. |
| Van Rijn et al., 2009 | *Aim*: A quantitative assessment of exposure–response relationships between work-related physical and psychosocial factors and the occurrence of CTS in occupational populations<br>*Conclusion*: The contradictory findings for computer use and the development of CTS are in agreement with the conclusion of a recent review (Thomsen et al., 2008). |
| | **Upper Extremity Musculoskeletal Disorders** |
| Gerr et al., 2004 | *Aim*: The epidemiological evidence examining associations between UEMSDs and computer use posture and keyboard use intensity (hours of computer use per day or per week).<br>*Conclusion*: Daily or weekly hours of computer use is more consistently associated with hand and arm MSDs than with neck and shoulder MSDs. |
| Wahlström, 2005 | *Aim*: To give a summary of the knowledge regarding ergonomics, musculoskeletal disorders, and computer work and to present a model that could be used in future research.<br>*Conclusion*: None. It is hypothesized that perceived muscular tension is an early sign of musculoskeletal disorder, which arises as a result of work organizational and psychosocial factors as well as from physical load and individual factors. |
| Village et al., 2005 | *Aim*: To evaluate the evidence supporting a causal relationship between computer work and musculoskeletal symptoms and disorders (MSDs) of the hand, wrist, forearm, and elbow.<br>*Conclusion*: There is consistent evidence of a positive relationship across numerous prospective and cross-sectional studies with increased risk most pronounced beyond 20 h/week of computer use or with increasing years of computer work. The disorders confirmed with physical examinations are wrist tendonitis and tenosynovitis, medial and lateral epicondylitis, and DeQuervain's tenosynovitis. The risk of carpal tunnel syndrome is increased with a use of a computer, especially with mouse use for more than 20 h/week. |
| Gerr et al., 2006 | *Aim*: To explore the epidemiological evidence of associations between upper extremity musculoskeletal symptoms and disorders and keyboard use intensity (hours of computer use per day or per week) and computer use postures<br>*Conclusion*: A somewhat consistent finding is an observed association between hours of computer use and adverse hand/arm MSD outcomes and, to a slightly lesser extent, between hours of computer use and adverse neck/shoulder outcomes.<br>The conclusion also points to severe methodological limitations in the literature. |
| Griffiths et al., 2007 | *Aim*: To draw attention to the potential risks to musculoskeletal health with the computerization of work among professional occupational groups.<br>*Conclusion*: The risk factors for work-related musculoskeletal symptoms with computer work have been extensively researched and are generally well established. |
| IJmker et al., 2007 | *Aim*: To get a more conclusive insight into the relationship between the duration of computer use and the incidence of hand–arm and neck–shoulder symptoms and disorders, a systematic review of longitudinal studies was performed.<br>*Conclusion*: This review showed moderate evidence for an association between the duration of mouse use and the incidence of hand–arm symptoms. Indications for a dose–response were found. In addition, the neck–shoulder region seemed less susceptible to exposure to computer use than the hand–arm region. |
| Waersted et al., 2010 | *Aim*: To examine the evidence between computer work and neck and upper extremity disorders (except carpal tunnel syndrome).<br>*Conclusion*: There is limited epidemiological evidence for an association between aspects of computer work and some of the clinical diagnoses. None of the evidence was considered as moderate or strong and there is a need for more and better documentation. |

## 3   ERGONOMICS PROGRAMS FOR OFFICE ENVIRONMENTS

Ergonomics is the design of jobs to match the capabilities and limitations of workers. Jobs designed ergonomically result in higher productivity and quality and improved workplace safety. To achieve such outcomes in ergonomics requires a managed health and safety process that targets the design of tasks, workstations, tools, equipment, and organizations to reduce risk factors that can contribute to injury and disability. Many believe the most effective ergonomics program in an office environment is one that properly fits an employee at their computer workstation with the chair, keyboard and mouse, monitor, or display at the correct height with proper seated posture. In reality, proper workstation adjustment is but a small component of an office ergonomics process.

The following guidelines, comprising Section 3 of this chapter, are adapted from the 2002 final draft of ASC Z365 Management of Work-Related Musculoskeletal Disorders (Accredited Standards Committee, 2002) and describe the elements of an ergonomics program and process for managing work-related musculoskeletal disorders (WMSDs) to reduce frequency and disability.

An ergonomics program for WMSDs has the following components:

- Employer responsibilities
- Training
- Employee involvement
- Injury and hazard surveillance
- Evaluation and management of WMSD cases
- Job analysis
- Job design and intervention

### 3.1   Employer Responsibilities

Effective implementation of a managed ergonomics process will require establishing priorities for prevention and control activities. The choice of priorities will depend on the progress made in addressing workplace factors and on the extent of problems already present in the workplace. Some will focus first on management of diagnosed WMSD cases and evaluation and intervention of the corresponding jobs. Others, in worksites with few or no WMSD cases or high employee turnover, may move straight to implementing proactive job surveys (e.g., employee interviews, checklists) so that potential problems associated with particular jobs can be identified and addressed before new WMSD cases appear.

The level and breadth of training and employee involvement may directly depend on how the program is initiated and progresses over time. As Figure 2 shows, there are three surveillance outcomes that could lead to job analysis. An employer may focus first on the employee reports and, in doing so, provide the appropriate training and employee involvement to accomplish this goal. As one moves to surveillance using existing records and job surveys, participants may change and so may the

corresponding level and breadth of training and employee involvement.

### 3.2   Training

Periodic training is necessary so that employees and managers can facilitate surveillance, job analysis, job design, and medical management. Be sure to provide training to appropriate management representatives and employees. Training may include:

- Recognition and reporting of the signs and symptoms of WMSDs that may be work related
- Record-keeping processes for reporting WMSDs
- Whom to contact for further assistance
- Roles and responsibilities in the surveillance procedures
- Recognition and management of WMSD risk factors
- Job analysis and design procedures
- Proper use, adjustment, and maintenance of tools, work equipment, and work stations
- Job interventions and best-work procedures and practices for minimizing risk of WMSDs

### 3.3   Employee Involvement

Give employees the opportunity to participate in the program for management of WMSDs. The following are examples of employee involvement:

- Submitting suggestions or concerns
- Participating in discussions related to their workplace and work methods
- Participating in employee surveys
- Participating in formal team meetings
- Using and operating tools and work equipment in the prescribed manner
- Participating in the design of work, equipment, and procedures
- Participating in the employer's WMSD problem-solving process
- Participating in WMSD education and training
- Notifying the employer of related WMSD symptoms and risk factors early

### 3.4   Injury and Hazard Surveillance

The results of surveillance are used to determine when and where job analysis is needed and where ergonomic interventions may be warranted. Each organization may want to establish criteria for when a job survey result or health surveillance data indicate the need for a job analysis. This information may be further used to assist in establishing job analysis and intervention priorities and assessing the program. Surveillance includes:

1. Initial review of existing records of work-related illnesses and injuries [e.g., Occupational Safety and Health Administration (OSHA) log and workers' compensation records] and at the start of surveillance, periodically thereafter. This

Program management

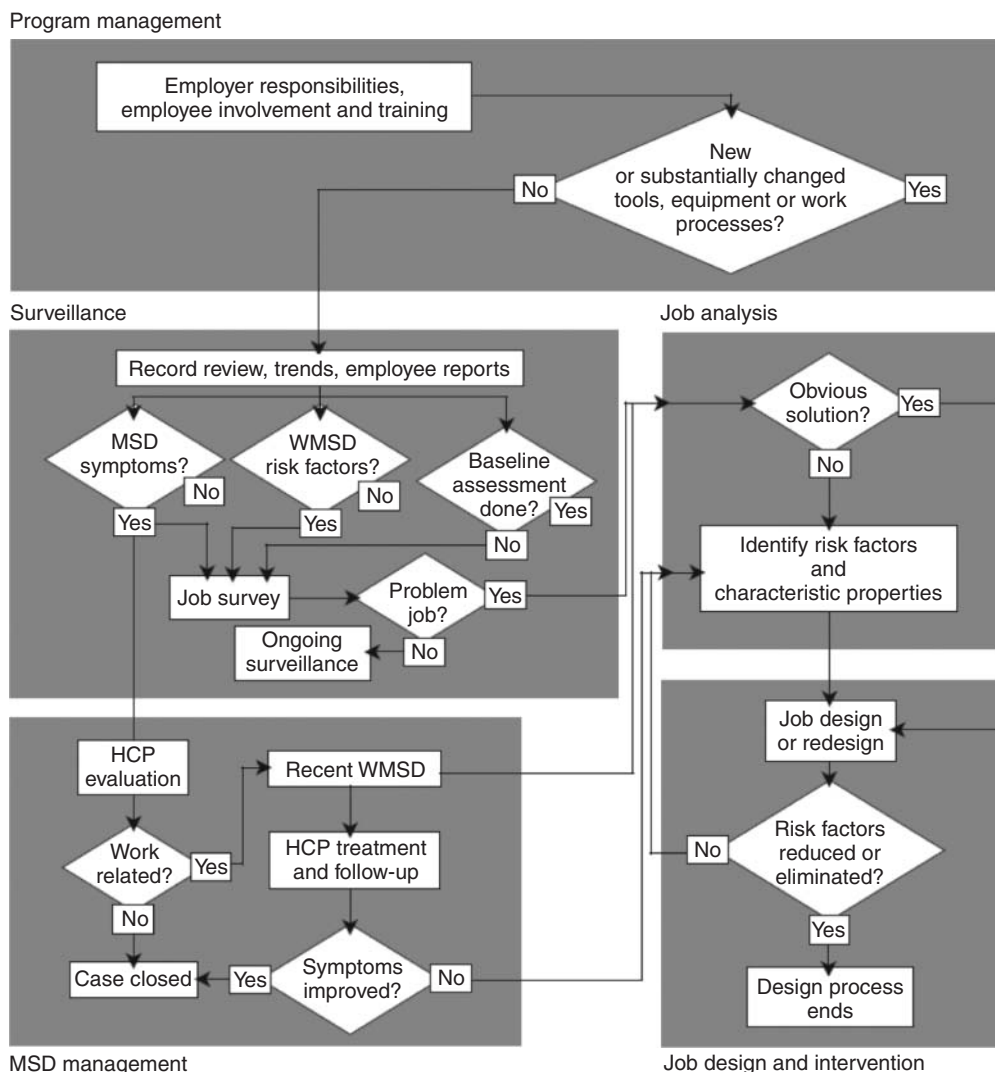

**Figure 2** Program for management of WMSD flowchart illustrating program elements. (Adapted from the 2002 final draft of ASC Z365 2002; Accredited Standards Committee, 2002.)

analysis will help determine where WMSDs are occurring and will help prioritize jobs needing further analysis.

2. Employee reports—There are two kinds of employee reports:
   a. Employee reports of WMSD symptoms
   b. Reports of employee concerns about WMSD risk factors
3. Job surveys—The aim of job surveys is to identify specific jobs and processes that may put employees at risk of developing WMSDs. Job surveys are considered a cursory or preliminary review of jobs, as compared to a more detailed

job analyses. Job surveys may include any of the following methods:
   a. Office walkthroughs
   b. Employee and supervisor interviews/questionnaires
   c. Computer workstation design assessment checklists
   d. Team problem-solving approaches

Job surveys can be incorporated into existing programs such as regular safety, health, team problem solving, or quality inspections and can expand their scope to include identification of WMSD risk factors. Results of job surveys may be applied to similar jobs within one or more departments or locations:

*Perform job surveys when*:

- New WMSD cases are reported, to help determine if risk factors exist across similar jobs that use similar tasks, equipment, tools, or processes. This might include a sampling of representative jobs.
- Employees report new MSD symptoms.
- Employees report WMSD risk factors.
- There is an unexplained high rate of turnover or absenteeism for a specific job. There may be many reasons for turnover or absenteeism not related to WMSDs.
- Surveillance activities are begun as a baseline assessment of job risk factors.
- A job, equipment, or process substantially changes to identify risk factors that may result from making these changes.
- New equipment or furniture or work processes are planned, purchased, or installed.

### 3.5 Evaluation and Management of WMSD Cases

Early assessment or establishing a diagnosis and initiating treatment may limit the severity, improve the effectiveness of the treatment, and allow for sufficient and timely recovery of the condition. Early identification of WMSDs can alert the employer to the need for job analysis of that employee's job or the need for further analysis if the job has already been evaluated.

***It is recommended that employers:***

- Examine existing policies, practices, and programs to ensure that they encourage prompt reporting of MSD symptoms or potential WMSD risk factors without reprisals.
- Once notified of recurrent or persistent MSD symptoms, facilitate a prompt evaluation of the symptomatic employee by an appropriate health care provider (HCP) consistent with state laws.
- Provide the HCP with a contact who is familiar with the job tasks.
- Provide HCPs the opportunity to become familiar with jobs and job tasks (e.g., site walkthroughs, review of job surveys, analysis reports, detailed job descriptions, job safety analyses, photographs, or videotapes).
- Ensure employee privacy and confidentiality regarding medical conditions identified during the assessment, as permitted by law.

***In addition, employers should:***

- Select or recommend HCPs with knowledge, experience, and training in workplace exposures and the evaluation and treatment of WMSDs.
- Whenever feasible, modify jobs, redesign the job, and/or accommodate employees with work restrictions as determined by a HCP.

*Note*: Refer to the Americans with Disabilities Act for guidance relevant to employees with disabilities.

***The HCP should:***

- Evaluate the symptomatic employee.
- Seek information and review materials regarding employee job activities.
- Be familiar with the management of WMSD cases or refer the employee to a HCP who is familiar with such management.

***Components of the HCP evaluation include:***

- A medical history (occupational and nonoccupational) which includes a complete description of symptoms.
- A description of work activities as reported by the employee and the employer.
- A review of exposure information relevant to the clinical findings.
- A physical examination appropriate to the presenting symptoms and history.
- An initial assessment or diagnosis and an appropriate treatment plan.
- Work restrictions or work modifications if appropriate.
- An opinion on the work-relatedness of the disorder based on professional guidelines [e.g., *A Guide to the Work-Relatedness of Disease* (Kusnetz and Hutchinson, 1979)].

***Employees with WMSDs should:***

- Provide input to and follow the treatment plan recommended by the HCP, including work restrictions.

The HCP should follow up with symptomatic employees to document symptom improvement or resolution or reevaluate the employee who may not have improved. The time frame for this follow-up depends on the type, duration, and severity of the employee symptoms. If symptoms do not improve within the expected time frame, the employee should be referred to an appropriate medical specialist and/or the job should be analyzed again.

When the employer has determined, based on the medical evaluation and exposure information (job description, walk through, etc.), that an employee has a WMSD, he or she should perform a job analysis of the employee's job or a sample of representative jobs and include input from the symptomatic employee.

### 3.6 Job Analysis

Job analyses are more detailed studies of the work than job surveys. Job analyses identify potential exposures to work-related risk factors and evaluate their characteristic properties.

***Perform job analyses:***

- When it is suspected that an MSD is work related.
- When a problem job is identified from a records review, a trend of WMSDs, or job surveys.

- When a problem persists after changes have been implemented.
- During the design or acquisition phase of equipment, processes, or jobs.

Work-related risk factors are present at varying levels for different jobs and tasks. The mere presence of a risk factor does not necessarily mean that an employee performing a job is at undue risk of injury. Generally, the greater the exposure is to a single risk factor or combination of risk factors, the greater the probability of a WMSD. For example, the risk associated with the first three risk factors may be increased in the presence of cold temperature (see Bernard, 1997; National Research Council & Institute of Medicine, 2001).

### Consider the following work-related risk factors in job analysis:

- Force and contact stress. Can include tasks other than keyboarding work as well, including gripping heavy file folders and heavy manual materials handling work
- Posture and motions
- Vibration
- Cold temperature

### Evaluate WMSD risk factors for the following exposure properties of the physical stresses listed above by qualitative or quantitative approaches:

- Magnitude
- Repetition
- Duration
- Recovery

Also consider work organization factors that can alter the characteristic properties or effects of physical stress exposure.

Work-related risk factors may pose minimal risk of injury if sufficient exposure is not present or if sufficient recovery time is provided. However, if there is sufficient exposure and insufficient recovery time, there will be a risk of injury. Reducing exposure to risk factors will result in reduced probability or severity of WMSDs. When work-related risk factors and their corresponding exposure properties are identified and prioritized from a job survey or analysis, job design or redesign, including feasible engineering or administrative changes, can eliminate or reduce exposure to work-related risk factors. The decision regarding which specific risk factor to reduce in job design or redesign is based on the scientific evidence, professional judgment, technical feasibility, and input from employees and management.

### 3.7 Job Design and Intervention

#### The job design and intervention process ends when:

1. exposures to work-related risk factors are reduced or eliminated as much as practical or surveillance indicates that the problem is under control or
2. appropriate exposure limits have been identified and met.

## 4 OFFICE FURNITURE DESIGN

Visual display terminals have been a subject of some concern as their use in business and industry has become almost universal. VDT technology improves productivity and simplifies work, but it also has the potential to cause problems when poor workplace design is coupled with high keying rates. Most of the reported problems have involved dedicated or full-time operators who use their VDTs for 4 or more hours a day.

Complaints have included back, neck, and wrist pains, eye strain, headaches, and stress. These symptoms are often associated with the fatigue and discomfort that can result from poor installation of VDT equipment. Applying ergonomic principles to the design of VDT workstations can alleviate many of these problems.

A well-designed VDT workstation will allow the operator to sit with good posture, see the screen clearly, and reach the keyboard and document easily. Operator comfort and sufficient room to work are key factors in improving productivity and reducing complaints. The best workstation designs allow independent height adjustment of the screen, keyboard, and chair. Many manufacturers now offer workstations and furniture designed specifically to meet the ergonomic needs of VDT users.

The diagrams and guidelines on the following pages give ergonomic considerations for selecting, installing, and adjusting VDTs and VDT workstations.

### 4.1 Seating and Viewing Considerations

The preferred chair type is a swivel chair on a five-point base, with a rounded front edge on the seat, easily height adjustable by the operator. Position the monitor so that the gaze angle to the center of the screen ranges between $15°$ and $20°$ below horizontal eye level. Always take into account the vision requirements of VDT operators who wear glasses or bifocals. The following considerations are adapted from ANSI/HFES 100 and BIFMA G1-2002 (BIFMA, 2002; HFES, 2007):

*Seat Height*. Seat height should be adjustable by the user within the recommended range of 15–22 in. (38–56 cm). If the operator is too short to keep both feet flat on floor in the suggested height range, provide a foot rest.

*Seat Depth*. Adequate seat depth supports the thighs and allows the user to sit back far enough to use the lower portion of backrest without creating pressure on back of the knees. If nonadjustable, seat depth should be no greater than 17 in. (43 cm). If adjustable, seat pan adjustment range should include 17 in. (43 cm) or less.

*Seat Pan Angle*. Seats may be designed with a fixed or adjustable seat angle (e.g., recline backward or forward from horizontal). If fixed, seats should be within the range from $0°$ (horizontal) to $4°$ rearward. If adjustable, seats should include some part of the range from $0°$ to $4°$ rearward.

*Backrest Height*. The backrest provides support for the back in various postures. The top of the

backrest should be at least 18 in. (45 cm) above the compressed seat height.

*Lumbar Support*. This helps maintain the natural curvature of the spine at the small of the back. The lumbar support area of the backrest should be located between 6 and 10 in. (15 and 25 cm) above the compressed seat height.

*Seat Pan–Backrest Angle*. Studies have shown that a recline angle of 30° from vertical reduces fatigue. The torso-to-thigh angle should be at least 90°. If adjustable, the backrest should recline at least 115° from vertical.

*Armrest Height*. Proper armrest height supports the neck and shoulders. Armrests should be adjustable from 7 to 11 in. (18–27 cm) above compressed seat height. All armrests should be detachable.

*Eye-to-Screen Distance*. Preferably at least 20 in. (51 cm); minimum 12 in. (30 cm).

*Angle between Upper Arm and Forearm*. Elbow angle between 70° and 135° is recommended.

*Work Surface Height*. Should accommodate the user population. Minimum range of adjustability should be 28 inches (56 cm to 72 cm) from floor.

### 4.1.1 Seated Postures

It is expected that VDT users will frequently change working postures to maintain comfort and productivity. Four reference postures (see Figure 3) are recognized and commonly observed at computer workstations. Movement within these postures is encouraged.

These working postures are acceptable as long as the workstation has been properly adjusted to the employee. Standing posture can occur when working at standing workstations or when getting out of a chair to do other work, for example, retrieving items from a printer.

### 4.2 Work Surface and Seated Clearance Considerations

The keyboard should be thin and detached from the console, and the mouse or track ball should be at the same level as the keyboard. Clearance guidelines are designed to accommodate upright, reclined, and declined sitting postures. The items that follow are adapted from ANSI/HFES 100 and BIFMA G1-2002 (BIFMA, 2002; HFES, 2007):

*Work Surface Width*. At least 27.5 in. (70 cm) wide.

*Palm Rest Depth*. Minimum 1.5 in. (3.8 cm).

*Input Device Support Surface*. For sitting postures, adjust in height per work surface height recommendations.

*Thigh Clearance (Height)*. If not adjustable, no less than 27 in. (68 cm) at front edge of work surface and 25 in. (64 cm) at 17 in. (43 cm) rearward from front edge of work surface. If adjustable, it should include a height clearance of 27 in. (68 cm) as part of the adjustment range.

*Thigh Clearance (Width)*. No less than 20 in. (50 cm).

*Knee and Feet Clearance (Depth)*. At knee level, no less than 17 in. (44 cm) deep and no less than 23.5 in. (60 cm) deep at foot level. Work surface depth should allow for knee and feet clearances and a viewing distance to monitor of at least 19.7 in. (50 cm).

### 4.2.1 Chair Selection Tips

- Chair adjustment controls should be easily operable from a seated position.
- The chair and adjustment mechanisms should be rugged.
- Supply chairs with both detachable and adjustable armrests. Remove them if they interfere with the task.
- Seat should be padded for comfort.
- Several chair styles should be available to accommodate different sizes and preferences of users. Seat pan adjustment is often an optional accessory so beware that one size chair may not fit all.
- Back-tilt tension should be adjustable.
- The chair should permit alterations in posture and freedom of movement.

Reclined sitting  Upright sitting  Declined sitting  Standing

(105–120°)  (between 90 and 105°)  (>90°)
**Figure 3** Reference working postures. (Based on, and adapted from ANSI/HFES 100-2007; HFES, 2007.)

- The backrest should be contoured to conform with the curve of the lower spine.
- Chair fabric should allow ventilation.
- Be sure that repair service is readily available.

### 4.2.2  Minimizing Glare

- Position screen at right angles to windows.
- Adjust the tilt and swivel of the monitor.
- Reduce bright outside light by means of curtains, drapes, or blinds.
- Adjust lighting levels to the range of 200–500 lux (20–50 foot candles).
- Use parabolic diffuser grids or indirect lighting to help reduce overhead lighting glare.
- Provide work surfaces with an antiglare (matte) finish.
- Moveable task lights are often helpful.
- Screen filters and/or hoods can also be used if necessary.

### 4.2.3  Additional VDT Considerations

- *VDT Stands*. Height adjustability is preferred. Liquid crystal displays (LCDs) take up much less room and are much lighter than cathode ray tube (CRT) monitors.
- *Color Displays/Monitors*. Select a light highlight color that contrasts with the characters.
- *Black-and-White Monitor*. Rare these days, but select a light background and dark characters.
- *Flicker*. Screen should be readable with no perceptible flicker (rate at which images are "refreshed" on a screen from scanning of the electron gun). Not an issue with LCD flat-panel displays.
- *Printers*. Acoustical enclosures are recommended if sound levels exceed 55 dBA.
- *Ventilation*. Additional ventilation or air conditioning may be needed to overcome heat generated by many VDT workstations in a room. LCD flat-panel displays are much more energy efficient than CRTs.
- *Cables and Cords*. Should be concealed, covered, or out of the way.
- *Training*. Train all operators how to adjust chair, workstation height, and VDT position.

Computers in the workplace include desktop units on workstation furniture in office and work-at-home environments and laptop or notebook computers used virtually anywhere. Either way, discomfort associated with computer use can be traced to improper workstation adjustment and use. Surveys have shown that people who operate computers and VDTs are more comfortable and experience less discomfort when their workstations are adjusted properly. The importance of getting a good ergonomic match between the operator and the work is clear. But how do you create that match?

## 5  GETTING A GOOD ERGONOMIC MATCH BETWEEN OPERATOR AND WORKSPACE

### 5.1  Talk to Your Employees

An investment in office furniture with the latest ergonomic features can be wasted unless operators are taught to adjust their workstations correctly and unless management follows through to see that the adjustments are made. Keyboard work is demanding. Let your employees know that you are concerned with their comfort and you want to minimize the physical stress of working with the computer. Figure 4 shows the factors that you need to consider to ensure operator comfort.

### 5.2  Making Height Adjustments

Two methods are common for performing computer workstation assessments. They include observational techniques that estimate correct height through knowledge of "neutral" posture and direct measurement techniques.

### 5.3  Direct Measurement Techniques

Measure each operator individually to determine the appropriate height adjustments for their workstations. Seat the operator on a table or desk as shown in Figure 4, so that the edge of the tabletop just touches the back of the knees.

### 5.4  Operator Measurements (Dainoff and Dainoff, 1986)

*A = Knee Height*

Measure from the crease behind the knee to the bottom of the heel. Make sure the person is wearing the type of shoes normally worn on the job.

*B = Elbow Height*

Measure from a fixed surface, that is, tabletop, to the tip of the elbow. The person should be relaxed but sitting up straight. This measurement is easier if the person holds the upper arm against the body and reaches the hand toward the neck.

**Figure 4**  Operator measurements.

$C = Eye\ Height$

Measure from a fixed surface, that is, tabletop, to the eyes. Again, the person should be relaxed but sitting up straight.

### 5.5 Adjust the Chair Height

Once you have measured knee height ($A$), elbow height ($B$), and eye height ($C$), set the height of the chair front at knee height ($A$) initially. The seat pan may drop an inch or two when the operator sits down. If this is the case, raise the seat pan to offset the height change.

It is important the employee be trained on every chair adjustment feature. Some adjustment features are optional, for example, the seat pan adjustment.

Manufacturers may offer different size chairs, for example, small, medium, and large chairs to allow for longer legs. Make sure the employee has been fitted with the right chair.

If the seat is too high and cannot be lowered to the appropriate level, get a footrest and adjust the seat so that the vertical distance between the footrest and the front edge of the seat is equal to knee height ($A$).

If the seat pan has a tilt mechanism, the operator should tilt the seat to the most comfortable angle for work. In jobs that require a lot of data entry, such as word processing, some operators prefer a forward-tilted seat. For less-intensive keyboard work, many operators prefer a backward-tilted seat. Tilting the seat pan usually changes the height of the seat; readjust the front edge of the chair to knee height ($A$).

### 5.6 Position the Keyboard and Mouse

The center (or home) row of the keyboard should be adjusted to a height equal to knee height plus elbow height ($A + B$) above the floor, as shown in the lower portion of Figure 5. If a footrest is necessary, its height should also be added. The intent is to place the center row level with the tip of the elbow, thus keeping the forearms in a horizontal position.

If the keyboard height is not adjustable, raise or lower the chair height so that the difference in height between the chair seat and the keyboard is equal to elbow height ($B$). Provide footrests if needed.
If the keyboard is thin (1–1.5 in.), place it about 2 in. back from the edge of the table. If the operator is using a thicker keyboard, provide a padded palm rest.

The mouse or input device should be at the same level as the keyboard. If using a keyboard tray, the tray should be wide enough to accommodate the mouse.

### 5.7 Position the Monitor

There are a variety of visual displays used in offices and they include CRT monitors and flat-panel LCD monitors. Configuration can be a single monitor or dual monitor set-up.

- Raise or lower the display so that the top of the screen is level with or slightly below the eyes, about equal to knee height plus eye height ($A + C$). If the operator wears bifocals or trifocals, a lower position may be more comfortable.

- Position the display at least 20 in. away from the operator's eyes or at arms length.

- For tasks in which the operator must read documents in addition to looking at the screen, move the visual display right or left of center to make room for a document holder (see Figure 5).

- Darken the screen while the operator checks for light reflectance or glare. Tilt the screen to eliminate as much glare or reflectance as possible. If the screen is right or left of center, moving it to the other side may help reduce glare.

### 5.8 Dual-Monitor Guidelines

- Both monitors should be matched in size and quality (luminance and contrast). If not matched in size, center viewing angle for documents on both screens should be the same.

- Flat-panel displays should not be paired with CRT monitors if possible.

- Both monitors should be placed at the same height and viewing distance. Viewing distance to each monitor should be a minimum of 20 in. or arms length away.

- Place both monitors as close to each other as possible.

- Provide adjustable monitor stands that are secure and allow for adjusting vertical height, screen tilt, and screen angle.

- Set up one monitor as the primary and the other as the auxiliary screen. Place the computer screen that is used more frequently closer to the center viewing angle and the auxiliary monitor to the side, left or right, and slightly angled toward the employee.

### 5.9 Laptop Computers

Laptop computers are no longer just for people who spend a large portion of their time away from a traditional office. Workers who rarely leave their office are using them too. Unfortunately this has led to complaints of back, neck, and wrist pain because the

**Figure 5** Desired workstation heights.

laptop is designed for portability, not ergonomics. With the keyboard and screen attached as one unit, the user must decide between a comfortable head and neck position or a comfortable wrist and arm position.

When discussing the use of laptop computers, there are two situations to consider:

1. An operator in an office environment with a docking station, external monitor, keyboard, and mouse
2. A mobile worker who uses laptops in airports, hotels, or offices without any external devices.

Operators in an office environment with an external device should follow the same height adjustment guidelines mentioned above. Mobile worker solutions are more challenging.

### 5.10 Positioning the Laptop

Positioning a laptop can be a challenge as placing the laptop low (in your lap or on a desk) for comfortable arm position means that you have to tilt your neck forward to view the screen; raising the screen to an acceptable level means that your hands are now reaching too high.

Some prefer placing the laptop on the work surface directly in front of the operator with the back elevated slightly to raise the display height. This can be accomplished inexpensively using specially designed laptop stands or three-ring binders with the binder at the back of the laptop. This also angles the keyboard, which may or may not be desirable. Tilting the screen too far may increase glare from overhead lights. Screen distance would follow the same guidelines as above.

Other operators prefer raising the entire laptop using a monitor stand or other means so the screen is at eye level and using an external keyboard and mouse. Inexpensive and portable monitor stands and external keyboards are readily available from mobile worker ergonomic accessory vendors and websites.

### 5.11 Other Considerations

Instruct the operator to:

Use a light touch when keying or using the mouse.

Use the index and middle fingers instead of the thumb to move the cursor via the touch screen. Move the hand toward the touch screen to eliminate stretching the fingers and alternate between hands.

Take short breaks every 20–30 min.

Use a bag with wheels when transporting the laptop. If the operator must carry the laptop, use a bag with a wide shoulder strap and alternate between shoulders.

Minimize the weight by carrying only what is needed. Reduce the number of peripherals such as disc drives and CD-ROM drives.

## 6   EYE STRAIN AND FATIGUE

While CTS may be the most infamous and possibly the most costly of all WMSDs, it is NOT the most prevalent malady of those who spend most of the working day interfacing with a computer. That distinction goes to yet another acronym, CVS, or computer vision syndrome.

The American Optometric Association (AOA) defines CVS as that "complex of eye and vision problems related to near work which are experienced during or related to computer use" and one that is very common among VDT workers (AOA, 2010). The following studies illustrate the importance of vision and visual fatigue on performance and safety associated with computer work:

- Visual symptoms occur in 50–90% of VDT workers while a National Institute for Occupational Safety and Health (NIOSH) study showed that 22% of VDT workers suffer from the more traditional musculoskeletal disorders (NIOSH, 1981).
- A survey of optometrists indicated that 10 million primary eye care examinations are provided annually in this country because of visual problems at VDTs (Sheedy, 1992).
- A 2000 NIOSH study concluded the addition of supplemental breaks such as a 5-min break during each hour decreased musculoskeletal discomfort, eye strain, and mood and did not affect performance in data entry workers (Galinski et al., 2000). A follow-up study published in 2007 provided further evidence that supplementary breaks reliably minimize discomfort and eyestrain without impairing productivity (Galinski et al., 2007).

On the human side of the VDT, the visual symptoms of an unsound interface have been broadly classified as "asthenopia," which is Greek for "MY EYES HURT," or as defined by the *Dictionary of Optometry and Visual Science*, "a subjective complaint of uncomfortable, painful and irritable vision" (Millodot, 1997).

On the process side of the VDT the symptoms of an unsound visual interface are work mistakes and lost productivity. A study that examined the relationship between the vision of computer workers and their productivity was conducted by the School of Optometry at the University of Alabama in Birmingham (Daum et al., 2004) and found a direct correlation between vision correction and process speed and accuracy.

### 6.1   CVS: Symptoms, Causes, and Controls

#### 6.1.1   Eye Muscle Fatigue/Strain

The energy for all structural movement in the body is provided by muscles and the movement of the eye is no different. The two primary muscle groups that are impacted by near work like viewing a computer screen are the large extraocular muscles that provide for the multidirectional movement of the eyeball and the smaller ciliary muscles that are attached to the lens capsule of the eye and provide the force necessary to change the lens shape when we focus on an object. Much of the eye irritation attributable to near-viewing activities like computer work is associated with the fatiguing and straining of these muscle groups.

### 6.1.2 Extraocular Muscle Strain/Fatigue

To understand how the extraocular muscles become fatigueg and strained, we must review the concept of the "resting point of convergence," which is that distance at which the eyes no longer need to cross to view an object. For most people the resting point of convergence is ≈40 in.

As the object we are viewing moves closer than 40 in., the medial rectus muscles will contract and pull the eyeballs inward toward the nose. This movement is called convergence and allows the eyes to maintain the alignment of the object we are viewing on the same place in both retinas, thus preventing double images. The closer the object, the stronger the contraction of the muscle and the more the muscle strain. Extended near viewing requires a prolonged contraction of the medial rectus muscles and increases the risk of muscle fatigue.

### 6.1.3 Ciliary Muscle Strain/Fatigue and Blurred Vision

To understand how the ciliary muscles become fatigue and strained, we must discuss yet another resting point, the "resting point of accommodation," which is defined as that point where the eye focuses when there is nothing to focus on. The resting point of accommodation will vary slightly from person to person but is ≈31 in. for young people and will increase with age. At this distance, the ciliary muscles, which focus the lens, will not be contracted.

As the object we are trying to focus on moves closer than ≈31 in., the small ciliary muscles will begin to contract to flex the lens into focus. The closer the focal point, the stronger the contraction of these muscles and the more opportunity for muscle strain. The risk of ciliary muscle fatigue also increases when our visual work area requires frequent changes of focal distances. These changes in focal distance are accommodated by the ciliary muscles repeatedly contracting and relaxing to change the shape of the lens and thus keep the visual object in focus.

### 6.2 Control Options for Eye Muscle Strain and Fatigue

#### 6.2.1 Monitor Distance

The closer the monitor, the more convergence and accommodation are required. By moving the monitor back, the load on both the extraocular and ciliary muscles will be reduced.

If you can see what you're looking at, the screen is not too far away. The only practical limit on how far away the monitor can be is the size of the letters and the workstation configuration. Fortunately many software programs allow us to change the font size, enabling us to write and edit with a larger font which is then changed before printing.

#### 6.2.2 Monitor Height

Because the resting points of convergence and accommodation both move inward with a downward gaze angle, lowering the monitor reduces the demand on these muscular systems. For example, a horizontal viewing angle has a resting point of convergence of ≈45 in. while a 40° downward viewing angle has a resting point of convergence of only 32 in.

#### 6.2.3 Focal Distance

- As much as possible keep all frequently accessed visual targets at a similar focal distance and in the same vertical plane.
- The use of a vertically oriented document holder helps to keep both the monitor screen and hard copy in approximately the same focal distance.

#### 6.2.4 Vision Breaks

Another way to reduce visual stress is to take "vision" breaks by looking at something that is well beyond your resting points of accommodation and convergence. We are all familiar with the term 20/20 as the descriptor of normal visual acuity. Just add another 20—20/20/20—and you have a great memory jogger for a visual work/rest regime.

Every 20 min take 20 s to focus on an object at least 20 ft away (Anshel, 1998).

## 7 MOBILE WORKERS: MANAGING SAFETY OF TELECOMMUTERS

Implementing a managed safety process is critical to optimizing the working environment of telecommuters, reducing the risk of claims and injury costs, and increasing profits. Key stakeholders inside and outside the organization are essential to the success of this program. Obtaining accurate and complete injury data and hazard information to effectively manage telecommuter safety is a challenge for managers. Three surveillance approaches are recommended by Robertson et al. (2003):

1. *Employee Reports*. Prompt reporting of hazards, injuries, or symptoms to the employer is important for treatment and prevention. However, some telecommuters are reluctant to do so, fearing that reporting work-related hazards or injuries may result in the cancellation of the telecommuting agreement. Rather than report a work-related injury, some may visit their personal physician and rely on health insurance to pay the bill.

2. *Review Existing Records*. Records such as workers compensation claims, reports, and OSHA logs provide valuable information. Check with your workers compensation (WC) insurer to make sure worker injuries occurring off-site are properly coded and tracked in your itemized loss statements.

3. *Job Surveys*. These include checklists and surveys dealing with hazards. Employers may not know what hazards exist in the home environment unless the worker voluntarily offers the information. Most companies rely on self-assessments of at-home workplaces.

**Table 3  Telecommuter Safety Program Evaluation**

1.  Do you offer guidelines for setting up a home office, including equipment and ergonomic accessories, and provide general recommendations?

2.  Do you have self-assessment surveys for ergonomics, computer workstations, and home hazards? If so, are these surveys administered online or by hard copy?

3.  What do you do with surveys after you receive them? What kind of follow-up exists to determine whether hazards are corrected?

4.  How is survey data collected, analyzed, and used for improving safety at off-site environments?

5.  Do you have a policy addressing what ergonomic accessories and office furniture will be paid for by the company?

6.  Do you offer training programs for work-at-home workers that include risk factors, ergonomic solutions, symptom recognition, and reporting? If so, are the training programs administered via the intranet, hard copy, or other means?

7.  Do you assess whether training is completed and learning has taken place?

8.  Is there a procedure for reporting computer and systems problems that impact the work-at-home employee? Are these problems promptly resolved? Do you know that for sure?

9.  How do work-at-home employees report symptoms and general health concerns they feel are work related? Do they feel they can do so without reprisal of job action? Is confidentiality of reports maintained?

10.  Does your WC insurer offer site coding in their claims databases for identifying injuries that occur to at-home or off-site workers? Do you use these data for determining safety and risk management priorities for off-site workers?

11.  Do you have a return-to-work strategy for disabled workers who work at home or off-site? Are workers able to receive quality health care? How do you know?

12.  Do work-at-home employees communicate regularly with their managers and peers, and are they kept current on company happenings?

If you have a safety program that addresses work-at-home employees, evaluate its effectiveness by answering the questions in Table 3 (Robertson et al., 2003). If an answer is "no" or "I don't know," target the item for improvement.

## 7.1  Tips for Working at Home

If you are considering a work-at-home policy, there are several issues to consider in order to maintain a safe and comfortable work-at-home environment.

### 7.1.1  Planning the Workspace

Identify a location that provides you with a physically separate workspace, preferably away from the flow of activity in your house. Interruptions by family members can be distracting.

When planning your space needs, a good rule of thumb for space allowance is to identify, at a minimum, a 6 × 6-ft space for your primary work area. Expect space requirements to grow depending on what you need for references or storage. Lateral files typically have a footprint of 36 in. × 18 in. while vertical files are 15 in. × 18 in. Bookcases require additional space.

Bookcases and filing cabinets should be placed so that one needs to stand up to access them. Walk around periodically. Do not sit continuously throughout the day. Plan movement into your office design and recognize that this adds to the space requirements.

Do not put your office in a small room without windows. A closed room needs two doors out for life safety. Ideally, you should have ready access to a view greater than 12 ft away. A window makes this easy. The longer view will allow the eye muscles to relax.

Avoid placing the computer next to a window. Windows that are close by create problems with visually demanding work because of the glare. It is best to find a space on a north wall. Be careful of extension cords and wiring that crosses the travel area, as they can produce trip and fall hazards. All cables and extension cords should be fastened up and out of the way.

Be sure you have a lockable door and can control entry into your work area. Try to have an understanding with family members or roommates that you need privacy to conduct business in a professional manner.

Your work area should have at least two means of egress. One way out can be a window if you have a safe means of getting from the window to the ground.

Select a location with access to sufficient electrical power outlets. If you have any questions about electrical supply, have a licensed electrician evaluate your needs and install additional outlets if necessary. Residential-type extension cords are not a good choice; look for a cord with a minimum of 14-gauge wire. If a power strip is used, look for types with surge and overload protection.

### 7.1.2  Selecting Furniture

Select your furniture carefully, especially your desk and chair. If your company provides furniture, know in advance where you intend to place it to be sure it will fit. If you are purchasing the furniture yourself, check with your manager or someone who is familiar with getting surplus furniture. Your desk will need to accommodate your computer, keyboard, phone, paper, references, stapler, sundry items like pen holders and paper clips, and possibly fax, CD drive, scanner, and printer; therefore desktop dimensions are important.

Watch out for the cheap office furniture in advertising fliers. This furniture offers little flexibility in monitor placement and adjustment. Those with cubby holes for the components can create problems if you have a large

terminal, want to use a document holder, or want to use a slant board to hold books or other large references. Sometimes leg space is inadequate as well.

If you have a typical VDT monitor, you will need a work surface with at least 30 in. depth. A work surface with less depth is going to create problems. It is not unusual to find that the depth of the terminal combined with the depth of the keyboard exceeds 24 in. In this case, you will need to install a keyboard support or tray.

Do not place the monitor to the side of the keyboard. This is a poor solution because your neck was not designed to be held in a twisted position and you will eventually begin to develop neck and shoulder pain.

The desk may have a fixed-height work surface or it may be adjustable. Adjustable is better because you will be able to set it at the correct height for you. Fixed-height desks or workstations are usually in the range of 28–29 in. This is a problem for many people. Some may find the keyboard is too high, even when using a standard office chair adjusted to its highest point. This requires an adjustable keyboard holder to bring the keyboard down to a comfortable position.

Keyboard trays or holders should be at least 26 in. wide and at least 10 in. deep or more. Keyboard holders or trays have some serious trade-offs. They are generally not as stable as a desk top and can be loose or bouncy. Trays push you away from the working surface and everything you have on that surface. The phone is harder to reach, you often have to stretch out your arm and get into awkward positions just to write, and you will find yourself leaning and stretching out to read documents.

Select a solid, substantial desk or workstation that does not tip over when loaded up or when an overloaded drawer is pulled out. Beware of raised edges, and look for good leg clearance (at least 17 in. deep at the knee) and a matte finish. Center-drawer desks are not a good choice because the drawer will not allow the keyboard to be adjusted to the correct height for you and still leave adequate leg clearance. A table is better, as long as the surface has cantilever support or is otherwise designed so there is no part of the frame impinging on leg room.

The chair is a critical component to your home office. A typical chair will create problems. Look for a commercial office chair with height adjustability, back-tilt mechanism, lumbar support, and a seat pan that is the right width and length. Select one wisely after trying some out. Most office chairs adjust in the range of 16–21 in. Even at 16 in., about 15% of the female population and 2% of the male population will need footrests.

Your chair should have a five- or six-point swivel base with wheels and a rounded or waterfall front edge. Some seat pans are strongly contoured; these can be a problem for some people. Be careful that armrests do not stop you from bringing yourself up close to the keyboard. If the chair has armrests, be sure they are neither too low, in which case you will be slumping in the chair all day, nor too high, in which case your shoulders will be raised into an unnatural posture. Armrest adjustability is preferable. The backrest should not be so wide that your elbows bump it.

Filing cabinets can be dangerous for young children. If upper drawers are pulled out and children climb on them, the cabinet can tip. Look for a means to secure the filing cabinet such as securing one to another or securing to a wall.

## 7.2 Using a Laptop Computer at Home

Many laptops lack the image clarity of a full-size VGA monitor and can create eye discomfort. Docking systems and simply attaching a full-size terminal are good solutions for those whose work requires a substantial amount of visual interaction with the screen. A full-size keyboard and mouse or other pointing device should be used as well.

If you are using a laptop, even with a detached keyboard, work surface depth of 24 in. should be suitable because the units are seldom more than 12 in. deep. The following steps can minimize the onset of eye fatigue and strain when using your laptop at home:

- Take "mini" breaks by focusing on a distant object for a few seconds before continuing work on your screen.
- Keep the screen clean at all times, using appropriate antistatic cleaning materials.
- It is better to make keyboard position your primary concern. If the keyboard is not separate, this will mean tipping the display back.
- Reflective lighting may be a source of annoyance for laptop users. Use drapes, shades, or blinds to control glare. Use indirect light whenever possible while avoiding intense or uneven lighting in your field of vision.
- Keep your head in a comfortable position, not overly turned or tilted. Adjust the screen brightness and contrast levels that allow you to comfortably view the screen. If you experience fatigue or visual discomfort after following these suggestions, consult an eye care specialist and inform that specialist of your computer use.

It is certainly a challenge to maintain comfortable hand and arm positions while using a laptop. The following recommendations may help:

- Change your position often to avoid discomfort and muscle fatigue. If you begin to feel uncomfortable, stop and rest.
- Take periodic breaks and stretch your arms, hands, and fingers. Many computer users find that frequent, short breaks are of greater benefit than fewer, longer breaks.
- Type with a light touch. Do not pound the keys. Make sure you are not pushing down on the keys harder than necessary.
- Keep your wrists in a straight, nonrigid position. Never position your wrists in an exaggerated angle or in a position that causes tension in your wrists.

- Your hands and wrists should be free to move when typing. Do not rest your wrists on a palm rest, a table, or your thighs while typing on a laptop.
- Keep your fingers relaxed and nonrigid when operating your laptop or an input device. Pay particular attention to your ring finger, pinkie finger, and thumb. Make sure you are not tensely holding them up in the air or scrunching them into the side of your hand when using your input device or typing.

Working with a laptop keyboard for long periods can be uncomfortable and fatiguing. Especially problematic is a laptop keyboard for someone who must work with numbers. A regular-size and configuration number pad as a peripheral is essential for those who work with numbers on a laptop computer.

### 7.3  Consider Your Environment

If you have a regular light-emissive terminal, the ambient lighting around the screen should not exceed 500 lux (50 foot candles). If you have a flat-panel display, you can increase the lighting to around 750 lux (75 foot candles). Bare incandescent bulbs do not make a visually comfortable workstation. Indirect fluorescent lighting or fluorescent lighting with diffusers that train the light directly downward are the best choice.

Avoid having any bright-light sources in your immediate field of view. The preferable location for light sources is behind you, over a shoulder at an angle, or at a right angle to you so that you do not see a reflection in the screen.

Walls and wall coverings should be nonreflective. Some walls have enamel paint or shiny wallpaper that can be very reflective. Avoid the impulse to put framed artwork or photographs in your immediate field of view because they tend to have a relatively high reflectance.

Most noise at home will come from televisions, stereos, and conversation. Demanding complete quiet while you work in the kitchen is unreasonable. Locating your office out of the mainstream of activity will allow your family or roommates to conduct normal lives.

The home office should have adequate ventilation. If the home has a forced hot-air system or central air, a duct should be in the work area.

Most home carpeting and carpet pads are softer and less durable than commercial carpeting used in offices. Your chair will not roll as easily and may be a problem for you to easily change position as you perform your tasks. A solid carpet protector can be helpful but can also be a problem if the chair rolls too easily.

If your office is below grade, have your work area tested for radon.

### 7.4  Making a Good Ergonomic Fit

Once you have installed your furniture and equipment, it is important to adjust your workstation to fit you.

A good ergonomic fit for your workstation includes a chair height adjustment which permits your feet to rest flat against the floor and the work surface for your keyboard to be about 1 in. lower than your elbow height.

If workstation design does not allow adequate adjustability for keyboard height, it may be necessary to adjust chair height to elevate your elbow about an inch above your keyboard, and support your feet with a footrest.

Position the monitor for a moderate downward gaze angle and at fingertip reach, or about 20 in. from your eyes. If you are a hunt-and-peck typist, it might be easier for you to have a closer, lower monitor so you are not moving your head and neck up and down. Eyes move fairly easily through an arc of about $30°$, so a fairly low monitor reduces $A$ and $A + B$ repeated neck motion. For those who touch type, a monitor at a higher position will probably be more comfortable.

A word on eye wear: A very common problem is presbyopia, the loss of the eye's ability to see close objects clearly. Presbyopia is usually corrected with bifocals or trifocals. If you are a touch typist or know the keyboard so well that you need not do more than glance at it occasionally, it would behoove you to get monocular lenses to replace the bifocals while working. The strength of the monocular lens should be set for the distance from your eyes to your screen. If you are a hunt-and-peck typist, special bifocal lenses for VDT use are a good option. In this case, the top lens is set for the terminal distance and the lower lens for the keyboard.

Document holders are often a case of personal preference. In most cases, the home worker or hoteler will be composing rather than transcribing, so it is often unnecessary to be concerned with a document holder. If your work involves a lot of transcription from a printed document, it will be very important to have a document holder. Generally, document holders are designed to be at the side of the terminal or between the terminal and keyboard. The location is a matter of personal preference but can be influenced by whether you are a touch typist, whether you have presbyopia, and what type of display you are using.

If your work surface is the wrong height and you decide to buy a keyboard holder or tray, be sure that you get one wide enough to hold your keyboard and mouse/mouse pad or track ball. This is usually about 28 in. unless you have a split keyboard or some other type that is wider than a standard expanded keyboard. Avoid situations where you must reach out for the mouse, especially with the shoulder raised. If you have multiple computers and terminals, it is best to get an "A–B" switch for your keyboard so you do not clutter the desktop with keyboards and mice.

Wrist rests are not for everyone and in some cases can be a problem. A wrist rest provides a soft place to relax the hands when not typing. It should not be used to support the hands while typing. Hands should be cupped and above the keyboard when typing while the wrist is straight or very slightly extended.

## 8  INTERVENTION STRATEGIES

Office ergonomics studies have revealed a variety of contributing factors to musculoskeletal and visual discomfort among computer users. These factors include

increased job demands and more hours working at a computer (e.g., Bernard et al., 1994; Faucett and Rempel, 1994), sustained awkward head and arm postures (Marcus and Gerr, 1996; Tittiranonda et al., 1999), increased levels of psychological stress and poor psychosocial work environment, (e.g., Bongers et al., 1993; Carayon and Smith, 2000; Faucett and Rempel, 1994; Marcus and Gerr, 1996), work organizational factors (e.g., Lassen et al., 2004; Punnett and Bergqvist, 1997), a lack of specific ergonomic features in the workstations and office buildings, and poor lighting (e.g., Daum et al., 2004; Nelson and Silverstein, 1998; Sauter et al., 1990). Typically, these studies are cross-sectional in design and only describe the work, safety, and health experiences of computer and office workers at one time period (Demure et al., 2000). Recently, the literature in workplace interventions intended to prevent or reduce musculoskeletal and visual symptoms among computer users has grown. However, few longitudinal field or lab studies have examined the effects of office ergonomics interventions on workers' health, safety, and performance (Brewer et al., 2006; Buckle, 1997; Karsh et al., 2001). Although there is a growing interest among employers to improve office workplaces, studies that investigated the effects of workstation, eyewear, and behavioral interventions on upper body musculoskeletal and visual symptoms are of mixed quality (Brewer et al., 2006; Karsh et al., 2001).

There is some evidence, however, that ergonomics training (Brisson et al., 1999) in workstation and building design (e.g., Aarås et al., 2001; Hagberg et al., 1995; Nelson and Silverstein, 1998; Sauter et al., 1990) can prevent or reduce musculoskeletal and visual discomforts and symptoms in office environments. One method for reducing the prevalence of musculoskeletal and visual symptoms is to provide specialized ergonomics training and workstation changes. Office ergonomics training helps employees to understand proper workstation set-up and postures (e.g., Bohr, 2000; Brisson et al., 1999; Ketola et al., 2002; Verbeek, 1991). Green and Briggs (1989) showed that merely providing adjustable furniture alone may not prevent the onset of overuse injury. However, a significant decrease in WMSDs and visual discomfort has been observed when workers were given an adjustable/flexible work environment coupled with ergonomics training (Amick et al., 2003; Robertson et al., 2008, 2009). Further, the provision of control over the work environment through adjustability and knowledge may enhance worker effectiveness as well as their health and safety (Hedge and Ray, 2004; McLaney and Hurrell, 1988; O'Neill, 1994; Robertson et al., 2008, 2009; Smith and Bayehi, 2003). Recent findings of a randomized control trial 15-day longitudinal laboratory study, replicating an 8-h customer service job, further supported these field intervention studies. It was observed in this study that the trained group who used sit/stand workstations exhibited minimal and significantly lower musculoskeletal and visual discomfort compared to a nontrained reference group also working in the same sit/stand configuration. Moreover, the trained group had significantly higher performance and effectiveness than the reference group as exhibited by

higher accuracy and quality control scores (Robertson et al., 2010). These findings, which indicate the ability to mitigate symptoms, change behaviors, and enhance performance through training combined with a sit/stand workstation, have implications for preventing discomforts in office and computer workers (Robertson et al., 2009). These results are also supported by the conclusions of a systematic review conducted by Brewer et al. (2006) with their critical and strict 11-point inclusion criteria of 31 studies. In this review only moderate evidence was observed for no effect of workstation adjustment alone and no effect of rest breaks and exercise on musculoskeletal or visual health. A positive effect of alternative pointing devices was found. They further concluded that for all other workplace interventions a mixed or insufficient evidence of effect was observed (Brewer et al., 2006).

When examining other office ergonomic intervention studies that may have weaker designs, such as nonrandomized control trial or no controlled group, positive and significant results have been observed consisting of various office ergonomics interventions (e.g., Dainoff et al., 1999; Hedge and Ray, 2004; Sauter et al., 1990; Smith and Bayehi, 2003; Smith and Carayon, 1996; Vink et al., 2009). Certainly these findings are limited in their generalizability due to lack of internal and external validity; however, they do provide insightful and useful information describing the effects of various office ergonomics interventions in either field settings or a control laboratory study with limited exposure variables consisting of real world issues. Other related areas of workplace interventions, such as participatory ergonomics interventions, have also shown mixed results (Rivilis et al., 2008). However, given mixed results of the effects of office and computer interventions, it appears that, when possible in this field research, having the ability to control some of the threats to validity can strengthen the study design and provide more definitive conclusions. Bridging laboratory with field intervention studies can also provide an important link between building conceptual models regarding office workers and associated risks and providing effective interventions and programmatic ergonomic recommendations. These and future studies grounded in high-quality research can all contribute to reducing and preventing symptoms among workers and providing an injury-free, comfortable, and productive work environment.

## 9 CONCLUDING REFLECTIONS

What are we to make of the current state of knowledge regarding office ergonomics? On the one hand, when rigorous methodological criteria are applied to the vast literature in the area, it is difficult to identify specific biomechanical risk factors in WMSDs. Hence, psychosocial variables are proposed as potential explanatory variables. And yet, we have an extended case study by the chief of experimental medicine at Beth Israel Deaconess Medical Center in Boston describing his own disabling wrist injury which he attributes to "banging clumsily at the (laptop) keyboard for many hours at a

time" (Groopman, 2007, Chapter 7). At the same institution, Boiselle et al. (2008) describe a prevalence rate of 58% of repetitive stress symptoms among radiologists who spend more than 8 h per day interacting with a standard radiological archiving and communication system (PACS). Symptom rates were reduced by introduction of and training on ergonomic workstations and chairs. The senior author of this chapter has similar personal knowledge of highly motivated professionals who suffered disabling wrist injuries attributed to prolonged computer use, injuries which were ameliorated by traditional ergonomic solutions. At the very least, these case studies would seem to question simple psychosocial explanations based on secondary gains through public expression of pain symptoms.

Two possible approaches to this dilemma are proposed for consideration.

### 9.1 More Complete Characterization of Exposure

It is conceivable that current Cochrane-based methodologies for attributing risk are more appropriate for traditional disease vectors than for describing the complexities of office work. An alternative approach to characterizing exposure relies on Ashby's (1956) principle of requisite variety, which states that the variety of the measurement system must match the variety of the system to be measured.

Using the terminology of Section 1., we might define a condition of maladaptive perception–action cycles if there is a mismatch of coordination of postural and supporting workstation degrees of freedom resulting in configurations of working postures in excess of some hypothetical three-dimensional spatial comfort zone (e.g., awkward posture), and such cycles proceed at a rate/pace in excess of a hypothetical temporal comfort zone. The causes of these presumed mismatches might be physically based (e.g., anthropometic variation, physical disability) and/or cognitive/behaviorally based (e.g., lack of understanding regarding adjustment mechanisms and the need to work at an appropriate work pace, lack of motivation to engage in appropriate adaptive behavior).

The outcome of such maladaptive PACS could be discomfort and pain. This may either resolve with the passage of time or progress to a medically significant event (diagnosis, compensation claim). Such pain might result from underlying tissue damage.

However, at the same time, we might consider that the impact of psychosocial factors on expressed pain might act through at least two pathways. The first involves the possibility that combinations of psychosocial factors might create and/or enable maladaptive perception–action cycles (e.g., increased work pace, lack of training, poor supervisory relationship, job content, equipment). The second is that emotional reactions to psychosocial stress have a direct influence on levels of pain (Marras et al., 2009). Unfortunately, the methodological challenges in subjecting the aforementioned complex nonlinear relationships to analysis by rigorous scientific method are considerable. Of particular difficulty is that the training and coaching required

to achieve adaptive control are also the same variables responsible for Hawthorne effects.

### 9.2 Focus on Quality and Performance

A second approach is to avoid the context of medical diagnosis and treatment and focus instead on achieving optimal and high-quality work performance. By this approach, maladaptive perception–action cycles are regarded as problems of management and work organization. As has been seen in Section 8, there is considerable evidence that the ergonomic practices discussed in Sections 3 through 7 can result in improvements in work performance and quality. Accordingly, reduction of discomfort/pain is a desirable management goal and, as such, is aligned with, rather than in conflict with, safety and health concerns (see, e.g., Dul and Neumann, 2009). In fact, in an extensive telephone survey of over 28,000 working adults, Stewart et al. (2003) determined that common pain at work is responsible for an annual loss of $61.2 billion in productivity in the United States, the bulk of which comes from reduced performance while at work. It might, therefore, be argued that use of ergonomic knowledge to provide an appropriate work system ought to be focused on optimizing overall work performance and quality and, having done so, the safety and health benefits are likely to result "for free."

# CHAPTER 57

# HUMAN FACTORS AND ERGONOMICS IN HEALTH CARE

**Pascale Carayon, Bashar Alyousef, and Anping Xie**
**Department of Industrial and Systems Engineering**
**University of Wisconsin—Madison**
**Madison, Wisconsin**

The U.S. health care industry is going through major changes under increasing pressures from the public for higher quality and lower cost. A major part of the 2010 health care reform is the push toward health information technology, which is assumed to provide major patient care benefits. The Health Information Technology for Economic and Clinical Health (HITECH) Act provides resources for health care organizations to implement health information technology (IT). Other pressures are exerted on the health care industry to redesign its systems, structures, and processes to better meet the needs of society in a safe, reliable, and efficient manner. For instance, the Joint Commission, which is the major organization that accredits health care organizations in the United States, has a set of national patient safety goals, such as improving the accuracy of patient identification and improving the safety of using medications. The national patient safety goals are updated on a regular basis. Every health care organization that is accredited by the Joint Commission is expected to implement systems, structures, and processes for meeting the national patient safety goals. There has also been a call by the National Academy of Engineering and the Institute of Medicine (IOM) to create a partnership between health care and industrial and systems

engineering, including human factors and ergonomics, in order to address the problems experienced by the health care industry (Reid et al., 2005). Multiple reports issued by the IOM have clearly highlighted the need for human factors professionals and researchers to be part of the effort to redesign health care systems, structures, and processes (IOM, 2006; Institute of Medicine Committee on Data Standards for Patient Safety, 2004; Institute of Medicine Committee on Quality of Health Care in America, 2001; Institute of Medicine Committee on the Work Environment for Nurses and Patient Safety, 2004; Kohn et al., 1999). For instance, the IOM (2006) report on medication errors calls for the consideration of human factors principles in designing health information technologies that can prevent medication errors, such as computerized provider order entry or bar coding medication administration technologies.

Numerous studies provide information on the various quality-of-care problems experienced across the continuum of care in the United States as well as in other countries. McGlynn et al. (2003) conducted phone interviews with a representative sample of adults living in 12 metropolitan areas of the United States; participants shared information about their health care experiences. In addition, medical record data were available for a

subset of the respondents. The researchers found that overall participants received 55% of recommended care; the level of recommended care provided was pretty consistent across the different categories of care: preventive care (53.5%; e.g., mammographic screening for breast cancer, documentation of smoking status), acute care (53.5%; e.g., prophylactic antibiotics given on day of hip repair surgery), and chronic care (56.1%; e.g., diet and exercise counseling for diabetic patients). Another set of quality-of-care problems received major public attention with the IOM report "To Err is Human: Building a Safer Health System" (Kohn et al., 1999). According to this report, between 44,000 and 98,000 people die each year as a result of (preventable) medical errors. A Canadian study on adverse events in hospital patients found that 7.5% of hospital admissions had an adverse event, such as unplanned readmission and hospital-acquired infection or sepsis (Baker et al., 2004). Thirty-seven percent of the adverse events were judged to be preventable. The Centers for Disease Control and Prevention has estimated the overall annual direct medical costs of health care–associated infections to U.S. hospitals at between $28.4 and $33.8 billion (Scott, 2009). Based on current practice and technology, it has been estimated that prevention strategies can eliminate 20–70% of health care–associated infections. These studies and others provide significant information about the need to redesign health care systems and processes in order to improve quality of care.

This chapter reviews various ways that the human factors and ergonomics (HFE) discipline can provide useful information for analyzing and redesigning health care systems and processes. The chapter begins with a description of the health care industry, including the various factors contributing to complexity in health care. We then review issues related to defining and involving end users in health care system design and other HFE improvement efforts. Given the complexity in health care, a major section of this chapter examines various systems approaches to health care. A separate section of the chapter examines HFE of medical devices and information technology. Special attention is given to patient safety and the role of HFE in understanding contributing factors to medical errors and error reporting and recovery mechanisms.

## 1 CHARACTERISTICS OF HEALTH CARE INDUSTRY

It is important to understand the unique characteristics the health care industry in order to know how human factors and ergonomics concepts, models, and methods can be applied or need to be modified and adapted for optimal outcomes.

### 1.1 Health Services Industry

In 2008, the health services industry was the largest in the United States, providing 14.3 million jobs (Bureau of Labor Statistics, 2010). The industry is comprised of the following segments (Bureau of Labor Statistics, 2010):

- Hospitals that employ 34.6% of all workers, 72% of hospital workers working in institutions with more than 1000 workers

- Nursing and residential care facilities, nursing aides providing the majority of direct care
- Physician offices, with physicians and surgeons having private practices or working in groups of physicians with similar or different specialties
- Offices of dentists
- Offices of other health practitioners, such as chiropractors
- Home health care services—one of the fastest growing sectors of the economy
- Outpatient care centers, such as dialysis centers and free-standing outpatient surgery centers
- Other ambulatory health care services
- Medical and diagnostic laboratories

The health services industry has 40 occupations and professions in the following categories: (1) management, business, and financial occupations (4.3% of employment); (2) professional and related occupations (43.8%); (3) service occupations (32.2%); and (4) office and administrative support functions (17.7%). The employment in the health services industry is expected to grow by 22.5% between 2008 and 2018. Some of the fastest growing occupations include home health aides (growth of 53.3%), physician assistants (growth of 41.3%), physical therapist assistants and aides (growth of 35.9%), medical assistants (growth of 35.1%), and occupational therapist assistants and aides (growth of 33.0%). A number of factors contribute to the growth in employment in the health services industry (Sultz and Young, 2001). The aging population is a primary factor that increases the demand for workers who provide long-term care, such as nursing home care and home health care. The increasing implementation of medical and nonmedical technology has also implications for the number and skill requirements of the health care work force (Sultz and Young, 2001). Health care changes have shifted health care delivery sites from acute-care hospitals to ambulatory, home care, and long-term-care settings (Sultz and Young, 2001).

The health care industry is a "people-intensive" industry involving many different types and categories of workers, patients and their families, and communities and society-at-large. As Van Cott (1994, p. 56) says, "the health-care system is people-centered and people-driven." Therefore, the discipline of human factors and ergonomics has much to offer to improve the performance, quality, and safety of the health care system. The current health care system is very decentralized: It is comprised of a range of subsystems connected with each other and including caregivers and patients (Institute of Medicine Committee on Quality of Health Care in America, 2001). The subsystems include hospitals, community pharmacies, clinics, laboratories, and long-term facilities. Because of the variety of systems and subsystems, different goals, values, beliefs, and norms of behavior are at work in the health care systems (Van Cott, 1994).

### 1.2 Complexity of Health Care

Different dimensions of system complexity have been identified (Carayon, 2006; Perrow, 1984; Vicente, 1999): (a) large problem spaces, (b) social, (c) heterogeneous

perspectives, (d) distributed, (e) dynamic, (f) potentially high hazards, (g) many coupled subsystems, (h) automated, (i) uncertain data, (j) mediated interaction with computers, and (k) disturbances. Health care systems possess many of the characteristics of system complexity (see Table 1).

### 1.2.1 Breadth and Depth of Health Care

Health care is composed of many different elements. The International Statistical Classification of Diseases and Related Health Problems (most commonly known by the abbreviation ICD) includes 155,000 codes for various diseases, symptoms, and others.

The United States spends a large amount of its gross domestic product (GDP) on health care: in 2009, health care expenditures represented 17.33% of the GDP, or $2.5 trillion (Truffer et al., 2010). The health care expenditures are distributed across hospital care (31%), physician and clinical services (21%), prescription drugs (10%), nursing home and home health (9%), and other services (29%).

### 1.2.2 Health Care as a Sociotechnical System

Health care is basically a sociotechnical system in which people have a preponderant role (see Section 2), for example, as providers, patients, families, and purchasers. People are customers and consumers of health care, and people are producers of health care. Effective functioning of health care depends largely on people and the communication and coordination among various health care staff and patients.

### 1.2.3 Heterogeneous Perspectives in Health Care

Workers in health care come from different background and may have different values regarding health care, its delivery, and its quality and safety. For instance, a study by Thomas et al. (2003) shows the discrepancy in the attitudes of critical-care physicians and nurses with regard to teamwork. A total of 90 physicians and 230 nurses from eight nonsurgical intensive care units (ICUs) in six hospitals were surveyed. Thirty-three percent of the nurses rated the quality of communication and collaboration with physicians as high or very high, whereas 73% of the physicians rated the quality of communication and collaboration with nurses as high or very high. Physicians were more likely than nurses to agree with the statement that "Input from ICU nurses about patient care is well received in my unit." Such discrepancy in perceptions and attitudes between workers in health care can have numerous consequences, such as dissatisfaction and poor well-being, and may also affect expectations regarding performance and ultimately the quality and safety of care provided to patients.

### 1.2.4 Distributed Health Care

People involved in the delivery of health care may be located in different places. One type of long-term care in which people are geographically dispersed is home services provided by home health care agencies (Wunderlich and Kohler, 2001). The home is fast becoming the primary site of care for most persons with acute or chronic illnesses. Indeed, with the current trend toward ambulatory procedures and increasing technologies, one-half of patients once cared for in hospitals now receive their care at home. The home health arena is unique because it has so many workers of various skill levels who are dispersed over large geographical areas. Workers in home care function in a geographically distributed environment, in which few workers ever see other members of their team on a day-to-day basis. Home health care workers have very high turnover rates (Wunderlich and Kohler, 2001), which

**Table 1  Complexity of Health Care Systems**

| Dimensions of System Complexity | Examples in Health Care |
|---|---|
| 1. Large problem spaces | ICD system includes 155,000 codes for diseases and other symptoms<br>Health care expenditures = 17% of GDP in the United states |
| 2. Social | People intensive<br>People centered<br>People driven |
| 3. Heterogeneous perspectives | Different goals, beliefs, values, and behavior norms<br>Different cultures and subcultures |
| 4. Distributed | Geographical dispersion (e.g., home care)<br>Telemedicine |
| 5. Dynamic | Changes in medical knowledge and technology<br>Delay between ''action'' and ''outcome'' (e.g., primary care and preventive medicine) |
| 6. Potentially high hazards | Patient safety and medical errors |
| 7. Many coupled subsystems | Both tight and loose coupling |
| 8. Automated | High levels of automation in certain parts of health care (e.g., radiotherapy) |
| 9. Uncertain data | Imperfect information<br>Imperfect knowledge<br>Patient factors |
| 10. Mediated interaction with computers | Medical devices and technologies (e.g., endoscopic technologies) |
| 11. Disturbances | Unanticipated events |

may be due to their poor working conditions and low quality of working life (Feldman, 1993; Wunderlich and Kohler, 2001). Stone and Wiener (2001) highlight the major issues affecting the long-term-care frontline workers, including difficulties in recruiting and retaining workers. They also discuss many of the negative effects of turnover, such as poorer quality and/or unsafe care, increased stress and frustration on the workers, reduced opportunities for on-the-job training and learning, and less peer support. Reasons for the turnover problem of home health care workers include poor working conditions, perceptions of inadequate resources, and a suboptimal environment for providing good safe care (Aiken et al., 2001; Blegen, 1993; Simmons et al., 2001). The discipline of human factors can provide the models and tools for improving working conditions and therefore improving retention and reducing turnover of home care workers. HFE can also be applied to understanding and improving quality and safety of home health care (Henriksen et al., 2009).

Telemedicine is one form of organizing care that puts distance between the patient and the health care providers. According to the American Telemedicine Association (2011, para. 1), "Telemedicine is the use of medical information exchanged from one site to another via electronic communications to improve patients' health status". A recent application of telemedicine for intensive care has been rapidly expanding (Lilly and Thomas, 2010). The tele-ICU care model can complement existing on-site ICU care activities. Patients are monitored by the tele-ICU staff (e.g., an intensivist and a critical-care nurse). There is much discussion about whether and how telemedicine such as tele-ICU can achieve positive results with regard to patient outcomes (quality of care) and cost, and very little is known about the HFE aspects of telemedicine. Such geographical separation poses unique challenges to communication and coordination between health care providers, which would benefit from input and advice from the HFE community.

### 1.2.5 Health Care as a Dynamic System

Complex systems are dynamic and rapidly changing. The health care industry has seen lots of changes in medical knowledge and technology that have been precipitated by large investments in biomedical research (Institute of Medicine Committee on Quality of Health Care in America, 2001). Much of the medical knowledge and information on evidence-based practice comes from randomized controlled trials (RCTs). Chassin (1998) shows that the number of publications from RCTs referenced in Medline has increased exponentially from 1966 to 1995: in 1966, there were about 100 RCT articles, whereas in 1995, there were over 100,000 RCT articles. The volume and complexity of this information pose unique challenges to health care practitioners and managers and add to the complexity of the health care system. Another time factor of system complexity is the time lag between action and response. Some health care action can lead very quickly to a response. For instance, using an electric heart defibrillation leads to an immediate physical reaction on the part of the patient.

The administration of certain drugs can also lead to immediate physiological reactions. There can also be long delays between actions done to the patient and their consequences. In addition, the consequences may not be easily linked to specific actions or may not be visible to the health care provider who performed the actions in the first place. This is particularly the case in primary and ambulatory care. For instance, the health effects of preventive services provided by primary care physicians may not be measured for many years.

### 1.2.6 Health Care as a Hazardous Industry

Operating a complex sociotechnical system can produce various hazards. In health care, the main hazards are those done to the patients, such as medical errors and lack of patient safety (see Section 5).

### 1.2.7 System Coupling in Health Care

Perrow (1984, pp. 93-94) defines the following characteristics of coupling in systems. First, "tightly coupled systems have more time-dependent processes," whereas "In loosely coupled systems, delays are possible." Second, the sequencing of tasks or process steps in tightly coupled systems is somewhat fixed and invariant. Third, in tightly coupled systems, there is typically only one way of designing and performing a process. One characteristic of loosely coupled systems is equifinality, that is, they have a common objective that can be achieved with different processes and tasks. Fourth, tightly coupled systems have little slack and bugger. A health care system can either be tightly coupled or loosely coupled (Cook, 2004). An example of tight coupling is the sequence of specific steps in the performance of a surgical procedure, for example, the surgery cannot occur before the anesthetic has been administered. An example of loose coupling is the preoperative process once a surgery has been decided: A number of tasks must occur, but not necessarily in a specific tight temporal sequence; for instance, the physical exam that the patient needs to have before the surgery can occur within a certain window of time, typically 1–3 weeks.

### 1.2.8 Automation in Health Care

Complex systems tend to be highly automated. Whereas automation is not widespread over the health care industry, there are parts of health care with high degree of automation. Radiotherapy is an example of patient care that relies on different forms of automation, such as connection between information from imaging devices and treatment devices. See Section 4 for a discussion of medical devices and information technology.

### 1.2.9 Uncertainty in Health Care

Uncertainty is another characteristic of complex system and is highly present in health care. The sources and types of uncertainty in health care include imperfect information, imperfect knowledge regarding medical treatment, and patient factors (e.g., impact of treatment on a particular patient). Uncertainty increases when patient-related information is not available or not provided in a timely manner (Schultz et al., 2007).

### 1.2.10 Technology-Mediated Interaction in Health Care

In health care, much of the interaction is mediated by devices and technologies. For instance, it is not possible to measure directly blood pressure of a patient during a surgery: There is a piece of equipment and a display that provide information on the patient's blood pressure. That type of technology-mediated interaction between the "worker" and the "work object" highlights the importance of cognitive ergonomics in health care. See Section 4 for a discussion of medical devices and information technology.

### 1.2.11 Unanticipated Events and Disturbances in Health Care

In complex systems, disturbances are very present and workers need to deal with unanticipated events. In order to maintain safety and performance, workers need to adapt to those events quickly. Health care, of course, is filled with unanticipated events to which workers need to react quickly in order to ensure the safety of the patients and maintain adequate performance. Weinger et al. (2003) conducted a study of nonroutine events in anesthesia. A nonroutine event was defined as "any event that is perceived by clinicians or skilled observers to deviate from ideal care for that specific patient in that specific clinical situation (Weinger et al., 2003, p. 110)." In-person surveys of anesthesia providers show that 27% of anesthesia cases ($N = 277$) had at least one nonroutine event (total of 98 nonroutine events). Data from quality improvement reporting systems in two hospitals yielded information on 135 events. An analysis of all of these 233 nonroutine events produced information on the factors contributing to those events: patient disease/unexpected response (67%); provider supervision, knowledge, experience, and judgment (33%); surgical issues (26%); logistical or system issues (19%); inadequate preoperative patient preparation (17%); equipment failure or usability (16%); coordination/communication (15%); and patient positioning (9%).

The complexity of the health care system has much impact on the practice of HFE. For instance, HFE projects in health care require one to spend more time on managing and implementing change than on deciding the content of change (Hignett, 2003).

### 1.3 Standardization

The report published in 2001 by the IOM on "Crossing the Quality Chasm" (Institute of Medicine Committee on Quality of Health Care in America, 2001) and the 1999 IOM report on "To Err is Human: Building a Safer Health System" (Kohn et al., 1999) emphasize the importance of standardization of care processes, which is believed to have the potential to reduce medical errors and improve quality of care (Field and Lohr, 1900; Reiling and Chernos, 2007). It is unclear whether we need more or less standardization (Brunsson and Jacobsson, 2000). Pros and cons of standardization are discussed in the literature. The IOM considers standardization an important redesign strategy that is assumed to reduce reliance on short-term memory and

allow those unfamiliar with a given process to use it safely (Kohn et al., 1999). Hospital administrators may use standardization to optimize their control over the hospital's increasingly complex structure (Timmermans and Berg, 2003). On the other hand, a survey of members of the American College of Physicians showed that although guidelines were thought to be able to improve the quality of care by 70% of respondents, 43% of respondents believed they would increase health care cost and 34% of respondents believed they would make medical practice less satisfying (Tunis et al., 1994). Critics argue that health care standardization will repeat the mistakes of scientific management by stifling professionals' creativity and autonomy, undermining clinical expertise, and rendering the profession vulnerable to oversight, substitution, and interference (Timmermans and Berg, 2003). In an environment with preset rules and regulations, patients may become numbers and interact with impersonal technologies and technicians, and health care workers bemoan the removal of mystery or excitement from their work lives (Reiser, 1978).

Timmermans and Berg (2003) proposed a useful approach to health care standardization, which is neither a "well-oiled machine" nor a "stifled robotscape." They stressed the importance of the content of standardization (i.e., what is standardized) and the manner in which standardization is designed and implemented (i.e., how it is standardized). With regard to content of standardization, several elements have been discussed, such as the physical design of health care settings, the design of medical devices, and health care procedures.

The physical design of a health care setting can have an impact on the quality of care. When leaders at St. Joseph's Community Hospital were working on the design of the new hospital facility, they looked for ways of designing the hospital and its spaces to ensure maximizing efficiency and quality and safety of care (Reiling et al., 2004). One of the hospital design principles was the complete standardization of patient rooms. According to Reiling and Chernos (2007), standardization of patient rooms should take every detail into consideration, including the location of the gas outlets, the bed controls, the cupboard where the latex gloves are stored, the charting process, and the switches on light fixtures. However, even if the ultimate goal is standardization, the design of patient rooms may vary because of physical constraints or design intentions (Saucier, 2010). Therefore, it is critical to identify and prioritize the elements of patient rooms that will benefit most from standardization. This type of standardization of the physical layout of health care settings can reduce the need for health care workers to memorize the location of equipment and supplies; this may contribute to efficiencies as well as reduce the likelihood of skill-based errors.

In the context of medical devices, lack of standardization may cause problems for users (Ward and Clarkson, 2007). For instance, an audit of the range of infusion devices in six National Health Service (NHS) hospitals shows that, on average, each hospital uses 31 different types of infusion devices [National Patient

Safety Agency (NPSA), 2004]. In a study of clinical needs assessment of intravenous (IV) therapy, standardization of IV pumps and accessories was a recommended strategy to reduce medication errors (Scroggs, 2008). Standardization of medical devices in a health care organization may support end users' performance: If there is only one type of each medical device, end users have to learn to use only this one type of medical device. In some instances, it may be important to allow end users to customize the interface of medical devices. A study of anesthesia alarms shows that tailoring can lead to improved performance if there is time to tailor the alarm, the means for adapting the alarm are present, and the benefits appear to outweigh the costs (Watson et al., 2004). Randell (2003) conducted an observational study of the customization of medical devices by ICU nurses. She found that nurses performed the following types of device customization: (1) customization to overcome limitations of the device and provide adequate patient care, (2) use of pen and paper to ease the use of the device (e.g., post-it notes attached to devices), and (3) change in the procedure for the usage of the device. Further research is needed to understand the safety and performance benefits and problems associated with standardization versus customization of medical devices.

Standardization of health care procedures is a highly controversial issue. Evidence-based medicine is the main attempt to accomplish this standardization at the level of the profession; this has led to an increasing number of clinical practice guidelines being implemented (Amalberti and Hourlier, 2007). By encouraging the use of current best evidence in making decisions about patient care, evidence-based medicine is assumed to lead to better and more efficient care, improved health care outcomes, better educated patients and clinicians, a scientific base for public policy, a higher quality of clinical decisions, and better coordinated research activities (Timmermans and Berg, 2003). However, many studies argue that guidelines may do little to change practice behavior (Donaldson et al., 1999; Grol et al., 1998; Woolf et al., 1999). One of the main reasons for noncompliance with clinical practice guidelines is that individual clinical autonomy takes precedence over the normative and prescriptive aspect of the guidelines (Timmermans and Berg, 2003). Ambiguities in the content of the guidelines (i.e., what is to be done, exceptions to the guidelines) and responsibility for the guideline implementation can also contribute to poor compliance with guidelines (Gurses et al., 2008).

In addition to what is standardized (content of standardization), it is important to consider the manner in which standardization is implemented. The IOM recommends an approach where systems and processes are designed for the usual, but the unusual is being recognized and planned for (Institute of Medicine Committee on Quality of Health Care in America, 2001). Similarly Walker and Carayon (2009) proposed a balanced approach to standardization. They suggested that, in addition to supporting appropriate standardization of routine tasks, value-added processes support intentional variation based on the uncertainty inherent in the patient's condition, the strength of the available evidence, patients' needs, local factors, and providers' professional judgment.

In summary, standardization may be an important principle of health care system design. The content of what can be standardized and how standardization can be implemented are two important elements of standardization. A balance between standardization and customization needs to be achieved; more research is needed to understand the HFE benefits and costs of standardization versus customization.

## 2 END USERS IN HEALTH CARE

The involvement and participation of users is a critical principle of human factors and ergonomics. In this section, we discuss some of the challenges to the application of this principle in health care: definition and determination of the users, involvement of laypersons who do not have medical/health care knowledge, and challenges related to participatory ergonomics.

### 2.1 End User Involvement in Health Care System Design

An overriding principle of human factors is to center the design process around the user, therefore creating a user-centered design (Meister and Enderwick, 2001; Norman, 1988). In the design of health care systems, the variety of potential end users needs to be considered in the design cycle.

### 2.1.1 System Design Process

There is much controversy about the system design process and its characteristics and components. However, the system design process can be conceptualized as being organized around four questions (Meister and Enderwick, 2001): analysis of the design problem, generation of alternative solutions, analysis of alternative solutions, and selection of preferred solution. From a human factors point of view, Wickens et al. (2004) describe major stages of system design in which human factors can provide important useful information: (1) front-end analysis, (2) iterative design and test and system production, (3) implementation and evaluation, and (4) system operation and maintenance and system disposal.

- *Front-end analysis*, including definition of the users, of the functions to be achieved by the system, of the environmental conditions under which the system will be used, and of the users' preferences or requirements for the system. This stage will typically include user analysis and task analysis.

An example of front-end analysis is the human factors and a macroergonomic approach used to study and analyze ultrasonic central venous catheter (CVC) guidance, placement, and care (Alvarado et al., 2008). In this study, ICU staff (physicians, nurses, and other technical personnel) were asked to participate in

individual observations and to complete a questionnaire assessing their current knowledge of CVC placement and care. The objective of this analysis was to understand the ICU work system and the CVC insertion tasks performed and to produce useful information to develop recommendations for redesigning CVC insertion work system and care processes in the ICU.

- *Iterative design and test and system production*: Initial specifications are used to create initial design or prototypes. At this stage, human factors input typically consists of identification of human factors criteria to the list of system requirements (e.g., usability requirements), function allocation, and design of support materials.

At the stage of creating and testing initial system specifications, it may be useful to conduct a more extensive HFE analysis, such as a proactive risk assessment (Carayon et al., 2009a). For instance, a hospital conducted an FMEA (failure mode and effects analysis) to examine the potential safety implications of implementing a new Smart IV pump technology (Wetterneck et al., 2006). This FMEA identified a number of design and implementation issues that were addressed before the new device was implemented (Carayon et al., 2008; Wetterneck et al., 2006).

- *Implementation and evaluation*: Various methods for system change implementation use basic human factors principles (e.g., participatory ergonomics). The evaluation should consider human factors variables (human performance, health and safety, and well-being).

Examples of human factors evaluations of system redesign include the evaluation of electronic health record (EHR) implementation in small clinics (Carayon et al., 2009b) and the evaluation of computerized provider order entry (CPOE)/EHR implementation in ICUs (Hoonakker et al., 2010). Both of these evaluations use multiple HFE data collection methods, including observational methods, interviews with key personnel, focus groups, a survey questionnaire, as well as other methods to assess medication errors and adverse drug events.

- *System operation and maintenance and system disposal*: Various human factors activities occur at those stages, for example, ensuring the reliability and functioning of medical equipment and devices for safe operations and designing an appropriate system for hazardous materials (e.g., needles).

After the implementation of a new system or a new technology, there may be lingering or new human factors issues that are discovered during the actual use phase. For instance, a study of nurses' use of bar code medication administration (BCMA) technology led to the discovery of many human factors problems, some of which are related to the design of the technology (Carayon et al., 2007). Data were collected using structured observations of medication administration and short interviews with nurses. Overall nurses were satisfied with the BCMA technology, but several potentially unsafe tasks and work-arounds were discovered. Recommendations for continued technology redesign and enhanced training came out from this post–technology implementation analysis.

### 2.1.2 End Users of Health Care Systems

Human factors engineers and ergonomists focus on the interactions between humans and other elements of the work system. In health care systems, the humans are varied: the health care providers and clinicians, the patients and their families, and other types of workers (e.g., housekeeping, biomedical engineering, purchasing, and administration). This large variety adds to the complexity of health care systems. For example, a single device such as an infusion pump is used by multiple users: The *nurse* programs the pump when administering medication to a patient; the *patient* is connected to the infusion via tubing; and the *biomedical engineer* maintains the pump and ensures its calibration. This example shows that a single device is used by different users performing different tasks. It is also important to note that this variety of end users is often related to a variety of physical and organizational settings. In the infusion pump example, the physical environment in which the pump is used varies from patient rooms to engineering laboratory. From an organizational viewpoint, the various users have probably received different level and type of training with regard to the usage of the pump.

Defining the "user" in a HFE project in health care is critical (Hignett, 2003). Every person is a potential user of the health care system in any country, but only a small proportion of a country's population is directly in "contact" with the health care system. Another complicating factor is the fact that very often the patients are not directly paying for the "health care service." All of these factors make the definition of the user a difficult task for the user-centered designer (Hignett, 2003). A structured review from a social science perspective of the published literature about user involvement in health care technology development and assessment from 1980 to 2005 in peer-reviewed journals (Syed et al., 2008) found that (1) the users of medical devices include clinicians, patients, care providers, and family members; (2) different kinds of medical devices are developed and assessed by user involvement and persons with different disabilities and impairments; (3) the user involvement occurs at different stages of the medical device technology life cycle and the degree of user involvement is in the order of design stage, testing and trials stage, deployment stage, and concept stage; and (4) methods most commonly used for capturing users' perspectives are usability tests, interviews, and questionnaire surveys.

## 2.2 Involvement of Laypersons

Recently, providing patient-centered care has been a focus of many health care organizational restructuring and quality improvement efforts. Patient-centered care has the potential to improve health status and can increase the efficiency of care by reducing diagnostic tests and referrals (Lutz and Bowers, 2000). The concept of patient-centered care covers two dimensions: (1) reorganization of services around patients' needs, requirements, wants, and expectations and (2) understanding patient-perceived needs, priorities, and expectations for health care (Lutz and Bowers, 2000). Patient-centered care should ensure access and continuity of health care, increase opportunities for patients to participate in the care process, provide self-management support, and coordinate care between settings (Bergeson and Dean, 2006).

Because of the increasing shift toward patient involvement in the care process, there has been much interest in examining the use of health care technologies by laypersons. For instance, automated defibrillators can be found in a variety of places, such as airports and other public places. Such devices need to be designed for people who do not have medical and clinical training. Callejas et al. (2004) show that naïve users and video-trained users were able to safely used two types of automated defibrillators.

Home care is a crucial extension of the health care system. Many health care activities occur at home, including self-help activities (following a balanced diet, maintain a balance of rest and activity, and engaging in the mental stimulation necessary to promote cognitive function) and self-care activities (primary and secondary preventions activities recognized and endorsed by health professionals). There are many people involved in home care, such as patient, family members, professional caregivers, nurses, physical therapist, and nursing assistants. Many home health care activities are carried out by the patient only or aided by family members, these laypeople are expected to collaborate with professionals in order to get adequate information and share roles in decision making and critical responsibilities to carry out health and healing practices (Zayas-Caban and Brennan, 2007). Therefore, the principles of HFE play a vital role to improve patient safety in home care through understanding the conditions and environment at home, laypeople cognitive and physical capabilities, communication methods, tools and technologies, and involvement of laypeople in designing and implanting home care tools and technologies (Henriksen et al., 2009; Zayas-Caban and Brennan, 2007).

## 2.3 Participatory Ergonomics in Health Care

Participatory ergonomics is a powerful method for involving the end users in system design (Wilson, 1995). Participation has been used in a variety of human factors processes, such as implementing ergonomic programs (Wilson and Haines, 1997). According to Noro and Imada (1991), participatory ergonomics is a method in which end users of ergonomics (workers, nurses, patients) take an active role in the identification and analysis of ergonomic risk factors as well as the design and implementation of ergonomic solutions. Participatory ergonomics was used to involve nurses in a process of developing and evaluating a nursing bag system for home care nurses (Lee et al., 2006). The participatory ergonomics approach began with seeking input from the entire nursing population that would be affected and then forming a working group to represent this population. The working group carried out an iterative process to develop a prototype for the nursing population to evaluate.

Evanoff and colleagues have conducted studies on participatory ergonomics in health care (Bohr et al., 1997; Evanoff et al., 1999). In one study, they examined the implementation of participatory ergonomics teams in a medical center (Bohr et al., 1997). Three groups participated in the study: a group of orderlies from the dispatch department, a group of ICU nurses, and a group of laboratory workers. Overall, the team members for the dispatch and the laboratory groups were satisfied with the participatory ergonomics process, and these perceptions seem to improve over time. However, the ICU team members expressed more negative perceptions. The problems encountered by the ICU team seem to be related to the lack of time and the time pressures due to the clinical demands. A more in-depth evaluation of the participatory ergonomics program on orderlies showed substantial improvements in health and safety following the implementation of the participatory ergonomics program (Evanoff et al., 1999). The studies by Evanoff and colleagues demonstrate the feasibility of implementing participatory ergonomics in health care but highlight the difficulty of the approach in a high-stress, high-pressure environment, such as an ICU, where patient needs are critical and patients need immediate or continuous attention. More research is needed to develop HFE methods for implementing participatory ergonomics programs in health care. Those programs should lead to improvements in human and organizational outcomes (e.g., reduced work-related musculoskeletal disorders) as well as improved quality and safety of care. This research should consider the high-pace, high-pressure work environment of health care.

## 3 HUMAN FACTORS SYSTEMS APPROACHES APPLIED TO HEALTH CARE

Human factors experts working in health care agree on the need to adapt and adopt systems approaches in health care systems (Bogner, 2004; Cook and Woods, 1994; Vincent, 2004). In this section, we review selected human factors systems approaches that have been applied to health care.

## 3.1 Work System Model

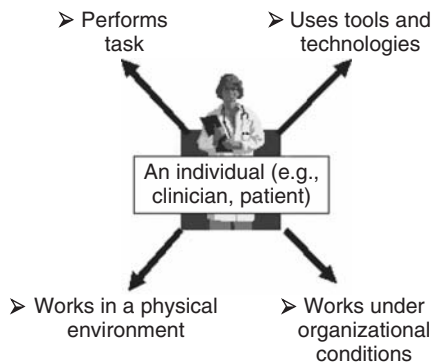
The work system model developed by Carayon and Smith describes the many different elements of work (Carayon and Smith, 2000; Smith and Carayon-Sainfort, 1989). The work system is comprised of five elements: the *individual* performing different *tasks* with various


**Figure 1** Adapted version of the work system model (Carayon and Smith, 2000; Smith and Carayon-Sainfort, 1989).

*tools and technologies* in a *physical environment* under certain *organizational conditions* (see Figure 1).

Given the complexity of the health care system (see Section 1), it is important to adopt a systems approach to the analysis of health care systems (Vincent, 2004). The work system model (Carayon and Smith, 2000; Smith and Carayon-Sainfort, 1989; Smith and Carayon, 2000) and its extension, the SEIPS [Systems Engineering Initiative for Patient Safety] model of work system and patient safety (Carayon et al., 2006b), has been applied to the analysis of medical errors, such as wrong-site surgery (Carayon et al., 2004a). An example of the application of the work system model is provided below: see Example 1 for how the work system model can be applied to the analysis of an ICU nurse. Gurses and colleagues provide additional information about the work system elements and performance obstacles experienced by ICU nurses (Gurses and Carayon, 2007, 2009; Gurses et al., 2009).

*Example 1: Work System Analysis of an ICU Nurse:* The following is a brief overview of the different work elements of an ICU nurse job.

*Task.* The tasks performed by the ICU nurses include (but are not limited to) direct patient care, continuous patient status assessment, carrying out physician orders, medication administration, and family interaction.

*Organizational Factors.* There is a range of organizational factors that are important to understand the job of an ICU nurse. Conflict among nurses and between physicians and nurses has been correlated with high stress and workload in ICUs (Gray-Toft and Anderson, 1981). The studies by Knaus, Rousseau, Shortell, Zimmerman, and colleagues have shown the importance of "caregiver interaction," which is a composite concept that includes several dimensions, such as communication and coordination (Knaus et al., 1986; Shortell et al., 1994).

*Environment.* Noise and other sensory disruptions abound in the modern ICU setting (Topf, 2000). The physical environment is often crowded and messy, with no one available to help with immediate clean-up of the

environment or equipment. The noise, the housekeeping, the level of constant activity, the size of the rooms or physicians' and nurses' personal space (if any), patients/staff coming and going, and crowds of people waiting to get a moment of the physician's or the nurse's time and attention may all make the physical environment more difficult to carry out tasks.

*Equipment and Technology.* The technology, tools, and equipment of modern ICUs have been identified as possible causes of errors and problems (Bracco et al., 2000). The availability of needed supplies, the type of supplies, tools, technology desired, the working condition of the equipment, and the new technology available or unavailable are but some of the tools and technology issues that can increase workload. Additionally, training and time for acclimation are needed to learn all the new tools and technology.

*How to balance the work system of an ICU nurse, in particular with regard to workload?*

As an example in the ICU setting, in efforts to reduce workloads and balance the overall work system, the physicians and nurses might review how often physical assessments are performed on the patients and who performs them. Typically, both the nurse and the physician perform a patient physical assessment every hour, or as needed by the patient's condition. Under this system, both the physician and the nurse perform the patient physical assessment and enter it into the patient's records. The process takes the health care provider at least several minutes or more, depending on the patient's status, out of every hour. This takes time away from other tasks and/or professional activities associated with the patient's care. In addition, others, such as specialty consultation services, may be waiting to review the patient record currently in use for the patient assessment. To balance this problem, the ICU physicians and nurses may redesign the patient assessment system based on clinical expertise and cooperation among the physicians and the nurses involved.

### 3.2 Care Processes

As highlighted in the SEIPS model of work system and patient safety (Carayon, et al., 2006b) and in the classic model of quality of care by Donabedian (1988), care processes are critical for understanding quality-of-care outcomes. According to Donabedian (1988), a care process is what is being done to the patient. A care process can be analyzed using the work system model (Carayon et al., 2006b; Smith and Carayon-Sainfort, 1989): It involves various people (e.g., physician, nurse, patient) who perform a range of care tasks (e.g., nurse administering medication) using various tools and technologies (e.g., physician using a stethoscope) in a physical environment (e.g., patient room) under certain organizational conditions (e.g., coordination between primary-care physician and specialist). Therefore, the performance of care processes is influenced by the various work system characteristics of different people involved in the process.

As an example, the outpatient surgery process is comprised of major steps, including patient work-up prior

to day of surgery, five steps occurring on the day of surgery (i.e., patient admission and preparation, patient surgery, first-stage patient recovery, second-stage patient recovery and discharge), and patient recovery at home (Carayon et al., 2006a). At each stage of the process, various performance obstacles occur that can affect the quality of care provided to the surgery patients. A survey of outpatient surgery staff highlighted communication to patient and coordination among various providers as the major performance obstacles (Carayon et al., 2006a). A follow-up study examined the specific phase of preoperative outpatient surgery and identified a range of facilitators and obstacles to information flow in the care transitions (Schultz et al., 2007).

Care transitions in the patient journey can be particularly vulnerable because of information flow problems (Coleman, 2003; Coleman and Berenson, 2004). However, care transitions also represent an opportunity for error detection and recovery (Cooper, 1989; Perry, 2004; Wears et al., 2003). Given the many challenges presented by care transitions, there needs to be further research to understand the functions of care transitions and their role in patient safety and quality of care. Human factors research in this area is only beginning (Patterson et al., 2004; Patterson and Wears, 2010) and should be further encouraged.

### 3.3 Levels of System Analysis

There is increasing recognition in the human error literature of the different levels of factors that can contribute to human error and accidents (Rasmussen, 2000). If the various factors are aligned "appropriately" like "slices of Swiss cheese," accidents can occur (Reason, 1990). According to Rasmussen (1997), the sociotechnical factors involved in safety include (1) government, (2) regulators and associations, (3) company, (4) management, (5) staff, and (6) work. These different levels of sociotechnical factors interact and influence each other to produce accidents. Karsh and Brown (2010) have proposed a macroergonomic model of patient safety that highlights the need to describe, measure, and analyze different system levels.

### 3.4 Health Care Team as a System

Over recent decades, teams have been a strategic choice for many organizations in various areas such as aviation, military, industry, health care, nuclear power plants, and engineering project teams; many of these teams carry out complex and difficult tasks (Salas et al., 2008). Work teams are defined as "small groups of interdependent individuals who share responsibility for outcomes for their organizations" (Sundstrom et al., 1990, p. 120).

In health care, people work together in a variety of teams, for example, multidisciplinary teams caring for patients with specific clinical conditions (e.g., ICU team) and operating room teams. Members of the teams often come from different disciplines and educational background (Kohn et al., 1999). For instance, multidisciplinary rounds (MDR) represent a patient-centered model of care that can facilitate interdisciplinary collaboration in the ICU that is a highly complex and dynamic work setting where interdisciplinary collaboration can

have a significant impact on patient outcomes. Teamwork can take different forms (e.g., autonomous work groups versus manager-led teams) and be implemented in various modes (e.g., temporary versus permanent teams) (Sainfort et al., 2001b).

The 1999 IOM Report on "To Err is Human—Building a Safer Health System" (Kohn et al., 1999) recommends the establishment of team training programs for personnel in critical-care areas, such as an emergency department, ICU, and operating room. The report published in 2001 by the Institute of Medicine on "Crossing the Quality Chasm" (Institute of Medicine Committee on Quality of Health Care in America, 2001) goes one step further and emphasizes the need for developing effective teams in order to meet the six challenges of providing safe, effective, efficient, personalized, timely, and equitable care.

The HFE discipline has contributed significantly to the science and practice of teams, teamwork, and team performance (Salas et al., 2008). Salas and colleagues (2008) summarized the following six major findings in the area of team performance over the past five decades from a human factors perspective: (1) shared cognition is important in team performance; (2) shared cognition can be measured; (3) team training promotes teamwork and enhances team performance; (4) team performance can be modeled; (5) researchers have defined factors that influence team performance such as shared collective orientation; and (6) well-designed technology can improve team performance. There has been significant human factors research on teamwork in health care. For example, Guerlain et al. (2002) have developed a system for evaluating performance of surgery teams in the operating room. Helmreich and colleagues (Helmreich and Merritt, 1998; Helmreich and Schaefer, 1994) have examined the performance of operating room teams.

The Department of Defense (DoD) and the Agency for Healthcare Research and Quality (AHRQ) developed a systematic approach of Team Strategies and Tools to Enhance Performance and Patient Safety (TeamSTEPPS™) to integrate teamwork into practice and improve team performance in health care (King et al., 2008). Accordingly, TeamSTEPPS™ is learning material designed to improve patient outcomes by educating teamwork among health care providers (Guimond et al., 2009). Figure 2 shows the TeamSTEPPS instructional framework (King et al., 1999).

## 4 HFE OF MEDICAL DEVICES AND INFORMATION TECHNOLOGY

In health care, technologies are often seen as an important solution to improve quality of care and reduce or eliminate medical errors (Bates and Gawande, 2003; Kohn et al., 1999). These technologies include organizational and work technologies aimed at improving the efficiency and effectiveness of information and communication processes (e.g., computerized order entry provider systems and electronic medical record systems) and patient care technologies that are directly involved
**Figure 2** TeamSTEPPS framework for health care teams (King et al., 2008)

in the care processes (e.g., bar code technology or smart infusion pump technology for medication administration). The 1999 IOM report recommends adoption of new technology, such as bar code technology, to reduce medication errors (Kohn et al., 1999). However, implementation of new technologies in health care has not been without troubles or work-around. For example, the study of Patterson and colleagues (2002) shows some of the negative side effects of bar code medication administration technology, such as degraded coordination between nurses and physicians. Technologies can change the way work is being performed, and because health care work and processes are complex, negative consequences of new technologies are possible (Cook, 2002). In this section, we focused on the following HFE issues related to medical devices and information technology: (1) design of technology (e.g., usability), (2) impact of technology on the work system, and (3) implementation of technology.

### 4.1 Health Care Technology Design

The human factors characteristics of the health care technologies' design should be studied carefully (Battles and Keyes, 2002). An experimental study by Lin et al. (2001) showed the application of human factors engineering principles to the design of the interface of an analgesia device. Results showed that the new interface led to the elimination of drug concentration errors and the reduction of other errors. A study by Effken et al. (1997) shows the application of a human factors engineering model, that is, the ecological approach to interface design, to the design of a hemodynamic monitoring device. New health care technologies may bring their own "forms of failure" (Battles and Keyes, 2002; Cook, 2002; Reason, 1990). For instance, bar coding technology can prevent patient misidentifications, but the possibility exists that an error during patient registration may be disseminated throughout the information system and may be more difficult to detect and correct

than with conventional systems (Wald and Shojania, 2001).

New digital technologies such as surgical navigation or robotic systems are changing the clinical working systems dramatically. The risk–benefit assessment of those emerging technologies is difficult. Such an assessment has to consider the utilization of the technologies and their impact on task completion as well as the long-term impact, such as the patient's condition five years after intervention. For instance, Cao and Taylor (2004) examined the impact of the introduction of a new robotic technology on performance and communication patterns in the operating room (OR) team. The new technology, a remote master–slave surgical robot, removes the surgeon from the surgical site. Results of the human factors analysis show large differences in amount and type of information required by the surgeon in order to accomplish the procedure with and without the robot. In the robotic work system, the surgeon has additional tasks to perform and additional decisions to make, therefore increasing the cognitive load.

One important health care technology design characteristic is the usability of a medical device. To what extent does the medical device perform in a safe, easy-to-use manner? For a given task and a unified group of users, usability is a measure of the fast (efficient), simple (effective), and satisfying use of a technical device (Bevan et al., 1991; Dumas and Redish, 1993; Ravden and Johnson, 1989; Staggers, 2003). In order to assess usability, various methods of usability engineering have been developed (Mayhew, 1999; Nielsen, 1992, 1993; Whiteside et al., 1988; Wiklund, 1993a). For the evaluation of the usability of medical devices, specific methods have been used, such as user questionnaire, usability inspection methods, and usability tests (Wiklund, 1993b, 1995). With the major push toward health information technology implementation throughout the U.S. health care system, the issue of usability of health information technologies such as electronic medical record and computerized provider order entry has received increasing attention (Koppel and Kreda, 2010; Li et al., 2006).

### 4.2 Health Care Technology Implementation

It is important to address issues of usability and usefulness of health care technology; however, in order to ensure the technology is used successfully and effectively, we also need to address implementation issues (Carayon and Karsh, 2000; Davis, 1993; Karsh, 1997; Venkatesh et al., 2002). The manner in which a new technology is implemented is as critical to its success as its capabilities and characteristics (e.g., usability) [see, e.g., Eason (1982) and Smith and Carayon (1995)]. For instance, inadequate planning when introducing a new technology designed to decrease medical errors has led to technology falling short of achieving its patient safety goal (Kaushal and Bates, 2001; Patterson et al., 2002). To promote end-user acceptance and effective use of technology, it is imperative to apply a human factors systems approach to technology implementation (Karsh, 2004). This proactive approach emphasizes simultaneous design of the technology and the work system, which aims at

achieving a balanced work system and preventing errors from happening in the first place.

### 4.2.1 Impact of Health Care Technology on the Work System

Whenever implementing a technology, it is essential to consider the work system factors that affect technology acceptance and satisfaction in the implementation plan (Karsh, 2004; Karsh and Holden, 2007; Smith and Carayon, 1995). We need to examine the potential positive and negative influences of the technology on the work system (Battles and Keyes, 2002; Sheridan and Thompson, 1994; Smith and Carayon-Sainfort, 1989). The implementation of technology in an organization has both positive and negative effects on the job characteristics that ultimately affect individual outcomes (quality of working life, such as job satisfaction and stress, and perceived quality of care delivered or self-rated performance) (Carayon and Haims, 2001). In a study of the implementation of an EHR system in a small family medicine clinic (Carayon et al., 2009b), a number of issues were examined: impact of the EHR technology on work patterns, employee perceptions related to the EHR technology and its potential/actual effect on work, and the EHR implementation process (Carayon and Smith, 2001). Employee questionnaire data showed that employees perceived increased dependency on computers and a small increase in perceived quantitative workload was found. This result was confirmed by the work analysis data, which indicated a dramatic increase in the amount of time spent on computers by the various job categories. While the EHR implementation did not change the amount of time spent by physicians on patient care, the work of clinical and office staff changed significantly. For clinical and office staff, the main differences between the pre- and the post-EHR implementation were decreases in time spent on distributing charts, transcription, and other clerical tasks.

### 4.2.2 Principles of Health Care Technology Implementation

The most common reason for failure of technology implementations is that the implementation process is treated solely as a technological problem, and the human and organizational issues are ignored or not recognized (Eason, 1988). Lorenzi and her colleagues (2009) discussed the implementation of an EHR system in small ambulatory practice settings. They divided the implementation process into several stages, including decision, selection, preimplementation, implementation, and postimplementation. Through this process, the authors emphasized the importance of developing a flexible change management strategy; identifying a champion; assessing and redesigning workflow; understanding financial issues; conducting training; and evaluating the implementation process. In a similar vein, Blumenthal and Epstein (1996) comment that "the science of behavior modification" has not been applied much in the health care field. It is important to consider the human and organizational aspects that can hinder or foster technological change and use in health care systems.

The way change is implemented (i.e., the process of implementation) is central to the successful adaptation of organizations to changes (Karsh, 2004; Korunka et al., 1993; Tannenbaum et al., 1996). A "successful" technology implementation can be defined by its "human" and organizational characteristics: reduced/limited negative impact on people (e.g., stress, dissatisfaction) and on the organization (e.g., delays, costs, reduced performance) and increased positive impact on people (e.g., acceptance of change, job control, enhanced individual performance) and on the organization (e.g., efficient implementation process). Various principles for the successful implementation of technological change have been defined in the human factors and ergonomics and business research literature (see Table 2).

*Employee participation* is a key principle in organizational change (Coyle-Shapiro, 1999; Korunka et al., 1993; Smith and Carayon, 1995). There is research and theory demonstrating the potential benefits of participation in the workplace. Benefits include increased employee motivation and job satisfaction, enhanced performance and employee health, more rapid implementation of technological and organizational change, and more thorough diagnosis and solution formation for ergonomic problems (Gardell, 1977; Lawler, 1986; Lawler III, 1986; Noro and Imada, 1991; Wilson and Haines, 1997). End-user involvement in the design and implementation of a new technology is a good way to help ensure a successful technological investment. Korunka and his colleagues (Korunka and Carayon, 1999; Korunka et al., 1993, 1997) have empirically demonstrated the crucial importance of end-user involvement in the implementation of technology to the health and well-being of end users. Previous research has made the distinction between *active participation*, where the employees and the end users are actively participating in the implementation of the new technology, and *passive participation*, where the employees and end users are *informed about and communicated with* regarding the new technology (Carayon and Smith, 1993).

*Communication* among end users, decision makers, and technical support is also important. It promotes the transmission of information about the implementation to end users to reduce uncertainty and enables end users to obtain quick *feedback* to questions about new technologies through the implementation process (Karsh and Holden, 2007). Feedback is an important element in order to change behavior (Smith and Smith, 1966) and has been emphasized as an important organizational design element in the health care literature (Evans et al., 1998; McDonald et al., 1996). The importance of feedback in managing the change process is also echoed in the literature on quality management [see, e.g., the plan–do–check–act cycle proposed by Deming (1986)].

Technology implementation in health care systems should be considered as an evolving process that requires considerable *learning* and adjustment (Mohrman et al., 1995). An aspect of learning in the context of technological change is the type and content of *training* (e.g., Frese et al., 1988; Gattiker, 1992). Training, which is designed to promote the transfer of knowledge and skills into work practice, can improve

**Table 2 Principles of Technology Implementation**

| Principles of Technology Implementation | Description | Examples in Health Care |
|---|---|---|
| Employee participation | Extent to which health care staff is involved in various decisions and activities related to the technology implementation (active participation)<br>Information/communication about the technology implementation (passive participation) | Involve nurses and pharmacists in implementing a bar code medication administration system |
| Communication and feedback | Extent to which health care staff is kept informed of the technology implementation through various means of communication and extent to which feedback is sought after/during the technology implementation | Develop structured communication networks between supervisors and health care staff to deal with the new technology<br>Provide feedback to health care staff to show them that their ideas are taken seriously |
| Learning and training | Extent and nature of the training provided to the health care staff and extent of learning by the health care staff<br>Use of simulation techniques | Design a science-based training program to train certified nursing assistants in nursing homes<br>Create a new simulated health care work system with new processes and structures<br>Use a simulator to help physicians try out new functions on a new computerized order entry system |
| Top-management commitment | Extent to which top management directly participate in the technology implementation | Conduct structured program for technology implementation and show health care staff where responsibility for the different aspects of the changes lie<br>Make resources available to the implementation of each of the other principles |
| Project management | Activities related to the organization and management of the technology implementation itself<br>Use of pilot testing | Analyze the current health care system into which the new technology will be implemented<br>Facilitate the implementation team to design and implement the change process<br>Implement pilot testing to debug the new technology in the context of use in nursing units, operating rooms, or outpatient clinics |

self-efficacy and demonstrate usability and usefulness of new technologies (Karsh and Holden, 2007). A questionnaire survey of 244 family practice residents' perceptions regarding the use of EHR showed that those residents who felt that the EHR-related training was adequate were more likely to report benefits due to the EHR, such as decreased time to review past records, increased documentation accuracy, and increased consistency of health maintenance (Aaronson et al., 2001). *Simulation* is an effective method of training delivery in health care (Issenberg et al., 1999; Nishisaki et al., 2007; Woodward et al., 2010). It is suggested to be designed into the implementation process as a means for planning, training, and continuous learning (Karsh and Holden, 2007).

The prerequisite to implementing all principles discussed above is the *commitment of top management*. True top-management commitment enables resources available to promote other strategies of implementation design and to ensure a successful implementation (Karsh, 2004; Karsh and Holden, 2007). An important indicator of top-management commitment is the presence of a structured program for implementation (Smith and Carayon, 1995).

It is suggested that *project management* concepts and methods (e.g., project structure, roles, timeline) be utilized for technology implementation (Carayon et al., 2009b; Lorenzi et al., 2009). Keys to a successful implementation project include (1) analyzing needs and preferences of medical providers and key administrators; (2) selecting a strong physician leader to champion the

project; (3) hiring a project manager with dedicated time to lead the project; (4) forming a project leadership team of key personnel from clinical, office, and information system staff; (5) gathering needs of other users early in the planning process; and (6) obtaining buy-in by clinicians and office staff early in the process. In many implementations of health care technology, *pilot testing* is conducted to identify additional problems that are not uncovered during proactive system analysis. Besides, it is also applied to the design of technologies themselves and other support systems to ensure successful implementation.

## 5   PATIENT SAFETY AND MEDICAL ERRORS

The discipline of HFE has much to offer to the understanding, reduction, and prevention of medical errors and therefore the improvement of patient safety (as well as employee safety) (Bogner, 1994).

### 5.1   Patient Safety

The safety of health care is very much discussed across the world, for example, in Australia (McNeil and Leeder, 1995) and the United Kingdom (U.K. Department of Health, 2002). In the United States, the 1999 publication of a report by the IOM has raised the level of public awareness regarding medical errors and patient safety (Kohn et al., 1999).

A 2000 report published by the U.K. Department of Health provides some data on the extent to which the English health care system fails to provide high-quality, safe care (U.K. Department of Health, 2002). About 400 people die or are seriously injured in adverse events involving medical devices. About 10,000 people report having experienced serious adverse reactions to drugs. The U,K, National Health Service pays around 400 million a year settlement of clinical negligence claims. Data for the United States indicate that "Preventable adverse events are a leading cause of death in the United States" (Kohn, et al., 1999, p. 26). It has been suggested that at least 44,000 and perhaps as many as 98,000 Americans die in hospitals each year as a result of medical errors. Much debate has occurred around the validity of those numbers (Leape, 2000). Whereas there is disagreement regarding the frequency of medical errors in health care, most people agree that system changes need to occur to improve the quality and safety of care (Institute of Medicine Committee on Quality of Health Care in America, 2001).

Different HFE approaches to patient safety emphasize the characteristics of the system (or structure) in which care processes occur and which lead to patient outcomes (Bogner, 2004, 1994; Moray, 1994). Therefore, the discipline of HFE has an important role to play in helping in the human-centered design of systems and processes in order to achieve both positive individual and organizational outcomes as well as improved patient outcomes (improved quality and safety of care) (Sainfort et al., 2001a).

### 5.2   Human Errors in Health Care

In the HFE literature, numerous models of and approaches to human error have been developed to understand the mechanisms leading to accidents and injuries. One of the most prevalent human error models was defined by Rasmussen (1983) and Reason (1990). This model defines two types of human error: (1) slips and lapses and (2) mistakes. In turn, mistakes can be categorized as resulting from either rule-based behavior or knowledge-based behavior. This taxonomy of human error has been successfully applied to analyze and evaluate accidents in a range of domains, including the nuclear industry (Moray, 1997; Rasmussen, 1982), aviation (Helmreich and Merritt, 1998), and more recently health care (Reason, 2000; Sexton et al., 2000).

Another important distinction brought up by the human error literature is that of active and latent errors (Reason, 1990). Active errors have effects that are felt or seen immediately and are associated with the performance of the "front-line operators," such as nurses. Latent errors are more likely to be related to organizational and management factors that are removed in both time and space from the front-line operations. The distinction between active and latent failures, or between the "sharp end" and the "blunt end" (Cook and Woods, 1994), has led to the recognition of the importance of organizational, management, and procedural factors in errors and accidents. This had led to the development of a number of models describing the "chain of events" that can lead to an accident or an adverse outcome. For instance, Vincent and colleagues (1998) proposed an organizational accident model that identifies the following chain of events: latent failures (i.e. management decision, organizational processes) influence conditions of work (i.e. workload, supervision, communication, equipment, knowledge/ability), which in turn can lead to unsafe acts or active failures (i.e., omissions, action slips/failures, cognitive failures, violations) that can lead to accidents or adverse outcomes if the barriers or defense mechanisms are insufficient.

Over the last decades, error recovery has been a focus of research in domains other than health care, including aviation, traffic control, process industry, and human computer interaction. In health care, error recovery mechanisms are important in a range of processes (e.g., medication) in order to improve patient safety and quality of care (Kanse et al., 2006). There are three phases involved in error recovery: (1) the detection of the failures or at least the immediate resulting deviation or problem, (2) followed by explanation of the problem and its causes, and (3) countermeasures aimed at returning to the normal situation or at least limiting the consequences, including recurrences, or even entirely skipping one or both of these last two phases, Figure 3 shows a graphical representation of the error recovery process (Kanse et al., 2006).

Numerous work system factors influence error recovery: person-related factors such as experience and knowledge, technical factors such as the design of the workplace, equipment and interfaces, and organizational factors such as culture, work design, and procedures and
**Figure 3** Model of error recovery process (Kanse et al., 2006).

management priorities (Kanse, et al., 2006). Improving these factors may contribute to (complete or partial) recovery once an error or failure has occurred, thus preventing or reducing the negative consequences of that error or failure (Van Der Schaaf and Kanse, 2000). Human factors and ergonomic principles can improve work system factors that influence error recovery through better understanding human cognitive and physical abilities and training to improve person-related factors; technology design, implementation and evaluation, cognition, and situation awareness to improve technical factors; and job design and task analysis to improve organizational factors.

In health care, error recovery has been studied in domains such as cardiac surgery (Carthey et al., 2001), hospital pharmacy (Jonathan et al., 2002; Kanse et al., 2006), critical-care units (Dykes et al., 2010), and surgery (Catchpole et al., 2008).

### 5.3 Error Reporting

Medical errors are a leading cause of death. The IOM report (Cohen, 2000) estimated that more than 1 million preventable errors occur annually in the United States and about 44,000–98,000 result in death. In addition, medical errors lead to loss of time, resources, and credibility and cost of delays and legal action (Holden and Karsh, 2007). Medical error reporting has been encouraged and implemented in order to enhance patient safety (Anderson et al. 2009; Cohen, 2000; Holden and Karsh, 2007; Karsh et al., 2006). The World Alliance for Patient Safety program of the World Health Organization (WHO) (2005) has published draft guidelines for adverse-event reporting and learning systems that can facilitate the improvement or development of reporting systems for patient safety.

Error reporting may enhance patient safety by providing information to guide the development of error prevention strategies and recommendations for work system and process redesign. Other benefits of error reporting systems include (1) opportunities to educate and train health care providers, management, patients, and family members about the importance of patient safety; (2) mechanism to provide manufacturer

feedback about issues with their products, devices, and technologies; and (3) demonstrated commitment to patient safety that can increase public assurance and awareness (Karsh et al., 2006). However, error reporting systems are not implemented widely in U.S. health care organizations (Farley et al., 2008). Even when a reporting system is implemented, the amount of underreporting to national monitoring organizations is estimated to range from 50 to 96% of discovered medical errors annually (Barach and Small, 2000).

Many researchers have examined barriers and concerns related to error reporting (Brady et al., 2009; Evans et al., 2006; Firth-Cozens, 2002; Holden and Karsh, 2007; Lawton and Parker, 2002; Uribe et al., 2002). A review of the literature categorizes these barriers into the following: (1) busyness and fatigue; (2) difficult reporting methods and lack of knowledge about the existence of the reporting system; (3) adverse consequences of reporting; and (4) lack of perceived system usefulness (Holden and Karsh, 2007). Several factors determine the success and usefulness of an event reporting system: (1) the culture of an organization; (2) the provision of standardized methodologies; (3) classification systems and tools for analysis; and (4) and the feedback given to staff (Kaplan and Rabin Fastman, 2003).

Health care professionals differ in their attitudes to reporting medication errors. Recent studies found that physicians are unlikely to report less serious medication errors; nurses and pharmacists are likely to report all types of errors, including less serious as well as serious medication errors, despite their fears of receiving disciplinary action (Sarvadikar et al., 2010).

Human factors play a vital role in enhancing error reporting systems (Johnson, 2007). Many studies used human factor theories and principles in designing, implementing, evaluating, and assessing error reporting systems such as usability evaluation, user-centered design, change management, workload assessment, and decision-making strategies. For instance, Karsh et al. (2006) used sociotechnical theory with focus on the concept of end-user design to explore barriers and facilitators for the design of a statewide medical error reporting system. Kaplan and colleagues (Battles et al., 1998; Callum et al., 2001) designed and

**Table 3 HFE Issues in Health Care Addressed in Other Chapters**

| More on . . . cognitive ergonomics | See Chapter 5 on information processing and Chapter 7 on decision making |

implemented a near-miss event reporting system for transfusion medicine aimed at improving transfusion safety. Johnson (2007) reviews the human factors of health care reporting systems by examining recent initiatives from the IOM and range of national patient safety agencies. He also discusses the problem of underreporting and introduces different architectures for error reporting systems.

## 6 FUTURE NEEDS FOR HFE IN HEALTH CARE

The discipline of HFE has much to offer in order to improve the performance, quality, and safety of health care systems. Given the people-intensive, people-centered, people-driven characteristic of health care, HFE can provide the models, concepts, and methods necessary to consider the people component of health care systems.

Some of the HFE models, concepts, and methods need to be adapted to the characteristics of health care (see Section 1). For instance, a key principle of HFE is user participation and involvement. Two characteristics of health care contribute to the difficulty of implementing this principle. First is the definition of the user (see Section 2). Second, health care is a very dynamic changing environment with much time pressure. This makes the application of participatory approaches difficult when the "users" have little time to spare and spend on those HFE activities (see Section 2.3). More work needs to be done to pursue and expand the effort of considering the unique characteristics of health care in HFE work. Hignett (2003) also argues for the discipline of HFE to develop "more context-sensitive methodology" for health care.

Another important issue in HFE in medicine is the necessity of combining HFE technical knowledge with health care knowledge. For instance, in observing medical work such as anesthesia processes, the observer needs to have knowledge of anesthesia in order to meaningfully interpret the activities (Norros and Klemola, 1999). On the other hand, Weinger et al. (1994) developed a highly structured task analysis that could be used by non–medically trained observers in the observation of anesthesiologist's work. Carayon and colleagues (2004b, 2004c) discussed criteria to consider when combining HFE and health care knowledge in observations

of clinical work. The impact of HFE on medicine will be strengthened by encouraging "encounters" between HFE and medicine knowledge and the development of collaborations between HFE and health care subject matter experts.

## 7 CONCLUSION

In this chapter, we have reviewed a number of HFE issues in health care; but a number of important HFE issues were not reviewed. For instance, the issue of working conditions and workload in health care has not been addressed in this chapter, but much has been written on this topic, in particular regarding nursing (Carayon et al., 2003; Institute of Medicine Committee on the Work Environment for Nurses and Patient Safety, 2004). Table 3 lists other important HFE issues in health care that are addressed by other chapters of this handbook.

# CHAPTER 58

# HUMAN FACTORS AND ERGONOMICS IN MOTOR VEHICLE TRANSPORTATION

**Paul A. Green**
**University of Michigan Transportation Research Institute (UMTRI)**
**Ann Arbor, Michigan**

## 1 CHAPTER ORGANIZATION AND PHILOSOPHY

This chapter provides background material, design guidelines, reference data, and equations that human factors engineers can use to design and evaluate motor vehicles to make them safe, useful, and easy to use. In addition, this chapter also identifies areas in which human factors research is needed.

Coverage of this chapter is intended to be global, though until now much of the research has been conducted in the United States, Western Europe, and Japan. Accordingly, information is lacking on China and India, important vehicle markets.

## 2 DRIVING CONTEXT (PEOPLE, VEHICLES, ROADS)

### 2.1 Who Are the Users, the Drivers?

In their seminal paper, Gould and Lewis (1985) describe three key principles to design useful and easy-to-use systems. The first is "early focus on users and tasks." Given that principle, the relevant questions are: Who drives? What do people drive? Where and when do they drive?

Legally, almost any adult can drive, subject to passing a test. Thus, the age distribution of potential drivers should closely match the distribution of adults in that country, though there are countries with gender restrictions for licensing, such as Saudi Arabia. There is little data on the distribution of driver age in aggregate for the world or by country, except for the United States [Figure 1; Federal Highway Administration (FHWA), 2009a]. Notice that most Americans still drive beyond age 65. To provide a specific example, 5% of all drivers in the United States are ages 65–69 and 94% of those in that age group are licensed drivers. Thus, older adults commonly drive and should be expected to use everything produced, even if they are not the intended market segment. Older drivers are likely to be the most challenged group for ingress/egress, reach, and telematics use.

In the United States, licensing requirements for passenger car drivers typically consist of a vision test, usually static visual acuity, a test of knowledge of driving rules and laws, and a brief driving test [Eby and Molnar, 2008; Leonard, 2002; International Council of Ophthalmology (ICOPH), 2002, 2006; http://www.md support.org/library/drivingrequirements.html, retrieved
**Figure 1**   Age distribution of U.S. drivers (developed from FHWA, 2009a, Table DL-20).

September 9, 2010]. In other countries, licensing requirements vary quite widely, and for some, obtaining a license may require minimal skill, training, or knowledge. Corruption can also be an issue (Bertrand et al., 2008). Globally, licensing requirements are generally more stringent for drivers of buses, trucks (especially large trucks), and vehicles with trailers (http://en .wikipedia.org/wiki/European_driving_licence, retrieved September 9, 2010).

### 2.2   What Do People Drive?

How are vehicles classified? In the United States, for fuel economy comparisons, cars are grouped into size categories (e.g., minicompact, midsized) by the Environmental Protection Agency based on interior volume (http://www.fueleconomy.gov/feg/info.shtml#size classes). Europe has two schemes, one as part of its Euro Car Segment description (ranging from A to F, with F being the largest) and a second, similar five-category scheme as part of its Euro New Assessment Program (http://en.wikipedia.org/wiki/Vehicle_size_class). Thus, in Europe, a particular vehicle might be described as B class, which would be a subcompact. China and Japan have different schemes. Multiple schemes exist due to practical and historical national differences in disposable income for purchasing vehicles, the price of fuel, road width, and the availability of parking. Noteworthy, for example, is the Kei (Keijidosha) class of cars in Japan, which are less than 3.4 m long and have engines of less than 660 cc.

Trucks are classified by their gross weight and the number of axles. Large trucks are either straight trucks or tractor-trailers. Tractor-trailers vary in their cab design (conventional or cab over engine), have two to four axles for the cab, and vary in the length of the semitrailer. In the United States, tractor-trailers usually have a single trailer, commonly 40 ft long but varying anywhere from 28 to 53 ft. The largest tractor-trailer combinations are Australian road trains, where a single tractor may pull three or four trailers. In Europe and Japan, straight trucks are more common, because there is less space to maneuver a vehicle.

Finally, one needs to consider the wide range of mopeds, motorcycles, and various types of three-wheel vehicles, which are relatively more common outside North America, especially in Asia.

Which vehicles are most popular? According to the International Organization of Motor Vehicle Manufacturers (OICA) (http://www.oica.net/category/ production-statistics/), there were approximately 51.1 million cars, 7.8 million light commercial vehicles, 1.3 million heavy commercial vehicles, and 0.3 million heavy buses produced in 2009. Though cars predominate in number, heavy vehicles and buses tend to be much more expensive on average than cars and accumulate more mileage per year and over their lifetime.

As shown in Table 1, China is the largest market for motor vehicles, with sales in China increasing by 45% between 2008 and 2009. India, which also has a large

**Table 1  2009 Sales for New Cars by Country**

| Rank | Country | Volume | Rank | Country | Volume |
|---|---|---|---|---|---|
| 1 | China | 13,600,000 | 6 | France | 2,270,000 |
| 2 | United States | 10,400,000 | 7 | Italy | 2,160,000 |
| 3 | Japan | 4,600,000 | 8 | United Kingdom | 1,990,000 |
| 4 | Germany | 3,870,000 | 9 | Russia | 1,470,000 |
| 5 | Brazil | 3,140,000 | 10 | Canada | 1,460,000 |

*Source:* http://www.thetruthaboutcars.com/2010/01/car-sales-around-the-world-in-2009-mostly-down/

population, has not yet seen such rapid growth, but it is expected in the future.

The kinds of vehicles that are popular vary among regions of the world. In the United States, the best-selling vehicle for many years has been the Ford F-series pickup truck, with an estimated half million to be sold in 2010, extrapolating from published data (http://online .wsj.com/mdc/public/page/2_3022-autosales.html). The number 2 vehicle is the Chevrolet Silverado, another pickup truck, and vehicles 8 and 9 of the top-10 best sellers are two sport utility vehicles (SUVs) (Honda CR-V and Ford Escape). Pickup trucks, such as the Ford F series, are uncommon in other parts of the world.

Much smaller than the car and truck markets are the markets for construction equipment, agricultural equipment, forestry equipment, and mining equipment. To provide some perspective, in 2010 an estimated 169,300 tractors of all types will be sold in the United States and an estimated 10,300 self-propelled combines, extrapolating from published data (http://www.aem.org/ MarketInfo/Stats/Reports/AgTCR-US/). The design of these work vehicles (e.g., motor graders, asphalt pavers, tractor loader backhoes, feller bunchers) is quite specialized and beyond the scope of this chapter.

Finally, there is also a separate body of literature concerning the design of military vehicles. To find information on them, readers should use Google to search for publications from the U.S. Army Human Research and Engineering Directorate of the Army Research Laboratory in Aberdeen, Maryland.

## 2.3 On What Kinds of Roads Do People Drive (and How Are Roads and Traffic Described)?

Most driving, at least in the developed world, occurs on roads. Roads are classified hierarchically [Transportation Research Board (TRB), 2010]. At the lowest level are local roads, the roads that go to individual homes or businesses. Above them are collectors, into which local roads intersect. Above them are minor arterials and major arterials, each of which aggregates traffic from lower subclasses. Above them are limited-access highways, which have only a few entrances and exits, and are generally divided. Expressways and interstate highways in the United States, TransCanada roads in Canada, and motorways in other parts of the word are typically limited-access highways.

In the United States, local roads comprise about two-thirds of the rural and urban lane miles (not road miles) but carry only about 13% of the traffic (measured in vehicle miles traveled). In contrast, interstate highways, representing 3% of all lane miles, carry about 25% of the traffic. (See http://www.fhwa.dot.gov/ policyinformation/statistics/2008/hm260.cfm.)

Data on the number of lane miles and vehicle miles traveled by road type are difficult to obtain for other than the United States and may be inaccurate. The best source of data on miles of public roads, the International Road Federation (IRF, 2009) report, lists a number of countries (e.g., Australia, Brazil) as having zero miles of "motorways," which seems counterintuitive.

Roads are also classified by the entity responsible for their construction and maintenance. In the United States, major roads that cross state boundaries (interstate highways, U.S. routes) are the responsibility of the federal government. Below them are state or provincial roads, for which those governmental units are responsible. Finally, there are usually county and sometimes city or town roads for which those governmental units are responsible.

Driving is also affected by a road's physical characteristics—the number of lanes, lane width (typically 12 feet on U.S. Interstates), shoulder width and surface material, presence of barriers and medians (and their size), clear zones, curve radii, slopes, and so forth. Urban roads will have gutters and curbs. Many of these characteristics are described in detail in the *Highway Capacity Manual* (TRB, 2010) and the American Association of State and Highway Transportation Officials (AASHTO, 2004) "Green Book." Except for studies in which an author with knowledge of civil engineering is involved, driving studies often provide insufficient detail in describing test roads (e.g., a two-lane rural road).

Driving is also influenced by traffic and should be reported in a quantitative manner in all studies of driving. Traffic is generally described as the number of vehicles per lane per hour and the percentage of the traffic that is composed of trucks, though the percentage of the vehicles that are bicycles or motorcycles is also of interest. The amount of traffic is often categorized using the level of service (LOS), an indicator of delay. LOS is analogous to grades in school ranging from A to F, with A being excellent/free flow and F being failing/breakdown flow/traffic jam (AASHTO, 2004; TRB, 2010; http://en.wikipedia.org/wiki/Level_of_service).

Signs and signals also influence traffic flow. Similar to the LOS scheme for road segments, there is also an LOS grading scheme for delays at traffic signals. (A is less than or equal to 10 s for a traffic signal, and F is greater than or equal to 80 s.)

Finally, and also important, is how roads are marked and signs are designed and placed. In the United States, road markings and signs are specified in the *Manual of Uniform Traffic Control Devices*, commonly referred to as the MUTCD (FHWA, 2009b) and the AASHTO (2004) "Green Book." In Europe and elsewhere, signs and markings follow the Vienna Convention on Road Traffic [United Nations Economic Commission for Europe (UNECE), 1968].

Most driving studies have people drive without purpose, yet the purpose often provides a context as to how people drive and influences the road driven, time constraints, number of passengers, and cargo. That information, in turn, has implications for design requirements for vehicle handling and ride, stowage, and other characteristics. Vehicle travel is one of the few topics in this chapter for which there is good worldwide data (from national travel surveys), data that are publically available on the Internet. As of the date of this chapter, the Wikipedia entry on travel surveys has an extensive listing. The best-known travel studies are from the United States [Research and Innovative Technology Administration (RITA), 2003] and the U.K. Department of Transport (DfT, 2010). Travel studies contain data on the purpose of trips (work, social, shopping, etc.),

the transportation mode used (car, bus, etc.), the trip duration, the time of day, the number of occupants if by car, driver characteristics, and so forth. As an example of the scope, the 2001–2002 U.S. travel survey had interviews from over 26,000 households and was supplemented later by another 40,000 interviews. Additional information can be obtained from Transportation Research Board Committee ABJ40 (Committee on Travel Survey Methods).

## 3 WHAT HAPPENS WHEN PEOPLE DO NOT DRIVE WELL?

### 3.1 Crash Databases and Statistics

According to the World Health Organization (WHO, 2009), more than 1.2 million people die in motor crashes each year, or approximately 3300 per day. Furthermore, somewhere between 20 and 50 million people suffer injuries each year. Motor vehicle crashes are the ninth leading cause of death and are the leading cause of death of adults ages 15–29 (WHO, 2009). If the current trends continue, by the year 2030, traffic crashes will become the fifth largest cause of death after heart attacks, stroke, pneumonia, and lung diseases of various types (WHO, 2009).

Shown in Table 2 is an example of selected national differences drawn from the WHO's *World Report on Road Traffic Injury Prevention* (Peden et al., 2004). Notice that the more developed countries have a lower percentage of pedestrian fatalities, but that is not always the case (e.g., Thailand). Also note that in the Netherlands the number of cyclist fatalities is relatively large, as bicycle use is very common there. To provide some additional context, the National Bureau of Statistics of China (http://www.stats.gov.cn/tjsj/ndsj/2009/html/W2213e.htm) reports that 73,848 people were killed in traffic crashes in China in 2008. Curiously, according to those data, 21% were killed using motorcycles, 3% were killed using tractors, 2% were pedestrians and others, and 1% were bicyclists.

Overall, 91% of the deaths occur in low- and middle-income countries that have only 48% of the registered vehicles. In fact, their fatality rates (per 100,000 population) are double those of high-income countries. The largest numbers of deaths occur in China and India, and those totals are expected to increase as those countries become more motorized.

In 2009, approximately 34,000 people died in the United States in motor vehicle crashes, a decline of almost 9% from the previous year, even though total vehicle miles traveled increased by 0.2% (to 1.16 deaths per 100 million miles) (NHTSA, 2010a). However, U.S. crashes account for only a few percent of the world total.

Additional details on motor vehicle crashes are difficult to obtain because the United States is the *only* country in the world for which anyone with access to the Internet can get to the raw crash data at any time for free. No permission is required. Everywhere else, only aggregate statistics are available, though they are more extensive for European countries (Louma and Sivak, 2007). This lack of crash data from other than the United States (and access to it) leads to an overreliance on data from the United States, which can be misleading.

Crash analyses rely on three U.S. databases, (1) the Fatality Analysis Reporting System (FARS), (2) the National Automotive Sampling System (NASS) General Estimates System (GES), and (3) the Crashworthiness Data System (CDS). FARS (http://www.nhtsa.gov/people/ncsa/fars.html, retrieved September 6, 2010) contains data for all fatal crashes in the United States. GES (www.nhtsa.gov/people/ncsa/nass_ges.html, retrieved September 6, 2010) is a nationally representative sample of police-reported crashes of all degrees of severity (death, injury, or property damage). CDS (http://www.nhtsa.gov/PEOPLE/ncsa/nass_cds.html, retrieved September 6, 2010) is an annual probability sample of approximately 5000 police-reported crashes involving at least one passenger vehicle that was towed from the scene (from a population of almost 3.4 million tow-away crashes). Minor crashes (involving property damage only) are not in CDS. CDS crashes are investigated by specially trained teams of professionals who provide far more detail than is given in police reports.

These databases are extremely useful for those developing systems to mitigate crashes. For example, suppose one was developing a system to monitor driver alcohol levels. Statistics on the age and gender of intoxicated drivers and passengers, when crashes

### Table 2 Percentage of Road Users Killed by Various Transportation Modes

| Country | | Pedestrians | Cyclists | Motorized Two-Wheelers | Motorized Four-Wheelers | Other |
|---|---|---|---|---|---|---|

**Table 3  Precrash Events**

| Critical Precrash Event | | Weighted Percent | Subtotal Percent |
|---|---|---|---|
| Vehicle traveling | Turning or crossing at intersection | 36.2 | 69.6 |
| | Off the edge of the road | 22.2 | |
| | Over the lane line | 10.8 | |
| | Other | 0.7 | |
| Other vehicle in lane | Stopped | 12.2 | 17.3 |
| | Traveling in same direction | 4.8 | |
| | Traveling in opposite direction | 0.1 | |
| | Other | 0.1 | |
| Vehicle control loss | Traveling too fast | 5.0 | 8.9 |
| | Poor road condition | 2.0 | |
| | Vehicle problem | 1.2 | |
| | Other | 0.7 | |
| Other vehicle encroachment | | | 1.3 |

NHTSA (2008).

occurred, the roads and speeds driven, the precrash maneuvers, and so forth, could provide insight into how to design the system to maximize its effectiveness.

Traffic injuries are classified using the abbreviated injury scale (AIS) [Association for the Advancement of Automotive Medicine (AAAM), 2008]. There are six categories: (1) minor, (2) moderate, (3) serious, (4) severe, (5) critical, and (6) unsurvivable. The injury scale may be applied by the body part, for example, an AIS of 4 for an arm but 3 for the chest. There are also scales for organ injury and fracture classification (Chawda et al., 2004; Copes et al., 1990; Petrucelli, 1981).

To prevent crashes, one needs to know where, when, why, and how crashes occur. The U.S. National Motor Vehicle Crash Causation Survey (NHTSA, 2008) examined a statistically representative sample of 5471 crashes from 2005 to 2007. This unique report aggregated crashes by road, vehicle, traffic, and driver factors for that purpose. As an example, Table 3 shows that the most common precrash event was turning or crossing at an intersection, which suggests that intersection warning systems could be extremely helpful in reducing crashes.

### 3.2  Passive Safety Systems

Crash data have influenced the design of active and passive crash protection systems. Although issues relating to injury mechanisms have been primarily the purview of bioengineers, human factors engineers have been involved in the assessment of restraint systems as well as in design and programs to encourage use. For seat belts, the recent research focus has been on assessing effectiveness and increasing wear rates, with the overwhelming majority of publications concerning the United States (Eby et al., 2005; Strine et al., 2010), though there has been some research in Europe (e.g., Gras et al., 2007) and China (Routley et al., 2010). There has also been some general research on increasing use (Young et al., 2008).

Similarly, for air bags, the focus has been on reducing unintended injuries, increasing effectiveness,

and determining where additional air bags are needed (Braver etal., 2010; Carter and Maker, 2010).

Booster seats (Reed et al., 2009) and child restraint systems (child safety seats) can be very effective in reducing crash injuries to children. However, well over half of the time child safety seats are installed incorrectly, with the major problems being loose harness adjustment and loose seat belt adjustment (Decina and Lococo, 2005; Decina et al., 2009; Tsai and Perel, 2009). Additional research is needed to determine how installation errors can be reduced.

## 4  HOW SHOULD VEHICLES BE DESIGNED?

### 4.1  What Do Customers Want? (Clinics and JD Power Surveys)

Customer responses to vehicles can be gauged using tests in driving simulators and instrumented test vehicles, in naturalistic driving studies, and via other methods described elsewhere in this chapter (Green, 1993). Two particularly influential sources of information are clinics and JD Power data.

In a clinic, a manufacturer rents a facility to display a future product along with current model competitors. Many subjects, sometimes more than 100, are escorted from vehicle to vehicle and respond to a wide range of questions about each vehicle relating to fit and finish, appearance, comfort, ease of use, and so on. To get appropriate demographic data, clinics involving the same vehicles may be conducted in multiple cities (Curtis, 1996). Details about clinics are quite limited in the literature as manufacturers wish to keep their methods and findings secret. Sometimes clinics are combined with focus groups (Jalopnik, 2005).

JD Power conducts several annual surveys, summarized in confidential (and very expensive) reports. Their best-known automotive surveys are conducted in the United States, but they conduct surveys in other countries as well (Dance, 2010).

The JD Power Initial Quality Study (IQS) covers the first 90 days of new vehicle ownership and is conducted each year soon after the new models are produced. In the 2008/2009 U.S. survey, the target was 450 responses per vehicle model and 100 responses per manufacturing plant. There were more than 82,000 responses to the 288-question survey (http://www.autoblog.com/2010/06/17/jd-power-2010-initial-quality-study-domestics-lead-imports/, retrieved October 22, 2010).

The APEAL (Automotive Performance, Execution and Layout) survey concerns how satisfying a new vehicle is to own and drive based on 80 attributes. The 2010 results were based on 76,000 responses for 245 vehicle models (121 cars, 71 trucks, 53 crossover and utility vehicles). Customer ratings were obtained for 10 categories: vehicle interior, vehicle exterior, storage and space, audio/entertainment/navigation, seats, climate controls, driving dynamics, engine/transmission, visibility/driving safety, and fuel economy (http://www.jdpower.com/autos/articles/2010-APEAL-Study-Results/, retrieved October 22, 2010).

The VDS (Vehicle Dependability Survey) is conducted after three years of ownership. The JD Power target is 225 responses per model, with subjects completing an eight-page survey concerning 200 problem areas. The return rate for the last sample was 19% (http://www.jdpower.com/autos/articles/2010-Vehicle-Dependability-Study-Results/, retrieved October 22, 2010).

Users of these reports often assign considerable importance to small differences in rankings that most likely are within the limits of statistical error. Furthermore, there are often halo effects that bias responses. For example, there have been instances where the same component will receive a higher rating on a Lexus than on a Toyota. Nonetheless, JD Power ratings are treated as the absolute truth, and often they are close to it.

## 4.2 Vehicle Handling

Ideally, a vehicle should be designed from the inside out to accommodate drivers, passengers, and cargo. Commonly, however, motor vehicles are designed from the outside in to fit market and cost constraints and then modified to fit packaging requirements and customer input. Thus, the initial steps are to determine the wheelbase, length, width, height, weight, and then the suspension system to provide desired handling. In brief, if a vehicle cannot be driven, it will not sell.

Procedures for testing vehicle handling have existed for some time (e.g., Dugoff et al., 1970). That protocol examined five maneuvers: (1) limit braking (no steering), (2) response to rapid, extreme steering (no braking), (3) braking in a turn (fixed, nonzero steering angle), (4) rapid lane change, and (5) combined drastic steering and braking. Variations of these measures are still used today. Test procedures require careful control of the vehicle tire pressures, the loading of the vehicle, and the road surface and, for that reason, are often conducted on "black lakes."

Handling characteristics vary among vehicles. For example, the 2010 Chevrolet Corvette ZR1 will stop in 101 ft from 60 mi/h and handle about 1.0 g on a skid pad. For a 2011 Infiniti QX-56 SUV those values are 123 ft and 0.69 g. (See the full test results on Insideline.com.) Further careful examination shows significant differences between vehicles of the same type, different models of the same vehicle (due to tires), and within models due to loading. For example, there was a 22-ft difference in the stopping distance of common American pickup trucks (http://special-reports.pickuptrucks.com/2008/11/braking.html). In a *Popular Mechanics* test, a 2008 Ford F-150 King Ranch stopped in 20 ft less when it was "loaded."

Over time, many of these procedures have been standardized [International Organization for Standardization (ISO) Standard 3888; ISO, 1999, 2002a; New Car Assessment Procedures (NCAPs) (Forkenbrock et al., 2005); and Society of Automotive Engineers (SAE) Standards J1060 (SAE, 2000) and J1441 (SAE, 2007c)]. The extent to which Consumers Union, trade and enthusiasts' magazines, and websites (e.g., *Popular Mechanics*, *Road and Track*, *Edmunds Inside Line*) follow the recognized standards as part of their testing is unknown.

As this topic has been the subject of considerable public attention because of problems related to rollover, maneuvers have received memorable names. The moose test, which became famous because several well-known vehicles failed to pass it, involves a sudden lane change and then a return to that lane. The test simulates a driver avoiding a large animal (actually an elk in Sweden). (See http://en.wikipedia.org/wiki/Moose_test.) Other maneuvers have names such as J-turn and fishhook. (See http://en.wikipedia.org/wiki/J-turn.)

Finally, when reading the literature on handling, readers will see several terms of which they should be aware. *Understeer/oversteer* describes what happens to a vehicle if it is turning and the driver releases the steering wheel. With understeer, the vehicle will tend to straighten itself out, to which a limited degree is desired. With oversteer, the turn radius will decrease, which leads to some degree of instability. *Bump steer* is when some variability in the road surface (a bump or pothole) interferes with the ability to control the vehicle. *Body roll* is when the vehicle leans to the outside of a turn, and increases with a softer suspension and a greater height of the vehicle center of gravity. The *static stability factor*, the track width divided by two times the height of the vehicle center of gravity, indicates the vehicle's propensity to roll over. The larger the value, the less likely rollover is to occur. Values are about 1.40 for passenger cars, 1.24 for minivans, 1.17 for SUVs and pickup trucks, and 1.12 for full-size vans. (See http://en.wikipedia.org/wiki/Automobile_handling, NAS, 2002; Walz, 2005.)

Although this section emphasizes empiric test procedures, most of the work on the design and evaluation of handling qualities is done using computer models of the vehicle (especially Car-Sim and Truck-Sim, www.carsim.com) and the driver (Jagacinski and Flack, 2003; Macadam, 2003). See also Zschocke and Albers (2008).

## 4.3 Ride Quality

Ride quality analyses have their theoretical origins in human response to vibration. Studies in the 1950s

(Griffin, 1990) established the resonant frequencies of various human body parts and therefore which resonant frequencies to avoid (5 Hz for the abdomen, 25 Hz for the head, 50–200 Hz for gripping the steering wheel) to reduce discomfort.

Analyses of vehicle ride typically begin with quarter-car models, which consider the springs and shocks, along with the sprung and unsprung weight for each wheel. The key determinant of how a vehicle will ride is the transfer function that relates the input signal (the road) to the output (what the customer feels). The focus of those analyses is on body bounce and axle hop. Body bounce occurs in the 1–3-Hz range, with a peak at about 1 Hz, and relates to the combined motion of the entire body, in particular when both front and rear axles are simultaneously excited. That motion is influenced by vehicle length and speed. Axle hop, which occurs in the frequency range of 10–20 Hz (with a peak at 10 Hz), has to do with the tire's ability to stay in contact with the road surface.

The input signal, the road roughness, is measured using the international roughness index (IRI), an objective measure of the road profile. IRI is determined by driving a test device fitted with a probe whose cumulative vertical travel over a road segment is recorded, measured in millimeters per meter or inches per mile. In metric units, values of about 2 are typical for runways and express-ways in good repair, 1.5–2.5 for most new pavement, 2.5–6.0 for older pavement, 2.5–10.0 for maintained unpaved roads, and 4.0–11.0 for damaged pavement (http://training.ce.washington.edu/wsdot/Modules/09_pavement_evaluation/09-2_body.htm). The proce-dure for measuring IRI is described in American Soci-ety for Testing and Materials (ASTM) E950/E950M-09 (ASTM, 2009), 1364-95 (ASTM, 2005), and E1926-08 (ASTM, 2008). See also Sayers and Karamihas (1998).

The subjective response to the input is determined by having adults sit in a vehicle and rate the ride on a scale where a rating between 0 and 1 is very poor, and between 4 and 5 is very good. Originally, this measure was referred to as the present serviceability rating (PSR). The relationship between PSR and IRI depends on the study, but PSR $= 5e^{-0.2\text{IRI}}$ should provide an estimate. Currently, a more complex procedure that uses groups of subjects but the same scale results in a mean panel rating which can be estimated using the ride number, a 0–5 value similar to the PSR. The ride number is a number that can change over time as the population of roads and vehicles changes. (See Loizos, 2008.)

In practice, each manufacturer has its own procedure to determine ride quality. Tests are typically done at the manufacturer's test track, where at great expense they have reproduced pavement sections that duplicate real roads that challenge vehicle suspensions. For example, the GM Milford Proving Ground has a section that dupli-cates 12 Mile Road in Detroit (http://en.wikipedia.org/wiki/General_Motors_Proving_Grounds). Evaluation of off-road vehicles is much more complex (Els, 2005).

## 4.4 Vehicle Packaging (Occupant Space, Reach, and Field of View)

Packaging refers to designing the vehicle to accom-modate the people and cargo to be carried. Important considerations include (1) the location of the windows so that drivers can see both outside (to other vehicles, road signs, and traffic signals) and inside (to vehicle controls and displays), (2) the position of the driver (and passengers) so that they can sit comfortably and reach controls, and (3) the location of openings, handles, door sills, and steps so that occupants can get in and out eas-ily and also access the engine compartment (for service) and cargo.

The key dimensions for occupant packaging are specified in SAE and ISO standards [e.g., SAE J1100 (SAE, 2008b)], and summarized in Macey and Wardle (2009). See Figure 2. The primary landmarks are the heel point (where the aft part of the heel contacts the floor or pedal) and the H point (essentially the hip pivot point). Dimensions are commonly referred to by number, not name.

For passenger vehicle design, what drivers can see and reach is of critical concern. Drivers need to see traffic lights mounted above the road when they are stopped at intersections, information on the instrument panel (often through the steering wheel), other vehicles in the mirrors and, when they turn their heads, objects to the rear, especially small children close to the vehicle when the vehicle is backing up. Eye position is determined by the SAE eyellipse as specified in SAE J941 (SAE, 2010b and SAE J1052 (SAE, 2002b). See also Devlin and Roe (1968) and Manary et al. (1998). The eyellipse, a pair of football-like objects represents the three-dimensional distribution of driver's eyes such that on one side of a tangent to the eyellipse is either 95 or 99% of the driver population.

SAE J1050 describes three methods to determine monocular and binocular field of view. The most impor-tant obstructions are the A pillars (that frame the wind-shield) and the steering wheel. In theory, a pillar that is less than 65 mm wide, the interocular separation, should not completely block the driver's view of the road. For the speedometer/tachometer cluster, engineers need to verify that the cluster is inside the "mustache," the area of the speedometer/tachometer cluster not blocked by the steering wheel, so known because of its shape.

Recently, special attention has been given to devel-oping methods to assess field of view from large trucks, buses, and other large vehicles and to relate field of view to crashes (Blower, 2007).

When drivers cannot see something directly, they must be able to see it using cameras and/or mirrors. Mir-ror requirements are specified by Federal Motor Vehicle Safety Standard (FMVSS) 111 (http://www.fmcsa.dot.gov/rules-regulations/administration/fmcsr/fmcsrruletext.aspx?reg=571.111). The 111 standard specifies the size and field of view for interior and exterior mirrors for cars, trucks, buses, and motorcycles and cross-view mirrors for school buses and provides an assessment procedure. A cross-view mirror allows the driver to see pedestrians, usually children obscured by the front of the bus. This is a particular problem for school buses with a "nose" (engine forward).

Recent research has also emphasized using cameras to replace exterior mirrors, mainly for reasons of aerody-namics. However, because the image can be processed,
**Figure 2** Commonly used dimensions in SAE J1100 (http://www.instructables.com/image/FJK5LHFJZ3EQHO916N/Anthropometry-and-component-parts.jpg). Typical values from Macey and Wardle (2009, p. 95).

| # | Name | Typical Value (mm or deg) | # | Name | Typical Value (mm) |
|---|---|---|---|---|---|
| H5 | H point to ground | 475–550 | W3 | Shoulder room | 1350–1550 |
| H30 | Chair height | 250–275 | W5 | Hip room | 1325–1450 |
| H61 | Effective head room | 975 | W20 | Lateral location | 350–400 |
| A40 | Back angle | 22.0–24.0 | | | |
| A60 | Upward vision angle | 13.0–15.0 | | | |
| A61 | Downward vision angle | 5.0–7.0 | | | |

cameras can have advantages over mirrors, especially where there is glare, rain, fog, or snow. Systems that provide a bird's eye view around the vehicle are being developed as parking aids (Walls et al., 2004a, 2004b). At this point, published design standards for those systems do not exist.

Comfortable driver reach is determined per SAE standard J287 (SAE, 2007a; Figure 3). Although the adult population has changed since then, the primary changes have been in girth, not length. (See Parkinson and Reed, 2006.)

After handling, ride quality, and interior packaging are addressed, driver and passenger entry and exit are given attention (El Menceur et al., 2008) as well as reach to/service of items under the hood and in the trunk. The trend is to make increasing use of computerized biomechanical models such as Jack to predict reach, vision, and ingress/egress (Chateauroux et al., 2007; Dufour and Wang, 2005). Although these tools are quite powerful, learning how to position the simulated user and move about the environment is not easy (McInnes et al., 2009).

Those interested in developments in this topic should consult the proceedings from the latest SAE Digital Human Modeling for Design and Engineering Conference.

## 4.5 Vehicle Exterior Lighting

What drivers can see also depends on the amount of light present, and as demonstrated by the relative increase of crashes at night, lighting is critical. The research on headlamp design has been ongoing for decades, with the goal of optimizing the trade-off between road illumination for the driver and glare to oncoming drivers (Perel et al., 1983). Current research concerns the advantages of steerable headlamps and beam modifications, ideas that have been discussed for some time but have only recently become technically effective (Sivak et al., 2002). Another recent development, from naturalistic and other driving studies, is the collection of more complete data on the normal use of lighting systems (Buonarosa et al., 2008).

At this point, even after decades of research, there nonetheless is no single harmonized headlamp pattern. The United States and Canada comply with federal motor vehicle safety standard 108 [U.S. Department of Transportation (DOT), 2004] and Europe adheres to the UNECE (2005b) regulation with its sharper cutoff.

## 4.6 Basic Controls and Displays

Control and display selection and design occur after the basic package is designed. The design of basic vehicle controls and displays is relatively unconstrained, in
**Figure 3** SAE reach contours (http://www.sanatekhodro.com/CrThumb.aspx?Pic=sanatekh%5CImages%5C48%5C 102346223185900.jpg&X=348&Y=240).

particular with regard to control and display placement once basic vision and reach requirements, described earlier, are satisfied.

ISO 4040 (ISO, 2009) specifies where controls can be located. Generally, there are no recommendations for the details of stalk, knob, or button design, including their size. The companion SAE practice is J1138-2009 (SAE, 2009a).

One of the best-supported standards is ISO 12214, which provides recommended control-display movement relationships based on direction of motion stereotypes. The companion SAE practice is J1139 (SAE, 2010a).

The topic of symbols receives considerable attention and, in fact, there is an ISO working group (Technical Committee 22/Subcommittee 13/Working Group 5) solely concerned with symbols for road vehicles. The applicable standard, ISO 2575 (ISO, 2010a), has several hundred symbols, and that collection is growing. For some purposes, such as navigation functions, for which hundreds of symbols are needed, there are no standard symbols, so each manufacturer or supplier creates its own symbols.

### 4.7  Driving Performance Measures and Statistics

In the last 10 years, two topics have received considerable attention in the human factors literature and popular press: (1) driver assistance and warning systems and (2) driver distraction/overload and workload. During that time period, considerable research on these topics has been conducted and systems have been produced, though their deployment is not yet universal. For these two topics, there is considerable emphasis on

evaluation, which requires a clear definition of what is to be measured.

There have been many attempts to define driving performance measures and statistics (Green, 1993; Ostlund et al., 2005). Unfortunately, for many of the common measures and statistics, consistent naming is not used, and statistics and measures are not rigorously defined (Savino, 2009). For that reason, SAE recommended practice J2944 (Operational Definitions of Driving Performance Measures and Statistics) is being developed, some of whose measures and statistics are summarized in the section that follows.

One indication that a driver has responded to an event (a vehicle movement or a warning) is some movement of the foot pedals. However, a careful analysis of pedal movements, especially the accelerator, shows the driver is constantly making small adjustments to the pedal position, so distinguishing an overt change over some small time frame from normal variation is difficult. Table 4 shows the proposed definitions for responses to events, measured using response time measures. The definitions from J2944 have been abridged to save space. The names could change. The brake activation time is also usually the total response time. Note that for several of the measures there is a variable that is part of the name. For braking, it is undetermined at this point if a 10%, 50%, 90%, or some other percentage of maximum brake pressure is the critical measure.

Steering responses to events are analogous to accelerator response time measures in that responding involves detecting some amplitude change that is greater than normal variability over some time window. The difference is that there quite commonly is an accelerator/braking response to an event, but steering occurs only sometimes.

**Table 4 Candidate Definitions for Driving Response Time Measures**

| Measure Name | Description |
| --- | --- |
| Accelerator response time | From when an event/stimulus begins until some movement of the accelerator occurs in response to that event, either option A (the response ends when the accelerator position signal changes by more than a specified amount over a specified time window) or B (when the accelerator position signal reaches zero) |
| Accelerator to brake time | From accelerator release to brake application, either option A (when the driver's shoe first contacts the brake pedal) or B (when the brake lights first illuminate) |
| Initial brake response time | Equals accelerator response time + accelerator to brake time |
| Brake movement time ($x$%) | From when the brake is first contacted (version A) or the brake lamps are illuminated (version B) until some desired $x$ percent of maximum pressure is reached |
| Brake activation time ($x$%) | Equals initial brake response time + brake movement time ($x$%) |

There are no agreed-upon values in the literature for steering changes that signify an overt response.

In addition to showing the effects of a single event, steering changes in response to ongoing demand, such as workload from an in-vehicle task. Statistics of interest include the number of steering wheel reversals over some time period or the steering wheel reversal rate, with drivers making fewer and larger corrections when occupied by a secondary task (MacDonald and Hoffman, 1980).

A more contemporary measure of distraction and workload is steering entropy (Boer et al., 2005). In its simplest form, steering entropy (randomness) is a prediction of how well previous steering wheel positions predict the future. The more attentive to driving, the more stable the computation. The computations are not easy to understand.

The third category of statistics is related to lateral position. In brief, the less attention the driver is paying to staying in the lane, the more likely he or she is to strike another moving vehicle or roadside object such as a tree or parked car. Thus, when drivers are not fully engaged in the primary task of driving, one would expect the variability of lane position to increase and there to be more extreme lane positions, specifically lane departures.

As per SAE J2944, a lane departure may be considered to occur when (definition A) a tire, usually a front tire, touches the inside edge of a lane boundary or when (definition B) the widest part of the vehicle (either a mirror or the curvature of the body) is over the centerline of the lane boundary or when (definition C) a tire contacts the outside edge of the lane boundary. As most lane boundary stripes in the United States are 4 in. wide, the difference between definitions A and C is 4 in., a difference of practical significance. However, there are cases of a larger difference, for example, for definition B, where the vehicle is a pickup truck with large extended mirrors. There is no truly best definition, as the definition that is preferred depends upon the purpose for which it is used and the technology available to collect the data. From a safety perspective, definition B is preferred, as it best represents the situation in which two identical vehicles in adjacent lanes would just contact each other. Definition A is sometimes easier to measure. The author does not recommend definition C.

Also of interest is the vehicle's lateral position, with the standard deviation of lane position being the most commonly reported driving performance statistic. Investigators need to be extremely careful in determining lane position. In some older simulators, the road edges were constructed of chords, not true curves. Depending on the geometry, the vehicle–chord and vehicle–curve lateral distances could differ by several inches.

Another concern is the actual placement of the painted stripes on real roads. Road crews try to follow the pavement edge and expansion joints when painting markings, but the paint stripes may not be exactly at the lane edge. Thus, lane widths may vary even if the pavement does not. This can be particularly problematic when lane position is determined using a single painted stripe, not two, so apparent lateral movement could be random variation of a single paint stripe.

When a lane departure is expected, the time to line crossing, commonly referred to as TLC, is of interest (Godthelp, 1988; Godthelp and Kaeppler, 1988). Time to line crossing is the time required for some part of the vehicle to reach the edge marking (usually for a tire to touch the inside edge of the line) if the driver keeps to the same course. TLC can be computed three ways: definition A, trigonometrically; definition B, using lateral distance and velocity only; and definition C, using lateral distance, velocity, and acceleration (Van Winsum et al., 2000). The trigonometric calculation uses lateral velocity, lateral distance, lateral acceleration, the radius of curvature of the road, the radius of curvature of the path, and so forth, to compute an exact and error-free time. Surprisingly, when comparing definitions B and C, sometimes the estimate improves when lateral acceleration is omitted. Until now, on-road studies have not used definition A because the global positioning system (GPS) and road geometry data available in real time have not been able to provide all of the data needed. Similar data are available in a driving simulator.

Longitudinally of interest is the safety margin from the front of the subject vehicle to the rear of a lead vehicle, referred to as the gap (Figure 4). A gap can be measured either by distance or time, hence the names time gap and distance gap. Gaps can also be to the rear.

The distance or time between the front bumper of a vehicle to the same location on a following vehicle is
**Figure 4** Headway and gap.

called headway. Headway is important to civil engineers as an indicator of traffic flow. However, in many human factors studies, the term headway is used when gap is intended.

When a gap reaches zero, vehicles or objects collide. The measure that indicates the amount of safe clearance is time to collision (TTC). Similar to TLC, TTC is the time after which two objects will collide if the driver or drivers continue to do what they are doing (Godthelp et al., 1984; van der Horst and Hogema, 1994). Before being used in statistical summaries, TTC data need to be filtered, as TTC values can be infinite. Unfortunately, filtering rules are often not given when TTC statistics are provided.

### 4.8 Distraction/Overload and Workload Quantification, Assessment, and Specifications

A very prominent use of these and other measures and statistics is in studies of driver distraction/overload and workload, popular topics in the last few years (Regan et al., 2008; Rupp, 2010). The focus has been on the interference of cell phone conversations, whether there are differences in interference between hand-held and hands-free phones, the problems associated with texting, and so forth (Caird et al., 2006; Horrey and Wickens, 2006; McCartt et al., 2006; Collet et al., 2010a,b). Soon the use of websites and video calls while driving will become major issues.

A few key points from that literature deserve emphasis (Green, 2010):

1. Distraction and overload are not the same. Distraction has to do with attracting a person's attention and causing them to remain engaged in the task even though it may be unwise to do so (such as answering a ringing phone under almost any circumstance). Whereas distraction is a task-switching problem, overload is where the aggregate load of multiple tasks is just too much for a person to handle. Think of this as the classic spinning plates act in show business, where a performer tries to keep multiple plates spinning on poles and madly dashes between them.

2. Many of the driving workload studies are flawed because the workload of the primary task is specified qualitatively (light or heavy), not quantitatively, so test conditions cannot be rigorously compared. To solve that problem,

Schweitzer and Green (2007) developed a rating method that provides an absolute indication of the workload. Workload is rated relative to two specific anchor clips (having values of 2 for light traffic and 6 for heavy traffic, both exactly determined by those clips). In addition, workload can also be estimated using the equation that follows based on road geometry and traffic.

$$\text{workload} = 8.07 - 2.72(\text{LogMeanRange125})$$
$$+ 0.48(\text{MeanTrafficCount})$$
$$+ 2.17(\text{MeanAxFiltered})$$
$$- 0.34[\text{MinimumVpDot}$$
$$(0\text{removed})]$$

where

| | |
|---|---|
| LogMeanRange125 = | logarithm mean distances (m) to the same-lane lead vehicles. If there is no lead vehicle, mean distance = 125 m |
| MeanTrafficCount = | mean number of vehicles detected [15° field of view (FOV)] |
| MeanAxFiltered = | mean longitudinal acceleration (m/s$^2$) of the subject vehicle |
| MinimumVpDot (0 removed) = | minimum acceleration of lead vehicle (m/s$^2$), excluding the case of no lead vehicle |

3. The workload of secondary tasks needs to be specified quantitatively, not qualitatively (e.g., "the cognitive load was light"). One approach is to rate the workload of each subtask using the visual, auditory, cognitive, and psychomotor (VACP) scales from the U.S. Army IMPRINT model. Table 5 shows the UMTRI enhancement of the visual scale used in the SAVE-IT project as an example. For all four scales and further details of their use, see Yee et al. (2007).

There are a number of standards and guidelines pertaining to the design of driver interfaces for telematics. Noteworthy are the several-hundred-page-long guideline documents from Battelle (Campbell et al., 1997), the Harmonization of ATT Roadside and Driver Information in Europe (HARDIE) project (Ross et al. (1996), and UMTRI (Green et al., 1993). The more recent Transport Research Laboratory (TRL) guidelines are also worthy of note (Stevens et al., 2002). All of these guidelines have some use, but their coverage of hierarchical menu systems is limited.

Contemporary interface assessment follows the procedures described in the Alliance of Automobile Manufacturers principles (AAM, 2006; especially principles 2.1 and 2.2), the Japan Automobile Manufacturers

**Table 5  Visual Scale of the UMTRI-Modified IMPRINT VACP Scales**

| Rating | Definition | Example |
|---|---|---|
| 0.00 | No visual activity | Self-explanatory |
| 1.00 | Register/detect image | Observe a warning light turn on |
| 3.70 | Discriminate (detect visual difference) | Determine which traffic light is on |
| 4.00 | Inspect/check (static inspection) | Check side-mirror position while parked |
| 5.00 | Locate/align (selective orientation) | Change focus to a car |
| 5.40 | Track/follow (maintain orientation) | Watch a moving car |
| 5.90 | Read (symbol) | Read a native language |
| 7.00 | Scan/search/monitor (continuous) | Look through glove compartment |

(JAMA, 2004) guidelines, and SAE recommended practices J2364 (the 15-s task time rule; SAE, 2004) and J2365 (the calculation procedure for J2364; SAE 2002). The AAM principles are an expansion of the European Union guidelines (UNECE, 1999) that later became the European Statement of Principles (UNECE, 2005a).

Table 6 shows the primary ISO telematics guidelines and standards. Very few of these documents contain test criteria. See Green (2008a,b) for additional information.

### 4.9 Driver Assistance and Warning Systems

Driver warning and assistance systems are designed to reduce the workload of driving, stabilize traffic flow, and most importantly reduce opportunities for crashes. Included are adaptive cruise control systems (Ervin et al., 2005), lane departure warning and assistance systems (LeBlanc et al., 2006), fatigue warning systems

**Table 6  Primary ISO Standards and Related Documents for Telematics**

| Document | Short Title |
|---|---|
| Std 15005:2002(E) | Dialogue management principles and compliance procedures |
| Std 15006:2004 | Specifications and compliance procedures for auditory information |
| Std 15007-1:2002(E) | Visual behavior measurement 1: Definitions and parameters |
| Trial Std 15007-2:2001 | Visual behavior measurement 2: Equipment and procedures |
| Std 15008:2003 | Legibility (visual presentation of information) |
| Technical Report 16352:2005 | Warnings literature review |
| Trial Std 16951:2004 | Message priority |
| Std 17287:2002 | Suitability of interfaces while driving |
| Std 16673:2007 | Occlusion method to assess distraction |
| Committee Draft Std 26022 | Lane change test to assess distraction |

(Grace and Stewart, 2001; Wierwille et al., 1994), lane change/merge warning systems (Olsen, 2004; Van Winsum et al., 1999), blind-spot detection systems (Kiefer, and Hankey, 2008), forward crash warning systems (Kiefer et al., 2005; LeBlanc et al., 2001), curve speed warning systems, and intelligent speed assistance, to a name a few. In addition to assessing specific warning systems, there has been some more general research on developing test methods (Ference et al., 2007).

Based on this research, a large number of SAE, ISO, and DOT New Car Assessment Procedure (NCAP) procedures have been developed (Table 7). There is significant overlap and in some cases duplication between those three sets of procedures for particular warning systems, such as adaptive cruise control (ACC).

The next step is to extend the operational range of these standards, for example, to convert the ACC from high speed only to stop and go and to create others for scenarios not covered, such as intersections or to fill gaps, such as the SAE Lane Keeping Assistance System document. At this point, motor vehicles are transitioning from being controlled primarily by the driver to having semiautonomous control. That topic is in need of additional research.

## 5  SOURCES OF FURTHER INFORMATION

Although there are a substantial number of books on this topic, there are very few that have a design perspective, the emphasis of this chapter. Probably the best single reference is Peacock and Karwowski (1993), a dated book that is more a collection of chapters rather than a single integrated text. In terms of background, the author would also recommend Dewar and Olson (2007), which is in the process of being revised (and now being edited by Alison Smiley). Lawyers and Judges Publishing, the publisher of the Dewar and Olson volume, has a number of other books that consider driving from a forensic perspective.

Other books relating to human factors and driving include several written by Leonard Evans, the most recent of which is *Traffic Safety* (Evans, 2004). Evans's background in physics is reflected in his thoughtful and rigorous analyses of crash data and statistics.

Also worthy of note is a recent book by David Shinar, *Traffic Safety and Human Behavior* (Shinar, 2007), which focuses on factors that affect driving

**Table 7 Assessment Procedures for Driver Assistance and Warning Systems**

| Document | Short Title |
|---|---|
| ISO Std 3888-1:1999 | Test track test for a severe double lane change |
| ISO Std 3888-2:2002 | Test track test for obstacle avoidance |
| ISO Std 15622:2010 | Adaptive cruise control performance requirements and tests |
| ISO Std 15623:2002 | Forward vehicle collision warning performance requirements and tests |
| ISO Std 17361:2007 | Lane departure warning systems performance requirements and tests |
| ISO Draft Std 17387:2008 | Lane change decision aid systems (LCDAS) performance requirements and tests |
| ISO Std 22178:2009 | Low speed following (LSF) systems performance requirements and tests |
| ISO Std 22179:2009 | Full speed range adaptive cruise control (FSRA) systems performance requirements and tests |
| ISO Advanced Work Item 22839 | Forward vehicle collision mitigation systems — Operation and performance, requirements |
| ISO Std 22840:2010 | Devices to aid reverse manoeuvres — Extended-range backing aid systems (ERBA) |
| ISO/NP 26684 | Cooperative intersection signal information and violation warning systems (CISIVWS) |
| SAE Std J2399 | Adaptive cruise control (ACC) operating characteristics and user interface |
| SAE Information Report J2400 | Forward collision warning systems: Operating characteristics and user interface |
| SAE Recommended Practice 2802 | Blind spot system operating characteristics and user interface |
| SAE Information Report J2808 | Road/lane departure warning systems human interface |
| US DOT FCW NCAP | Forward crash warning system confirmation test |
| US DOT LDW NCAP | Lane departure warning system confirmation test |
| US DOT ESC NCAP | Electronic stability control confirmation test |

performance (e.g., driver capacities related to vision and age, driving style, alcohol, drugs, distraction, fatigue). The book is very thorough.

A useful complement to these books is the *H-Point* book (Macey and Wardle, 2009), which is concerned with vehicle packaging and is much more design oriented. It is not a human factors text per se but does contain useful background information.

The driving context is specified by three primary references used by civil and traffic engineers, of which all those doing automotive human factors work should be aware—the *Transportation Research Board (TRB) Highway Capacity Manual (* TRB, 2010), the *AASHTO "Green Book" (* AASHTO, 2004), so named because of the color of its cover, and the Manual of Uniform Traffic Control Devices (*MUTCD) Handbook (* FHWA, 2009b). These books were all described in Section 2.3.

Although books provide useful reference information, most professionals keep current by attending relevant technical conferences. Many automotive human factors engineers attend the annual Society of Automotive Engineers World Congress, for which there are sessions on human factors, vehicle lighting, and biomechanics. The Detroit location is convenient for those with offices in southeastern Michigan but draws attendees from all over the world. The meeting is held in mid-April. The SAE World Congress tends to have a very high acceptance rate, and paper quality is mixed.

Also well attended is the Transportation Research Board annual meeting, held in Washington, DC, in mid-January. The meeting draws a large number of government officials and has a strong highway focus, though there are sessions on other transportation modes as well. The meeting is quite large, and sessions are held at several hotels. The human factors workshops and the meetings of TRB safety and human factors committees are quite informative (http://www.trb.org/Safety HumanFactors/TRBCommittees.aspx).

For those interested in the cognitive aspects of driving, the best conference is Driving Assessment (drivingassessment.uiowa.edu/). This small, biennial conference is held in June at a resort. The papers are of high quality. The conference is single track and there are many opportunities for networking.

For those interested in the physical aspects of vehicle design, especially issues related to crash injuries, the primary conference is the Stapp Car Crash Conference (www.stapp.org/). This conference is usually held in late October or early November in a southern location in the United States. The paper quality is excellent.

Technical journals are the archival repository for engineering and scientific information. There are numerous journals of potential relevance to this topic, all of which have been referenced earlier. The journal that is most useful depends on one's interests—crash data analysis and cognitive aspects of driving or crash biomechanics. For research on the former, the primary journals are *Accident Analysis and Prevention* and *Transportation Research, Part F (Traffic Psychology and Behavior)* and to a lesser degree *Human Factors*. For the second category, the primary journal is the *Journal of Traffic Medicine*.

For many, the Internet is a popular source of information, generally searched using Google. In general, the quality of scientific and engineering information in journal articles and conferences is much better than websites because only the former are vetted. Using unsubstantiated information is risky. For that reason, scholar.google.com is preferred over google.com for searches.

Finally, for the purposes of this chapter, readers will find Cacciabue and Martinetto (2004) to be quite helpful. Many reports, along with many of the design guidelines, have been aggregated on the author's website (www.umich.edu/~driving).

## 6   KEY POINTS

1. Although there is reasonably good information on U.S. drivers, much less is known about drivers in emerging and critical markets such as China and India, making it difficult to design for customers in those countries. To a large extent, data on the kinds of vehicles they drive, the types of roads on which they drive, and their travel patterns are also limited. Additional information is needed.

2. There are several schemes for classifying vehicles that are well known. Similarly, how roads should be described is well established. This information should be more widely included in human factors reports to improve the replicability of human factors evaluations.

3. Except for the United States, no countries offer free, unconstrained, online access to crash databases. As the predominant types and causes of crashes vary between nations, relying on only data from the United States can be misleading.

4. Motor vehicle design is strongly influenced by the results from the JD Power IQS, APEAL, and VDS surveys.

5. Vehicle characteristics that determine handling and ride quality are established early in design. Handling and ride quality are assessed using accepted objective and subjective methods and statistics (e.g., moose test, ride number).

6. SAE J287, J941, J1100, and J1052 specify the vehicle packaging requirements.

7. ISO 4040, ISO 12214, SAE J1138, and SAE J1139 specify basic control design. ISO 2575 specifies symbols.

8. Driving performance measures and statistics are often undefined, and when they are defined, they are not defined consistently. Use of SAE J2944 should solve that problem.

9. Test conditions in distraction/overload and workload studies must be specified. The UMTRI workload equation and UMTRI-modified VACP scales could be used for that purpose.

10. There is a long list of SAE, ISO, and NCAP standards that pertain to the design of driver

assistance and warning systems and telematics. Most important are those that provide performance criteria (e.g., SAE J2364, AAM guidelines).

# CHAPTER 59

# HUMAN FACTORS AND ERGONOMICS IN AUTOMATION DESIGN

**John D. Lee and Bobbie D. Seppelt**

**Madison, Wisconsin**

## 1 INTRODUCTION

Automation has a long history marked by many successes and equally notable failures. In the early nineteenth century the Luddites in northern England protested against the introduction of automation in the weaving industry by sabotaging the machines. Although the term *luddite* now refers to technophobes, these people correctly foresaw some of the highly damaging changes that automation would bring to their lives. Automation and the industrial revolution radically changed the craft-centered culture of the time. More recently, information technology has had an equally important effect on industries as diverse as process control, aviation, and ship navigation.

The Luddites foresaw the threat to their lifestyle. Of greater concern are situations in which people fail to recognize the risks of adopting automation and are surprised by unanticipated effects (Sarter et al., 1997). Automation frequently surprises designers, operators, and managers with unforeseen mishaps. As an example, the cruise ship *Royal Majesty* ran aground because the global positioning system (GPS) signal was lost and the position estimation reverted to position extrapolation based on speed and heading (dead reckoning). For over 24 h, the crew followed the compelling electronic chart display and did not notice that the GPS signal had been lost or that the position error had been accumulating. The crew failed to heed indications from boats in the area, lights on the shore, and even salient changes in water color that signal shoals. The surprise of the GPS failure was discovered only when the ship ran aground [National Transportation Safety Board (NTSB), 1997; Lutzhoft and Dekker, 2002]. This mishap demonstrates the power of technology to either make us smart or surprisingly stupid (Norman, 1993). Automation exemplifies this power.

*Automation* has been defined as a device or system that performs a function previously performed by a human operator (Parasuraman et al., 2000). However, automation does not simply supplant the person, but enables new activities, creates new roles for the person, and changes existing activities in unexpected ways (Woods, 1994). As a result, automation often produces surprises at many levels, from the societal, as with the

Luddites, to the individual, as with the *Royal Majesty*. For automation to achieve its intended benefits, its design must anticipate these changes. The need to anticipate and avert automation-related surprises is more difficult now than ever. One of the ironies in automation design is that as automation increasingly supplants human control, it becomes increasingly important for designers to consider the contribution of the human operator (Bainbridge, 1983). This chapter draws upon over 30 years of research to identify general automation-related failures and to identify strategies for improving automation design.

## 2   AUTOMATION PROMISES AND PITFALLS

Automation has many clear benefits. In the case of the control of cargo ships and oil tankers, it has made it possible to operate a vessel with as few as 8–12 crew members compared to the 30–40 that were required 40 years ago (Grabowski and Hendrick, 1993). In the case of aviation, automation has reduced flight times and increased fuel efficiency (Nagel, 1988). Similarly, automation in the form of decision support systems has been credited with saving millions of dollars in guiding policy and production decisions (Singh and Singh, 1997). Automation promises greater efficiency, lower workload, and fewer human errors; however, these promises are not always fulfilled.

Many pitfalls plague the introduction of automation. Well-documented failures of information technology show that it seldom provides the promised economic benefits (Landauer, 1995) and often fails to provide promised safety benefits (Perrow, 1984). When automation is introduced to eliminate human error, the result is sometimes new and often more catastrophic errors (Sarter and Woods, 1995). Automation often fails to provide expected benefits because it does not simply replace the human in performing a task but also transforms the job and introduces new tasks. These new tasks are not always recognized and so designers fail to provide operators with adequate feedback and support. Automation also fails because the role of the person performing the task is often underestimated, particularly the ability to compensate for the unexpected, and that role is not supported. Although any list of automation-related problems and surprises will be incomplete, changes in feedback, task structure, and relationships represent critical challenges of automation design (Lee and Seppelt, 2009).

### Feedback changes:
- Out-of-the-loop unfamiliarity
- Surprising mode transitions
- Inadequate training and skill loss

### Task structure changes:
- Clumsy automation
- Automation task errors
- Behavioral adaptation

### Relationships change:
- Mismatched expectations and eutactic behavior
- Inappropriate trust (misuse, disuse, and complacency)
- Job satisfaction and health

### 2.1   Feedback Changes

Automation often fails because it dramatically changes the feedback the operator receives. Diminished or eliminated feedback is a common occurrence with automation and it can leave people less prepared to detect automation failures or to intervene.

*Out-of-the-loop unfamiliarity* refers to the diminished ability of people to detect automation failures and to resume manual control (Endsley and Kiris, 1995). Several factors underlie this problem. First, automation might reduce feedback, and the remaining feedback may be qualitatively different than that received when operating under manual control (McFadden et al., 2003). With manual control operators often have both proprioceptive and visual cues, whereas under automatic control they may have only visual cues (Wickens and Kessel, 1981). Automation also reduces feedback because it distances operators from the process. Introducing automation into papermaking plants eliminated the informal feedback associated with vibrations, sounds, and smells that many operators relied upon (Zuboff, 1988). Second, monitoring the performance of automation involves passive observation of changes in system state, which is qualitatively different than the active monitoring associated with manual control (Gibson, 1962; Eprath and Young, 1981). In manual control, perception actively supports control, and control actions guide perception (Flach and Jagacinski, 2002). Monitoring automatic control disrupts this process. Third, automatic control can induce the operator to disengage and direct attention to other activities, further compromising the feedback from the system. The tendency to rely complacently on automation, particularly during multitask situations, may reflect this tendency to disengage from the monitoring task (Parasuraman et al., 1993, 1994; Metzger and Parasuraman, 2001). Finally, the operator's mental model may be inadequate to guide expectations and control. In particular, the automation may use control algorithms that are at odds with the control strategies and mental model of the person, making it difficult to anticipate the actions and limits of the automation (Goodrich and Boer, 2003). Operators with substantial previous experience and well-developed mental models detect disturbances more rapidly than operators without this experience, but extended periods of monitoring automatic control may undermine this skill and diminish operators' ability to generate expectations of correct behavior (Wickens and Kessel, 1981). This skill loss may also undermine operators' self-confidence, which can make them less inclined to intervene (Lee and Moray, 1994). Overall, out-of-the-loop unfamiliarity stems from disrupted feedback that diminishes the ability to form correct expectations, detect anomalies, and control the system manually.

An example of out-of-the-loop unfamiliarity occurs in driving. Adaptive cruise control (ACC) has the

potential to induce out-of-the-loop unfamiliarity, leading to delayed and less effective braking responses in situations in which the ACC is not able to respond to a braking lead vehicle (Stanton and Young, 1998). ACC uses sensors to maintain not only a set speed, as with conventional cruise control, but also a set distance to cars ahead. When drivers engage ACC, they no longer receive the haptic feedback that conveys the degree of braking needed to slow the vehicle in response to the braking behavior of vehicles ahead. Drivers also revert to passive monitoring of other vehicles rather than directing their attention toward the active control of their headway. Most important, ACC may induce drivers to direct their attention to nondriving activities such as cell phone conversations or reading the newspaper (Ward, 2000). Such distractions clearly delay driver response (Lee and Strayer, 2004). More subtly, drivers may have a poor mental model of the ACC control algorithms and so may not be able to anticipate situations that lie beyond the capabilities of the automation.

The difficulty of anticipating the behavior of the automation has also been seen in aviation, in which verbal protocol data show that pilots have problems with automation because of poor feedback and difficulties developing expectations regarding the behavior of the automation (Olson and Sarter, 2001). Analysis of eye movements, mental model probes, and pilot behavior showed that inadequate feedback and the associated poor monitoring are major contributors to automation mishaps (Sarter et al., 2007).

*Mode errors* often result from poor monitoring associated with poor feedback (Woods, 1994; Sarter and Woods, 1995). These arise when operators fail to detect the mode or recognize the consequence of mode transitions in complex automation. Substantial research with cockpit automation demonstrates that flight management systems often surprise pilots with unexpected mode transitions. These complex systems use a combination of the pilots' commands and system coupling to transition between modes. Mode transitions are often not commanded explicitly by the pilot and sometimes go unnoticed (Sarter and Woods, 1995).

Electronic charts in maritime navigation also offer the potential for mode errors. Such charts have several modes for determining a ship's position. One uses GPS data, another uses position extrapolation based on speed and heading (dead reckoning) to estimate the ship's position. If the GPS signal is lost, the electronic chart system changes automatically to the dead reckoning mode. This mode transition is signaled by a short alarm. If the alarm is not detected, however, the mariner may not notice that the GPS signal is no longer the basis for position estimates. Furthermore, many electronic charts do not maintain a continuous visual record of the vessel track. A track line is shown as long as the same chart or scale is used, but if the scale is changed, the track line is lost. The lack of track line continuity further undermines the ability of mariners to detect a transition from GPS to dead reckoning position estimates. If the mariner does not notice this mode transition, the ship can drift many miles from the intended course while the electronic chart continues to display the position

as if the vessel were following that course precisely. This is exactly what happened in the grounding of the cruise ship *Royal Majesty*, where the GPS signal was lost and the position estimation transitioned to the dead reckoning mode. The mode transition was noticed only when the ship ran aground (NTSB, 1997).

*Skill loss* refers to automation that leaves the operator without the appropriate skills to accommodate the demands of the job. In situations in which the automation takes on the tasks previously assigned to the operator, the skills of the operator may atrophy as they go unexercised (Endsley and Kiris, 1995). Part of this skill loss reflects diminished feedback. This is a particular concern in aviation, where pilots' aircraft handling skills may degrade when they rely on the autopilot. In response, some pilots disengage the autopilot and fly the aircraft manually to maintain their skills (Billings, 1997).

## 2.2 Task Structure Changes

*Clumsy automation* refers to the situation in which automation makes easy tasks easier and hard tasks harder (Wiener, 1989). As Bainbridge (1983) notes, designers often leave the operator with the most difficult tasks—those designers are unable to automate. Because the easy tasks have been automated, the operator has less experience and an impoverished context for responding to the difficult tasks, as a result of the out-of-the-loop problem mentioned above. In this situation, automation has the effect of both reducing workload during already low-workload periods and increasing it during high-workload periods. For example, a flight management system tends to make the low-workload phases of flight (such as straight and level flight or a routine climb) easier but high-workload phases (such as the maneuvers in preparation for landing) more difficult, as pilots have to share their time between landing procedures, communication, and programming the flight management system. Such effects are seen not only in aviation but also in the operating room (Cook et al., 1990b; Woods et al., 1991). The unfortunate tendency of operators to more willingly delegate tasks to automation during periods of low workload, compared to situations of high workload (Bainbridge, 1983), increases the prevalence of clumsy automation. This observation demonstrates that clumsy automation is not simply a technical problem, but one that depends on operator attitudes such as trust (Lee and See, 2004; Madhavan and Wiegmann, 2007).

The burden of clumsy automation is more prevalent than reported because operators adapt to clumsy automation, either tailoring their tasks or configuring the automation to adapt to poorly designed automation (Cook et al., 1990a). These strategies can mask the effects of clumsy automation in routine situations and make it appear more effective than it really is. When operators encounter abnormal situations, the problems of clumsy automation may emerge unexpectedly.

An example of potentially clumsy automation in maritime navigation occurs when the GPS is integrated with digital charts to create electronic chart display and information systems (ECDISs). When combined

with existing advanced maritime navigation systems (e.g., automatic radar plotting aid), these technological innovations tend to reduce repetitive physical activity while potentially increasing the mental demands made on the crew. The reduction in physical demands implies the possibility of reducing the number of personnel required on the bridge from as many as four people (captain, watch officer, helmsman, and lookout) to one. Recent studies suggest that under proper conditions workload declines and performance rises with one-person operations (Schuffel et al., 1988); however, this research has addressed only routine performance and has not considered more stressful conditions. Software failures and dense traffic situations combine to increase the workload substantially relative to the traditional system (Lee and Sanquist, 1996). This finding is consistent with poorly designed automation in the aviation and operating room, which reduces workload under routine conditions but increases it during stressful conditions (Wiener, 1989; Woods, 1991).

Clumsy automation can occur at the individual and organizational levels. Automation promises to reduce the need for human labor; during routine circumstances, fewer people are able to control the system effectively. The dramatic reduction in crew members needed to operate large ships testifies to this fact. However, clumsy automation at the macrolevel can occur when abnormal situations or high-tempo operations challenge the resources of the diminished crew (Lee and Morgan, 1994). Frequently, the wider effects of automation on training and recruitment go unexamined (Strain and Eason, 2000). Clumsy automation at the microlevel of the operator and the macrolevel of the organization represent critical challenges in anticipating the effect of automation.

*Automation–task errors* refer to the new forms of human error associated with new tasks generated by the introduction of automation. Managers and system designers often introduce automation to eliminate human error. Ironically, new and more disastrous errors can sometimes result. Automation often extends the scope of human actions and delays feedback associated with those actions. As a consequence, human errors may be more likely to go undetected and do more damage.

New automation-related tasks imply new skills are needed. Sophisticated automation eliminates many physical tasks and leaves complex cognitive tasks that may appear superficially easy, leading to less emphasis on training and a poor understanding of the automation. On ships, misunderstanding of new radar and collision avoidance systems has contributed to accidents (NTSB, 1990). One contribution to such accidents is training and certification that fail to reflect the demands of the automation. An analysis of the exam used by the U.S. Coast Guard to certify radar operators indicated that 75% of the items assess skills that have been automated and are not required by the new technology (Lee and Sanquist, 2000). The new technology makes it possible to monitor a greater number of ships, enhancing the need for interpretive skills such as understanding the rules of the road and the automation. These are the very skills that are underrepresented on the Coast Guard exam. While increasing automation might relieve the operator

of some tasks, they are likely to create new and more complex tasks that require more, not less, training.

*Brittle failures* are typical of human–automation interactions in which novel problems arise or even simple data entry mistakes are made with systems that completely automate the decision process and leave operators to assess the automation's decision (Roth et al., 1987; Roth and Woods, 1988). Such failures contrast with *graceful degradation*, a common characteristic of time-tested manual processes. Brittle failures are characterized by a sudden and dramatic decline in system performance, whereas graceful degradation is characterized by a more gradual and predictable decline. For example, a flight-planning system for pilots can induce dramatically poor decisions because it assumes that weather forecasts represent reality and lacks the flexibility to consider situations in which the actual weather might deviate from the forecast (Smith et al., 1997).

In maritime navigation, electronic charts introduce the potential for brittle failures in position estimation. Electronic charts distance mariners from the process of recording vessel position, leaving them with little insight into the factors that might lead to erroneous position estimates. The manual process of recording a position on a paper chart superimposes at least two position estimates, one based on extrapolation of the previous position and one based on visual bearings or other position information. These complementary position estimates help identify errors in determining position (Hutchins, 1995). Unlike the manual position recording on paper charts, electronic charts show the quality of the position estimation only indirectly, in terms of GPS signal quality; however, many mariners have little understanding of the relevance of these numbers, and gross errors in position can result (Lee and Sanquist, 2000).

Automation-related tasks also introduce the opportunity for *configuration errors*. Many forms of automation involve complex configurations or setups, and mistakes made during this process can later prove disastrous. For example, with electronic charts that aid maritime navigation, it is possible to configure the system to test the actual position automatically against the intended track using a feature in which an acceptable safety margin can be specified. If the ship deviates beyond this distance, an alarm sounds (provided that the feature was engaged and the GPS is functioning normally). Failing to engage this feature could jeopardize ship safety if mariners have come to rely on the automated warning. Also, because any one of several mariners can configure the system, system configuration and behavior can change in unanticipated ways as different mariners enter different safety margins. The danger of an inappropriate or unanticipated chart configuration is not a failure mode associated with paper charts but represents an automation-induced error that can threaten ship safety.

Brittle failures and configuration errors tend to undermine individual reliability and may have even greater detrimental effects on team performance (Skitka et al., 2000b). These automation-related errors may be particularly troublesome if the automation also undermines effective error-correcting strategies such as feedback and redundancies in the multiperson position-fixing process

(Hutchins, 1995). For example, because poor position fixes are visible to all team members, crew members who generate these fixes are corrected quickly. Through configuration errors, automation also creates the potential for one team member to induce errors in other team members. These factors all point toward the need to consider automation-induced errors at the level of the team and at the level of the individual.

*Behavioral adaptation* refers to the tendency of operators to adapt to the new capabilities of the automation, particularly to change behavior and tasks so that the potential safety benefits of the technology are not realized. Automation intended by designers to enhance safety may instead lead operators to reduce effort and leave safety unaffected or even diminished. Behavioral adaptation occurs at the individual (Wilde, 1988, 1989; Evans, 1991), organizational (Perrow, 1984), and societal levels (Tenner, 1996).

Antilock brake systems (ABSs) for cars show behavioral adaptation. The ABS modulates brake pressure automatically to maintain maximum brake force without skidding. This automation makes it possible for drivers to maintain control in extreme crash avoidance maneuvers, which should enhance safety. However, ABSs have not produced the intended safety benefits, in part because with them drivers tend to drive less conservatively, adopting higher speeds and shorter following distances (Sagberg et al., 1997). Similarly, vision enhancement systems make it possible for drivers to see more at night, potentially enhancing safety; however, drivers tend to adapt to the systems by increasing their speed (Stanton and Pinto, 2000).

Behavioral adaptation can also undermine the benefits of automation if the automation causes a diffusion of responsibility and a tendency to exert less effort when automation is available (Mosier et al., 1998; Skitka et al., 2000a). As a result, people tend to commit more omission errors (failing to detect events not detected by the automation) and more commission errors (concurring incorrectly with erroneous detection of events by the automation) when they work with automation. Automation can lead people to conserve cognitive effort rather than increase detection performance. This effect parallels the adaptation of people when they work in groups. Diffusion of responsibility leads people to perform more poorly when they are part of a group compared to individually (Skitka et al., 1999). A similar phenomenon is seen with decision support automation. People often use decision support systems to reduce effort rather than to enhance decision quality (Todd and Benbasat, 1999, 2000). The strong tendency of people to minimize effort and adapt their behavior to the most salient feedback they receive merits careful consideration in the design and implementation of automation. The effects of behavioral adaptation, particularly the diffusion of responsibililiy, suggest automation can change relationships between people, a topic we turn to next.

## 2.3 Relationships Change

Automation redefines not just tasks but also relationships between co-workers, with management, and between designers and users. Critical to defining these relationships is the degree to which people rely and comply with automation. Often designers and managers expect operators to rely on automation in a way that diverges from how people actually use the automation, or how they need to use the automation to maintain system safety and performance.

*Eutactic behavior* is behavior that approximates an optimal or satisficing response to the automation (Moray, 2003). As a consequence, eutactic behavior is not an instance of inappropriate reliance on automation but an instance of appropriate reliance that may be inconsistent with the expectations of the designers or managers. Misuse and disuse may sometimes reflect poorly calibrated trust, automation bias, or complacency. However, misuse and disuse may also reflect eutactic behavior and appropriate reliance once the costs and benefits are assessed completely. Automation that is generally reliable should be relied upon, even if it fails periodically, if the costs of a failure are modest, and if it relieves the operator of substantial mental effort. Careful monitoring to catch the periodic failure might not be worth the effort in such a case. What may appear to be complacent behavior may actually be appropriate given the costs of monitoring.

Discriminating between complacency and eutactic behavior requires optimizing a cost function that includes the cost of failing to detect failures *and* the cost of monitoring (Moray, 2003). Overreliance may be appropriate given the cost of monitoring. Similarly, disuse may also be appropriate. The new tasks associated with programming, engaging, monitoring, and disengaging automation can make the burden of managing the automation outweigh its benefit (Kirlik, 1993). In this situation, the aid will go unused by a well-adapted operator (Kirlik, 1993). Such behavior is eutactic and should be expected, but designers might be surprised if they fail to consider the burden of automation-related tasks.

Not all over- and underreliance is appropriate. Often operators respond to automation inappropriately, exhibiting a tendency toward misuse and disuse. *Misuse* refers to the failures that occur when people inadvertently violate critical assumptions and rely on automation inappropriately, whereas *disuse* signifies failures that occur when people reject the capabilities of automation (Parasuraman and Riley, 1997).

Another useful distinction in how operators use automation is that of reliance and compliance (Meyer, 2001). *Reliance* refers to the situation in which the operator does not act because the automation has not issued a warning or seems to be performing adequately. In contrast, *compliance* refers to the situation in which the operator acts in response to a warning or command from the automation. Overreliance results in errors of omission (failing to detect events not detected by the automation), and overcompliance results in errors of commission (concurring incorrectly with erroneous detection of events by the automation; Skitka et al., 2000a). Underreliance and compliance are differentially affected by false alarms and misses. Automation prone to false alarms affects compliance and reliance, but miss-prone automation tends to affect only reliance (Dixon et al., 2007).

The influence of false alarms on reliance and compliance is complicated. Although a high rate of false alarms often induces a cry wolf effect and an associated disuse of automation (Bliss et al., 1995), in some cases, such as air traffic conflict alerting systems, the relatively high rate of false alarms did not lead to disuse (Wickens et al., 2009). One reason for this effect is that false alarms are not a homogeneous class of warnings. Users may view some false alarms as useful and other false alarms might help them understand the system and so do not undermine compliance and reliance (Lees and Lee, 2007).

Misuse and disuse of automation may depend on certain attitudes of users, such as trust and self-confidence (Lee and Moray, 1994; Dzindolet et al., 2001). As an example, the difference in operators' trust in a route planning aid and their self-confidence in their own ability was highly predictive of reliance on the aid (de Vries et al., 2003). Many studies have demonstrated that trust is a meaningful concept to describe human–automation interaction, in both naturalistic settings (Zuboff, 1988) and laboratory settings (Halprin et al., 1973; Lee and Moray, 1992; Muir and Moray, 1996; Lewandowsky et al., 2000). People tend to rely on automation they trust and to reject automation they do not trust. In the context of operator reliance on automation, trust has been defined as an attitude that the automation will help achieve an operator's goals in a situation characterized by uncertainty and vulnerability (Lee and See, 2004).

Inappropriate reliance associated with misuse and disuse depends in part on how well trust matches the true capabilities of the automation. Calibration, resolution, and specificity of trust describe the match between trust and the capabilities of automation. *Calibration* refers to the correspondence between a person's trust in automation and the automation's capabilities (Lee and Moray, 1994; Lee and See, 2004). Definitions of the appropriate calibration of trust parallel those of misuse and disuse in describing appropriate reliance. Overtrust is poor calibration in which trust exceeds system capabilities; with distrust, trust falls short of automation capabilities. Figure 1 shows good calibration as the diagonal line where the level of trust matches automation capabilities. Above this line is overtrust and below is distrust. Overreliance on automation has sometimes been termed *complacency* and can result from trusting the automation more than is warranted.

*Resolution* refers to how precisely a judgment of trust differentiates levels of automation capability (Cohen et al., 1999). Figure 1 shows that poor resolution occurs when a large range of automation capability maps onto a small range of trust. With low resolution, large changes in automation capability are reflected in small changes in trust. *Specificity* refers to the degree to which trust is associated with a particular component or aspect of the trustee. Functional specificity describes the differentiation of functions, subfunctions, and modes of automation. With high functional specificity, a person's trust reflects capabilities of specific subfunctions and modes. Low functional specificity means that the person's trust reflects the capabilities of the entire system. Specificity can also describe changes in trust as a function of the situation over time. High temporal specificity means that a person's trust reflects moment-to-moment fluctuations in automation capability, whereas low temporal specificity means that the trust reflects only long-term changes in automation capability. Although temporal specificity implies a generic change over time as the person's trust adjusts to failures in the automation,

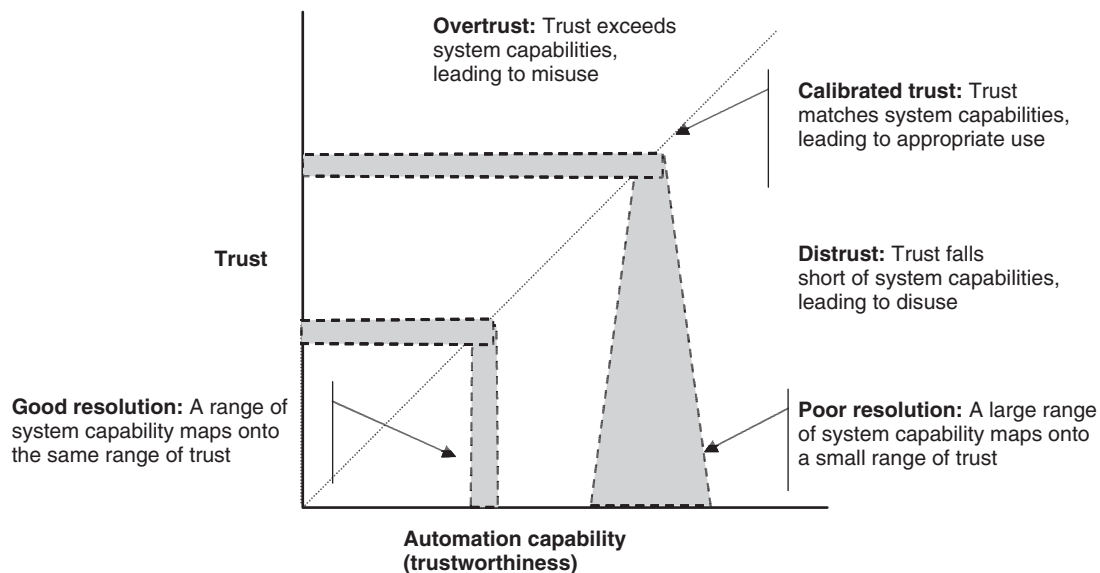

**Figure 1** Calibration, resolution, and automation capability define appropriate trust in automation. Overtrust may lead to misuse, and distrust may lead to disuse. (Reprinted with permission from Lee and See, 2004. Copyright 2004 by the Human Factors and Ergonomics Society.)

temporal specificity also addresses adjustments that should occur when the situation or context changes and affects the capability of the automation. High functional and temporal specificity increase the likelihood that the level of trust will match the capabilities of a particular element of the automation at a particular time. Good calibration, high resolution, and high specificity of trust can mitigate misuse and disuse of automation.

The information required to support appropriate trust can be considered in terms of attributional abstraction, which varies from the demonstrations of competence to the intentions of the automation (Lee and See, 2004). A recent review of trust literature concluded that three general levels summarize the bases of trust: ability, integrity, and benevolence (Mayer et al., 1995). Lee and Moray (1992) made similar distinctions in defining the factors that influence trust in automation and identified performance, process, and purpose as the general bases of trust.

*Performance* refers to the current and historical performance and reliability of the automation. Performance information describes *what* the automation does. More specifically, performance refers to the competency or expertise of the system, as demonstrated by its ability to achieve the operator's goals. Because performance is linked to the ability to achieve specific goals, it demonstrates the task- and situation-dependent nature of trust. This is similar to Sheridan's (1992) concept of robustness. The operator will tend to trust automation that performs in a manner that reliably achieves his or her goals.

*Process* is the degree to which the algorithms of the automation are appropriate for the situation and able to achieve the operator's goals. Process information describes *how* the automation operates. In interpersonal relationships, this corresponds to the consistency of actions associated with adherence to a set of acceptable principles (Mayer et al., 1995). Process as a basis for trust reflects a shift away from focus on specific behaviors and toward qualities and traits attributed to the automation. With the process dimension, trust is in the automation and not in the specific actions of the automation. As an example, knowing why automation failed increased trust even when it was not warranted (Dzindolet et al., 2003). In contrast, trust tends to drop with any sign of incompetence of the automation, even if the overall system performance is unaffected (Muir and Moray, 1996). Thus, the process basis of trust relies on dispositional attributions and inferences and is similar to Sheridan's (1992) concept of understandability. The operator will tend to trust the automation if its algorithms can be understood and it seems capable of achieving the operator's goals in the current situation.

*Purpose* refers to the degree to which the automation is being used within the realm of the designer's intent. It addresses the question of *why* the automation was developed. With interpersonal relationships, this depends on the intentions and motives of the trustee. This can take the form of abstract, generalized value congruence (Sitkin and Roth, 1993), which can be described as whether and to what extent the trustee has a motive to lie (Hovland et al., 1953). The purpose basis of trust reflects the attribution of these characteristics to the automation. Frequently, whether or not this attribution takes place will depend on whether the designer's intent has been communicated to the operator. If so, the operator will tend to trust the automation to achieve the goals it was designed to achieve. Often, the complexity, authority, and autonomy of the automation lead to a perceived animacy, in which the automation seems capable of independent and willful action independent of the operator (Sarter and Woods, 1994). In this situation, the intents that the operator infers may have little relationship to the purpose of the design, leading to a serious miscalibration of trust.

Although trust depends heavily on the interactions between an operator and the automation, the team and organizational structure within which they function may have an important effect on the diffusion of trust among co-workers. Communication with co-workers augments direct interaction with the automation and may have a strong influence on trust in the automation. A model of trust in automation and evolution of trust in multiperson groups that share responsibility for managing automation showed substantial influence of sharing automation-related information on trust and cooperation of other team members (Gao and Lee, 2006). In this situation, sharing information regarding the performance of the automation not only develops appropriate trust in the automation but also develops appropriate trust in team members who also manage the automation.

One of the ironies of automation is that operators often express a desire for simple and reliable automation, but want the automation to aid them with their most complex tasks (Tenney et al., 1998). Similarly, a highly sensitive warning system that results in many warnings can undermine trust because operators feel that the warnings fail to reflect the danger of the situation accurately (Gupta et al., 2002). These results suggest that understandable and reliable performance on easy tasks may not leave operators willing to rely on the automation to handle more difficult situations. Poor performance of automation on easy tasks severely undermines trust and reliance (Madhavan et al., 2006). Designing automation to promote appropriate trust may help resolve these conflicts. Ideally, trust in automation guides reliance when the complexity of a system makes complete understanding impractical and when the situation demands adaptive behavior (Lee and See, 2004). However, how to design automation to promote appropriate trust, particularly for complex automation that cannot be fully understood by the operator, is a substantial challenge.

One challenge to designing for appropriate trust is that trust has a strong emotional component and may respond to influences that would not be considered in the traditional information processing model that often underlies automation design. As an example, passenger attitudes towards an automated pilot depended on ticket price, suggesting price is used to infer quality. More importantly, inducing positive affect led to higher ratings, providing evidence that ratings of trust are strongly influenced by feelings (Hughes, et al., 2009). These results confirm a more general finding that emotion strongly influences attention, judgment and

decision making with respect to automation interactions (Lee, 2006).

*Job satisfaction and health* often depend on automation in unexpected ways, in part because automation changes the relationship between operators and managers and between operators and work. The issues noted above have addressed primarily the direct performance problems associated with automation. The issue of job satisfaction goes well beyond performance to consider the morale and moral implications of a worker whose job is being changed by automation. Automation that is introduced merely because it increases the profit of the company may not necessarily be well received. Automation often has the effect of de-skilling a job, suddenly making obsolete skills that operators worked for years to perfect. Properly implemented, automation should re-skill workers and enable them to leverage their old skills into new ones that are extended by the automation. Many operators are highly skilled and proud of their craft; automation can thus either empower or demoralize them (Zuboff, 1988). Unhappy operators may fail to capitalize on the potential of an automated system or may even actively sabotage the automation, similar to what the Luddites did.

Automation can also change the relationship to work, increasing demands and decreasing decision latitude. Such an environment can undermine worker health, leading to problems ranging from increased heart disease to increased incidents of depression (Vicente, 1999). However, if automation extends the capability of the operator, it can enhance both satisfaction and health if operators are given sufficient decision latitude. As an example, night shift operators had greater decision latitude than that of day shift operators who worked under the eye of the managers. The night shift operators used this latitude to learn how to manage the automation more effectively (Zuboff, 1988). These effects demonstrate the need to consider the management and implementation of the automation.

### 2.4 Interaction between Automation Problems

Although described independently, the problems of automation often reflect an interacting and dynamic process. One problem may lead to another. Figure 2 summarizes the general problems with automation and identifies some of the important interactions. In many of these relationships, positive feedback reinforces the problem, creating vicious cycles that exacerbate the difficulty. As an example, inadequate training and skill loss may lead the operator to disengage from the monitoring task. This, in turn, will exacerbate the out-of-the-loop unfamiliarity, which will further undermine the operator's skills, and so on. A similar dynamic exists between clumsy automation and automation-induced errors. Clumsy automation produces workload peaks, which increase the chance of mode and configuration errors. Recovering from these errors can further increase workload, and so on. Designing and implementing automation without regard for human capabilities and defining the human role as a by-product has been referred to as automation abuse (Parasuraman and Riley,

**Figure 2** Interactions among the problems with automation.

1997) and is likely to initiate the negative dynamics shown in Figure 2.

## 3 TYPES OF AUTOMATION

The first step in minimizing the problems and maximizing the benefits of automation is to clarify what is meant by the term *automation*. Automation is not a homogeneous technology. Instead, there are many types of automation and each poses different design challenges. Automation can highlight, alert, filter, interpret, decide, and act for the operator. It can assume different degrees of control and can operate over time scales that range from milliseconds to months. The type of automation, its limits, the operating environment, and human characteristics interact to produce the problems just discussed. Descriptions of automation from different perspectives can reveal the implications of automation for system performance. One such description considers automation in terms of the four stages of human information processing and levels of automation (Parasuraman et al., 2000). Another description considers popular metaphors for automation: tools, prostheses, and agents. Finally, automation can be considered in terms of the scope of the tasks it supports: strategic, tactical, and operational. Any such low-dimensional description of a high-dimensional space will certainly fail to capture important distinctions; nevertheless, these perspectives can make meaningful distinctions that can support design decisions.

### 3.1 Information-Processing Stages and Levels of Automation

If automation is considered as technology that replaces the human in performing a function, it is then reasonable to describe automation in terms of the information-processing functions of the person. Although imperfect,

the information process model of human cognition provides a useful engineering approximation that has been widely applied to system design (Broadbent, 1958; Rasmussen, 1986). The basic information-processing functions—information acquisition, information analysis, action selection, and action implementation—provide simple distinctions that can describe human and automation functions in a common language. A different type of automation corresponds to each stage of information processing. For each of these four functions, different degrees of automation are possible, ranging from full automation to manual control (Sheridan and Verplank, 1978). Information-processing stages and the degree of automation combine to describe a wide array of automation in a way that can guide automation design (Parasuraman et al., 2000).

*Information acquisition automation* refers to technology that complements the process of human attention. Such automation highlights targets (Yeh and Wickens, 2001; Dzindolet et al., 2002), provides alerts and warnings (Bliss, 1997; Bliss and Acton, 2003), and organizes, prioritizes, and filters information. Highlighting targets exemplifies a low degree of information acquisition automation because it preserves the underlying data and allows operators to guide their attention to the information they believe to be most critical. Filtering exemplifies a high degree of automation, and operators are forced to attend to the information the automation deems relevant. *Information analysis* refers to technology that supplants perception and working memory in the interpretation of a situation. Such automation supports situation assessment and diagnosis. As an example, critiquing a diagnosis generated by the operator represents a low degree of automation, whereas automation that provides a single diagnosis represents a high degree of automation. *Action selection automation* refers to technology that combines information in order to make decisions for the operator. Unlike information acquisition and analysis, action selection automation suggests or decides on actions using assumptions about the state of the world and the costs and values of the possible options (Parasuraman et al., 2000). Providing the operator with a list of suggested options represents a relatively low level of action selection automation. In contrast, automation that commands the operator to respond, as in the verbal "pull up, pull up" command of the ground proximity warning system, represents a high level of action selection automation. *Action implementation automation* supplants the operators' activity in executing a response. Olson and Sarter (2001) describe two degrees of action implementation automation *management by consent*, in which the automation acts only with the consent of the operator, and a greater degree of automation *management by exception*, in which automation initiates activities autonomously.

Each of these four stages of automation combines with the degree of automation to describe how the technology supplants the operator's role in perceiving and responding to the environment. Figure 3 shows two hypothetical systems. System B replaces the operator to a relatively high degree for all information-processing stages. In contrast, system A represents a generally

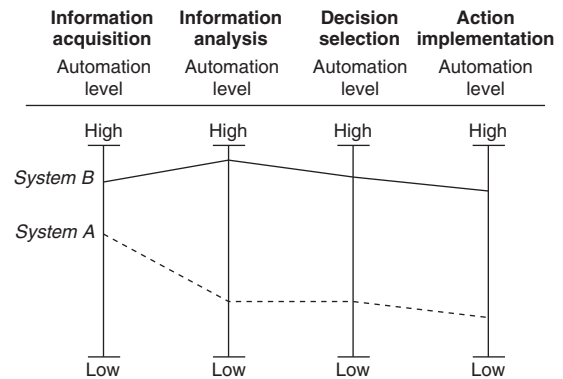

**Figure 3** Two examples of automation defined by a profile of the degree of automation over the four information-processing stages. (From Parasuraman et al., 2000. Copyright © IEEE 2000.)

lower level of automation, with only a moderate degree of automation in the information acquisition stage (Parasuraman et al., 2000).

## 3.2 Tool, Prostheses, and Agents

As automation becomes more complex, considering it simply as a replacement for the information-processing functions of the operator may not differentiate adequately between important types of automation. In many situations, automation is not merely a system that operators engage and disengage. Often, automation consists of a complex array of modes and levels that operators must manage. Interacting with the automation involves coordinating multiple goals and strategies to select a mode of operation that fits the situation (Olson and Sarter, 2000). The simple distinction of engaging manual and automatic control does not capture the complexity of many types of automation. Important design issues emerge as automation evolves from a tool the operator uses to act on the environment to a prosthesis that replaces a human ability to an agent that acts on behalf of the operator. Increasing capacity of automation makes the metaphor of automation as a team member increasingly apt (Klein et al., 2004). The metaphors of automation as a tool, prosthesis, and agent provide complementary perspectives to the information-processing metaphor of automation.

Automation, considered as a *cognitive tool,* extends and complements human capabilities. According to the tool metaphor of automation, operators work directly on the environment, but automation augments their interactions. Just as a hammer augments human action in physical tasks, automation can augment operators in cognitive tasks (Woods, 1987). The benefit of automation as a tool is that its influence is clear and its failures are obvious. An example of automation as a tool that augments human capabilities is a haptic gas pedal, which increases the resistance as the driver approaches a car ahead. This contrasts with adaptive cruise control that automates car following or collision warnings that

only alert the driver when he or she gets too close to the car in front. The continuous feedback of the haptic pedal provides the driver with a useful tool that improves car-following performance (Mulder et al., 2008)

Automation, considered as a *cognitive prosthesis,* acts to replace human function with a more capable computer version. Often, designers adopt this approach in an attempt to enhance system performance or safety by eliminating human error. A cognitive prosthesis eliminates a variable or error-prone aspect of human behavior and replaces it with a consistent computer-based process. The cost of this approach is lost flexibility and reduced ability to adapt to unforeseen situations (Roth et al., 1988). For these reasons, the cognitive prosthesis approach is most appropriate for routine, low-risk situations where decision consistency is more important than adapting to unusual situations. Automation that must accommodate unusual circumstances should adapt a cognitive tool perspective that complements rather than replaces human decision making.

Automation considered as an *agent* acts as a semiautonomous partner with the operator. According to the agent metaphor, the operator no longer acts directly on the environment but acts through an intermediary agent (Lewis, 1998) or intelligent associate (Jones and Jacobs, 2000). As an agent, automation initiates actions that are not in direct response to operators' commands. The authority, autonomy, and complexity of many advanced automated systems make them seem like intentional agents to operators, even if the designers had not intended to adopt this metaphor (Sarter and Woods, 1997). This autonomy and authority can lead to instances of poor coupling and coordination breakdowns because the agents fail to communicate their intentions (Sarter and Woods, 2000; Hoc, 2001). One of the greatest challenges with automated agents is that of mutual intelligibility. Instructing the agent to perform even simple tasks can be onerous, but agents that try to infer operators' intent and act autonomously can surprise operators, who might lack mental models of agent behavior. One approach to improve operator–agent cooperation is for the agents to learn and adapt to the characteristics of the operator through a process of remembering what they have been told to do in similar situations (Bocionek, 1995). After the agent completes a task, it can be equally challenging to make the results meaningful to the operator (Lewis, 1998). Because of these characteristics, agents are most useful for highly repetitive and simple activities, where the cost of failure is limited. In high-risk situations, constructing effective management strategies and providing feedback to clarify agent intent and communicate behavior become critical (Olson and Sarter, 2000; Sarter, 2000).

The differences between automation as a tool, prosthesis, and agent reflect a shift in the locus of control. With a tool, the operator firmly maintains control, but with an agent, the locus of control is more ambiguous and may pass back and forth between the operator and the automation. Ambiguity in the locus of control introduces important considerations regarding inferred intent and the dynamic coordination of actions (Woods, 1994).

The metaphors of tool, prosthesis, and agent complement the information-processing description of automation in important ways. The information-processing metaphor emphasizes the idea that automation replaces the person in performing a function but that function and system remain unchanged. Other metaphors, such as that of automation as an agent, emphasize the far-reaching changes that automation may induce. Rarely is automation a simple replacement of the human, rather, as Woods (1994, p. 4) describes, "technology change produces a complex set of effects. In other words, automation is a wrapped package—a package that consists of changes on many different dimensions bundled together as a hardware/software system." Just as the information-processing metaphor of automation leverages a long history of experimental psychology research, the agent metaphor may leverage recent developments in distributed cognition and team effectiveness (Seifert and Hutchins, 1992; Hutchins, 1995). Such a shift may lead to a change in the boundaries that define the unit of analysis, from one centered on a single operator and a single element of automation to one that considers multioperator, multiautomation interactions (Hollan et al., 2000; Gao and Lee, 2004).

### 3.3 Multilevel Control

The scope of automation varies dramatically, from decision support systems that guide corporate strategies over months and years to antilock brake systems that modulate brake pressure over milliseconds. Substantially different human limitations govern operator interaction with automation at these extremes. A three-level structure that has been used to describe driver behavior seems appropriate for discussing the more general issue of human–automation coordination (Michon, 1985; Ranney, 1994). Figure 4 shows three levels of control that provide a framework for considering issues of coordination and communication of intent. Each level of the figure defines a different level of control that could be supported by a different type of automation. *Strategic automation* concerns balancing values and costs as well as defining goals; *tactical automation*, on the other hand, involves priorities and coordination. Finally, *operational automation* has to do with perceptual cues and motor response.

The bottom of Figure 4 shows operational automation, which governs system behavior over the span of approximately 0.5–5 s. Automation at this level concerns the moment-to-moment control of dynamic processes. An example in the driving domain is ACC, which controls the speed of the car and its distance to the vehicle ahead. The middle of Figure 4 shows tactical automation, which governs system response over a time span of seconds to minutes. In driving, this automation would include route guidance systems that notify drivers of upcoming turns. At the top of the figure is strategic automation, which governs behavior from minutes to days. In driving, this automation helps drivers to select routes and plan trips.

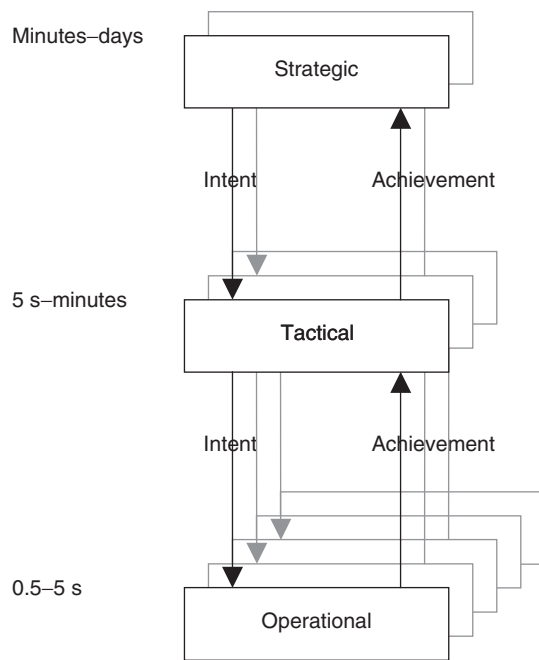
The multilevel control perspective shown in Figure 4 identifies design considerations for the different types of automation and the interaction between different


**Figure 4** Strategic, tactical, and operational automation describe types of automation that reveal important coordination and feedback requirements.

elements of automation. First, automation at one level may have unanticipated effects on behavior at another level. For example, automatic control at the lower level might lead people to adopt different behaviors at a higher level, such as when ACC reduces the attention needed in routine car following at the operational level and influences decisions at the tactical level, such as deciding to engage in a cell phone conversation. Second, time constants have a critical effect on monitoring and control behavior. Detection of low-frequency events requires sustained monitoring best suited to time scales at the operational level (0.5–5 s), but such events often occur on a time scale that is orders of magnitude greater. At the other extreme are systems that demand responses on a time scale so short that it exceeds human capabilities. For these systems, automation may need to assume final authority for actions (Moray et al., 2000; Inagaki, 2003). The three-level structure highlights qualitative differences in the time constants of system control that automation design should consider (Hoc, 1993). Third, this perspective highlights the critical issue of communicating intent and the achievement of intent. Figure 4 highlights this requirement because automation at the operational level must be coordinated to achieve the intent developed at the tactical level. Adequate performance of an element of automation at the operational level does not guarantee success at the tactical level unless it is coordinated properly. Automation at one level of control must be managed to minimize interference between agents that might otherwise jeopardize

achieving common tasks at another level of control (Hoc, 2001). Finally, Figure 4 points to the need to consider what some have termed *macrocognition* (Klein et al., 2003). Macrocognitive processes include situation assessment, planning, and coordination. Typical laboratory studies of automation have focused on *microcognition*, associated with operational and tactical levels; however, many critical problems with automation lie at the strategic level and in the interaction between the strategic and tactical levels.

The term *automation* represents a broad array of technology, and no one dimension or framework will capture the many factors that contribute to the problems often encountered with its implementation. Metaphors of information-processing systems, tools, prostheses, agents, and multilevel control all provide complementary perspectives on the nature of automation and how it influences operator performance. These perspectives are not mutually exclusive. A given instance of automation could be described using any or all of the three perspectives. Each provides a different description to guide automation design. Similarly, each perspective provides a partial and distorted description of the true complexities of automation. Although each perspective is limited, each can enhance our understanding of human–automation interaction.

## 4 STRATEGIES TO ENHANCE HUMAN–AUTOMATION INTERACTION

Defining the problems encountered with automation should instill caution in those who believe that automation can enhance system performance and safety by replacing the human operator. The perspectives on the nature and types of automation reveal the complexity of automation. Neither caution nor perspective, however, is sufficient to develop successful automation. In this section we describe specific strategies for designing effective automation, which include:

- Fitts's list and function allocation
- Dynamic function allocation (adaptable and adaptive automation)
- Matching automation to human performance characteristics
- Representation aiding and multimodal feedback
- Matching automation to mental models
- Formal automation analysis techniques

### 4.1 Fitts's List and Function Allocation

One approach to automation is to assess each function and determine whether a human or automation would perform that function better (Kantowitz and Sorkin, 1987; Sharit, 2003). Functions better performed by automation are automated and the operator remains responsible for the rest and for recovering during the periodic failures of the automation. Fitts's list provides a heuristic basis for determining the relative performance of humans and automation for each function (Fitts,

**Table 1  Fitts's List: Relative Strengths of Automation and Humans for the Four Information-Processing Stages**

| Information-Processing Stage | Humans Are Better At: | Automation Is Better At: |
| --- | --- | --- |
| Information acquisition | Detecting small amounts of visual, auditory, or chemical signals | Monitoring processes |
| | Detecting a wide range of stimuli | Detecting signals beyond human capability |
| Information analysis | Perceiving patterns and making generalizations | Ignoring extraneous factors and making quantitative assessments |
| | Exercising judgment | Consistently applying precise criteria |
| | Recalling related information and developing innovative associations between items | Storing information for long periods and recalling specific parts and exact reproduction |
| Action selection | Improvising and using flexible procedures | Repeating the same procedure in precisely the same manner many times |
| | Reasoning inductively and correcting errors | Reasoning deductively |
| Action implementation | Switching between actions as demanded by the situation | Performing many complex operations at once |
| | Adjusting dynamically to a wide range of conditions | Responding quickly and precisely |

1951). Table 1 shows a revised Fitts list for the stages of automation identified earlier. The relative capability of the automation and human depend on the stage of automation (Sheridan, 2000).

Using the heuristics in Table 1 to determine which functions should be automated mitigates skill loss and lack of training by clearly identifying the human role in a system. This approach also enhances job satisfaction by designing a role for the operator that is compatible with human capabilities. Ideally, the function allocation process should not focus on what functions should be allocated to the automation or to the human but should identify how the human and the automation can complement each other in jointly satisfying the functions required for system success (Hollnagel and Bye, 2000).

Applying the information in Table 1 to determine an appropriate allocation of function has, however, substantial weaknesses. One weakness is that there are many interconnections between functions. Any description of functions is a somewhat arbitrary decomposition of activities that masks complex interdependencies. As a consequence, automating functions as if they were independent has the tendency to fractionate the operator's role, leaving the operator with only those tasks too difficult to automate (Bainbridge, 1983). Automation must be designed to support the job of the operator as an integrated whole. Another weakness with this approach is the situation dependence of the automation and human performance. The same function may require improvisation in some circumstances and precise application of a fixed response in others. Another weakness is that the work and the automation coevolve, with the automation making unanticipated work practices possible and the work leading to unanticipated applications of the automation (Dearden et al., 2000). A final weakness with function allocation using Fitts's list is the diminishing list of situations in which human abilities exceed those of the automation. Strict adherence to the application

of Fitts's list to allocate functions between people and machines has been widely recognized as problematic (Parasuraman et al., 2000; Sheridan, 2000).

Although imperfect, Table 1 contains some general considerations that can improve design. People tend to be effective with complete patterns and less so with highly precise repetition. Human memory tends to organize large amounts of related information in a network of associations that can support effective judgments requiring the consideration of many factors. People also adapt, improvise, and accommodate unexpected variability. For these reasons it is important to leave the "big picture" to the human and the details to the automation (Sheridan, 2002).

## 4.2  Dynamic Function Allocation: Adaptable and Adaptive Automation

Using Fitts's list or some other method to allocate functions between humans and automation results in static function allocation in which the division of labor is fixed by the designer. Functions once performed by the human are now performed by automation. Static allocation of function contrasts with dynamic allocation of function, in which adaptable and adaptive automation makes it possible to adjust the division of labor between the human and the automation over time (Scerbo, 1996; Sarter and Woods, 1997). Dynamic allocation of function addresses the need to adjust the degree and type of automation according to individual differences, the state of the operator, and the state of the system. Adaptable and adaptive automation is often preferable to automation that is fixed and rigid.

*Adaptable automation* is that which the operator can engage or disengage as needed. The operator adapts the level and type of automation to the situation. Giving operators the option of manual or automatic control can be more effective than making available only automatic or only manual control (Harris et al., 1995).

More generally, adaptable automation gives operators additional degrees of freedom needed to accommodate unanticipated events (Hoc, 2000). The decision to rely on the automation or to intervene with manual control depends on many factors, including perceived risk, workload, trust, and self-confidence (Riley, 1989, 1994; Lee and Moray, 1994). To the extent that operators trust the automation appropriately and have appropriate self-confidence, they tend to rely on the automation appropriately and avoid some of the out-of-the-loop unfamiliarity problems. Allowing operators to transition easily between automatic and manual control can also mitigate clumsy automation. On the other hand, one of the critical deficiencies of adaptable automation is that it gives the operator the additional tasks of engaging and disengaging the automation. If the effort associated with these tasks is great, adaptable automation can increase the workload of demanding situations and thus become an example of clumsy automation.

*Adaptive automation* goes a step further than adaptable automation by automatically adjusting the level of automation based on the operator's performance, the operator's state, or the task situation (Rouse, 1988; Byrne and Parasuraman, 1996). Often, adaptive automation focuses on increasing the level of automation when either the operator's workload increases or the operator's capacity decreases. One way to estimate operator workload is through physiological measures such as heart rate and electroencephalography (EEG) signals (Byrne and Parasuraman, 1996). For example, it is possible to moderate an operator's workload by using closed-loop control algorithms to adjust the level of automation according to the operator's EEG signal (Prinzel et al., 2000). Other estimates of workload depend on models that relate the task situation to expected cognitive load and operator performance. For example, by combining operator performance and task variables it is possible to engage automation and mitigate predictable workload increases (Scallen and Hancock, 2001). Most promising is an approach that combines data from all three sources along with model-based predictions of workload. By engaging higher levels of automation during periods of high workload, adaptive automation promises to solve some of the problems of clumsy automation.

Alleviating overload is often the motive behind the development of adaptive automation. It may be equally important, however, to consider how it can mitigate problems of underload. Both underload and overload stress an operator's ability to respond (Hancock and Warm, 1989), and automation that returns tasks to the operator during underload situations may place operators in a less stressful situation. Similarly, operators who monitor reliable automation for long periods become surprisingly inefficient at detecting automation failures. Adaptive automation can mitigate this automation-induced complacency by returning manual control periodically to the operator (Parasuraman et al., 1996). Adaptive automation that used EEG signals led to higher levels of situation awareness and lower levels of workload compared to adaptable automation that

required people to manage the users to engage the automation (Bailey et al., 2006).

Adaptive automation is a sort of meta-automation that can suffer from some of the same problems of automation if implemented improperly. Adaptive automation relieves the operator of the task of engaging and disengaging the automation, but it imposes the additional task of monitoring the adaptive automation, which can also increase workload (Kaber et al., 2001). In addition, adaptive automation faces challenging measurement and control problems. Adaptive automation depends on a precise measure of operator state, which can include physiological variables. If the time constant of these variables is longer than the time constant of the demands of the environment, automation will not adapt quickly enough. Even if operator state can be measured in a precise and timely manner, developing control algorithms that relate the operator state to an appropriate level of automation is difficult. Many of the limits of applying the Fitts list to static allocation of function also make dynamic allocation of function a challenge. Finally, even if an appropriate algorithm for adjusting the automation dynamically can be defined, the operator might respond in unexpected ways. For example, operators may manipulate their physiological state to influence the automation (Byrne and Parasuraman, 1996). Most important, operators may not understand the adaptive automation and so will view the system as behaving erratically. Such dynamic changes also introduce interface inconsistencies and increase the potential for mode errors.

## 4.3 Matching Automation to Human Performance Characteristics

Another approach to automation design considers how operators respond to different types of imperfect automation (Parasuraman et al., 2000). How well an operator is able to recognize and recover from automation failures often governs overall system performance. As a consequence, an important approach to automation design is to consider how human performance characteristics interact with the type of automation. The objective of this design approach is to minimize the tension that arises from mismatches between human performance characteristics and the type of automation (Sharit, 2003). A specific example of this approach considers the levels of automation and types of automation as defined by the stages of information processing. Primary considerations for automation design include workload, situation awareness, complacency, and skill maintenance (Parasuraman et al., 2000). These considerations do not specify a universally applicable degree of automation for each information-processing stage. Instead, appropriate automation design depends on the reliability of the automation and the consequences of failure as well as on technical and economic considerations (Parasuraman et al., 2000). In the context of air traffic control, human performance characteristics argue for the following upper bounds on the level of automation: information acquisition (high), information interpretation (high), action selection (medium), and action implementation (medium).

As an example, displays that indicate the status of the system (information interpretation automation) are preferable to those that advise the operator on how to respond (action selection automation) (Crocoll and Coury, 1990). Specifically, alerts regarding hazardous road conditions presented as a command (e.g., merge left) led to more dangerous lane changes compared to the same information presented as a notification (e.g., road construction in right lane) (Lee et al., 1999). Similar findings for a decision aid to help pilots make decisions regarding the dangers of aircraft icing suggest that status displays are preferable to command displays in high-risk domains where the automation is imperfect (e.g., space flight, medicine, and process control) (Sarter and Schroeder, 2001). Action implementation automation can be helpful when reliable but dangerously compelling when unreliable. Operators benefit more from action implementation automation than from action selection automation, but only when the automation performs reliably (Endsley and Kaber, 1999). Although a greater degree of automation enhances performance and reduces workload during routine situation, it can also reduce situation awareness and undermine the ability to respond—when the automation fails, operators perform better with lower levels of automation (Kaber et al., 2000). In addition to the reliability of the automation, time pressure influences the benefit of a greater degree of automation. Pilots preferred management by consent, a relatively low level of automation; however, during periods of high time pressure and high workload, they preferred management by exception, a higher level of automation (Olson and Sarter, 2000).

Expert systems represent a high degree of decision automation that has frequently failed to meet expectations. Typically, an expert system acts as a prosthesis, supposedly replacing flawed and inconsistent human reasoning with more precise computer algorithms. Unfortunately, the level of automation associated with such an approach often conflicts with the range of situations the automation must face: The system gives the wrong answer when confronted with cases for which the automation is not fully competent. In addition, the operator typically plays a passive role such as entering data or assessing automation decisions, which leads to brittle failures (Roth et al., 1988).

A lower degree of automation, which places the automation in the role of critiquing the operator, has met with much more success. In critiquing, the computer presents alternative interpretations, hypotheses, or choices that complement those of the operator (Guerlain et al., 1999; Sniezek et al., 2002). A specific example is a decision support system for blood typing (Guerlain et al., 1999). Rather than using the expert system as a cognitive prosthesis to identify blood types, the critiquing approach suggests alternative hypotheses regarding possible interpretations of the data. In cases where the automation was fully competent, the operators made correct diagnoses 100% of the time, compared to 33–63% for those without the critiquing system. In cases where the critiquing system was not fully competent, performance degraded gracefully and operators still correctly diagnosed 32% more cases than those without

the critiquing system. In situations where the automation is imperfect or the cost of failure is high, a lower level of automation, such as that used in the critiquing approach, is less likely to induce errors. Although much of the benefit of a critiquing system stems from the lower degree of automation and the greater involvement of the operator in the decision process, representation aiding plays an important role in supporting efficient operator–automation interaction.

## 4.4  Representation Aiding and Multimodal Feedback

Even if the type of automation is well matched to the task situation and human capabilities, inadequate feedback can undermine human–automation interaction. Inadequate feedback underlies many of the problems with automation from developing appropriate trust and clumsy automation to the out-of-the-loop phenomenon (Norman, 1990). However, providing sufficient feedback without overwhelming the operator is a critical design challenge. Poorly presented or excessive feedback can increase operator workload and undermine the benefits of the automation (Entin et al., 1996). In addition, without the proper context, abstraction, and integration, information regarding the behavior of complex automation may not be understandable. Representation aiding and multimodal feedback are two approaches that can help people understand how the automation works and how it is performing.

*Representation aiding* capitalizes on the power of visual perception to convey complex dynamic relationships. For example, graphical representations for pilots can augment the traditional airspeed indicator with target airspeeds and acceleration indicators. Integrating this information into a traditional flight instrument allows pilots to assimilate automation-related information with little extra effort (Hollan et al., 2000). Using a display that combines pitch, roll, altitude, airspeed, and heading can directly specify task-relevant information such as what is "too low" (Flach, 1999). Integrating automation-related information with traditional displays and combining low-level data into meaningful information are two important ways to enhance feedback without overwhelming the operator.

In regard to process control, Guerlain et al. (2002) identified three specific strategies for visual representation of complex process control algorithms. First, create visual forms whose emergent features correspond to higher order relationships. Emergent features are salient symmetries or patterns that depend on the interaction of the individual data elements. A simple emergent feature is *parallelism*, which can occur with a pair of lines. Higher order relationships are combinations of the individual data elements that govern system behavior. The boiling point of water is a higher order relationship that depends on temperature and pressure. Second, use appropriate visual features to represent the dimensional properties of the data. For example, magnitude is a dimensional property that should be displayed using position or size on a visual display, not color or texture. Third, place data in a meaningful context. The meaningful context for any variable depends on what

**Figure 5** (a) Comparison of a traditional interface for automation; (b) example of representation to support operator understanding of automation.

comparisons need to be made. For automation, this includes the allowable ranges relative to the current control variable setting and the output relative to the desired level. Figure 5 shows some of the principles of representation aiding—use analog rather than digital or text, provide meaningfully integrated rather than raw data, and provide a context to support visual rather than mental comparisons.

Representation aiding makes it more likely that operators will trust automation more appropriately. However, trust also depends on more subtle elements of the interface (Lee and See, 2004). In many cases, trust and credibility depend on surface features of the interface that have no obvious link to the true capabilities of the system (Briggs et al., 1998; Tseng and Fogg, 1999). For example, in an online survey of over 1400 people, Fogg et al. (2001b) found that for websites credibility depends heavily on "real-world feel," which is defined by factors such as response speed, a physical address, and photos of the organization. Similarly, a formal photograph of the author enhanced trustworthiness of a research article, whereas an informal photograph decreased trust (Fogg et al., 2001a). These results show that trust tends to increase when information is displayed in a way that provides concrete details that are consistent and clearly organized.

A similar pattern of results appears in studies of automation for target detection. Increasing image

realism increased trust and led to greater reliance of the cueing information (Yeh and Wickens, 2001). Similarly, the tendency of pilots to follow the advice of the system blindly increased when the aid included detailed pictures (Ockerman, 1999). Just as highly realistic images can increase trust, degraded imagery can decrease trust, as was shown in a target cueing situation (MacMillan et al., 1994). Adjusting image quality and adding information to the interface regarding the capability of the automation can promote appropriate trust. In a signal detection task, the reliability of the sources was coded with different levels of luminance, leading participants to weigh reliable sources more than unreliable ones (Montgomery and Sorkin, 1996). These results suggest that the particular interface form can increase the level of trust, particularly the emphasis on concrete realistic representations.

Trust and reliance can also be enhanced with information that conveys the performance and expected value of automation. Such information can address appraisal errors—failures to properly judge the benefit of the automation. In one study, performance feedback reduced disuse rates from 84 to 55% (Beck et al., 2007). This result suggests that even when operators understand the expected value of the automation, they persist in disuse, indicating a John Henry effect in the form of intent errors. Intent errors were mitigated with scenario training that conveyed the appropriate thought process for interpreting automation suggestions. When combined with feedback, scenario training reduced disuse to 29% (Beck et al., 2007). The degree of personal investment operators have in performing the task has a strong influence on the prevalence of intent errors and, consequently, the importance of scenario training (Beck et al. 2009). Such

Representation aiding tends to focus on interfaces that require focal as opposed to peripheral vision. Operators already face substantial demands on focal vision, and presenting automation-related information in that channel may overwhelm the operator. *Multimodal feedback* provides operators with information through haptic, tactile, auditory, and peripheral vision to avoid overwhelming the operator. Haptic feedback has proved more effective in alerting pilots to mode changes in cockpit automation compared to visual cues (Sklar and Sarter, 1999). Pilots receiving visual alerts detected 83% of the mode changes; those with haptic warnings detected 100% of the mode changes. Importantly, the haptic warnings did not interfere with the performance of concurrent visual tasks. Similarly, peripheral visual cues also helped pilots detect uncommanded mode transitions and did not interfere with concurrent visual tasks any more than did currently available automation feedback (Nikolic and Sarter, 2001). Haptic warnings may also be less annoying and acceptable compared to auditory warnings (Lee et al., 2004). Although promising, multimodal interfaces lack the resolution of visual interfaces, making it difficult to convey complex relationships and detailed information.

### 4.5 Matching Automation to Mental Models

The complexity of automation sometimes makes it difficult to convey its behavior using representation

aiding or multiple-modal feedback. Sometimes a more effective strategy is to simplify the automation (Riley, 2001) or to match its algorithms to the operators' mental model (Goodrich and Boer, 2003). This is particularly true when a technology-centered approach to automation design has created an overly complex array of modes and features. The out-of-the-loop unfamiliarity problems result partially from the difficulties that operators have in generating correct expectations for the counterintuitive behavior of complex automation. Automation designed to perform in a manner consistent with operators' preferences and expectations can make it easier for operators to recognize failures and intervene.

Adaptive cruise control is a specific example of where matching the mental model of the operator may be quite effective. Because drivers must focus their attention on the roadway, representation aiding could be distracting. Because ACC can apply only moderate levels of braking, drivers must intervene if the car ahead brakes heavily. If drivers must intervene, they must quickly enter the control loop because fractions of a second matter. If the automation behaves in a manner consistent with that of the driver, he or she will be more likely to detect and respond to the operational limits of the automation (Goodrich and Boer, 2003). To design an ACC algorithm consistent with drivers' mental models, driver behavior was partitioned according to perceptually relevant variables of inverse time to collision and time headway. Inverse time to collision ($T_c^{-1}$) is the relative velocity divided by the distance between the vehicles. Time headway ($T_h$) is the distance between vehicles divided by the velocity of the driver's vehicle. These variables define the boundary that separates speed regulation and headway maintenance from active braking associated with collision avoidance. Figure 6 shows this boundary in the space defined by time headway and inverse time

**Figure 6** Driver braking behavior, showing a clear boundary between headway maintenance (○) and collision avoidance (×) that could be used to define operational limits of ACC. (From Goodrich and Boer, 2003. Copyright © IEEE 2002.)

to collision. This boundary provides a template for designing ACC—the ACC should signal the driver to intervene as the driving situation crosses the boundary.

For situations in which the metaphor for automation is an agent, the mental model that people may adopt to understand the automation is that of a human collaborator. If the template for understandable automation is the operator's mental model, an agent should respond as would a human. Specifically, Miller (2002) suggests that computer etiquette may have an important influence on human–automation interaction. Etiquette may influence trust because category membership associated with adherence to a particular etiquette helps people to infer how the automation will perform. Specific rules for automation etiquette adapted from Miller and Funk (2001) include:

- Make many correct interactions for every erroneous interaction.
- Make it very easy to override the automation.
- Do not make the same mistake twice—stop a behavior if corrected by the operator.
- Do not enable interaction features just because they are possible.
- Explain what is being done and why.
- Be able to take instruction.
- Do not assume every operator is the same—be sensitive and adapt to individual, contextual, and cultural differences.
- Be aware of what the operator knows and do not repeat unnecessarily.
- Use multiple modalities to communicate.
- Try not to interrupt.
- Be cute only if it furthers specific interaction goals.

Developing automation etiquette could promote appropriate trust, but it could lead to inappropriate trust if people infer inappropriate category memberships and develop distorted expectations regarding the capability of the automation. Even in simple interactions with technology, people often respond as they would to another person (Reeves and Nass, 1996; Nass and Lee, 2001). If anticipated, this tendency could help operators develop appropriate expectations regarding the behavior of the automation; however, unanticipated anthropomorphism could lead to surprising misunderstandings of the automation.

An important prerequisite for designing automation according to the mental model of the operator is the existence of a consistent mental model. Individual differences may be difficult to accommodate. This is particularly true for automation that acts as an agent, in which a mental model–based design must conform to complex social and cultural expectations. In addition, the mental model must be consistent with the physical constraints of the system if the automation is to work properly (Vicente, 1990). Mental models often contain misconceptions, and transferring these to the automation could be counterproductive or deadly. Even if operators

have a single mental model that is consistent with the system constraints, automation based on a mental model may not achieve the same benefits as automation based on more sophisticated algorithms. In this case, designers must consider the trade-off between the benefits of a complex control algorithm and the costs of a poorly understood system. Representation aiding can mitigate this trade-off.

## 4.6 Formal Automation Analysis Techniques

Effective representation aiding depends on identifying the relevant information needed to understand the behavior of the automation. With complex automation, this can be a substantial challenge. One approach to meeting this challenge is to use formal verification techniques (Leveson, 1995; Degani and Heymann, 2002). Specifically, state machines can define the behavior of the automation and the operator's model. The state machine that defines the operator's model is constructed from the training materials and the information available on the interface. State machines provide a formal modeling language to define mismatches between the operator's model of the automation and the automation. These mismatches cause automation-related errors and surprises to occur.

State machines identify the legal and illegal states defined by the task constraints that the automation and operator must satisfy. When the automation model enters an illegal state and the operator's model does not, the analysis predicts that the associated ambiguity will surprise operators and lead to errors (Degani and Heymann, 2002). Such ambiguities have been discovered in actual aircraft autopilot systems (Degani and Heymann, 2002). Mismatches between the operator and automation models indicate deficiencies in the operator's mental model that should be addressed by changing the automation, training, or interface (Heymann and Degani, 2007). The state machine formalism makes it possible to generate training and interface requirements automatically.

Often, designers overestimate the benefit of automation because of the surprising interactions between the automation, environment, and operator. Formal analysis that considers these interactions in terms of expected-value calculations can reduce the surprise and guide design. In the example of a rear-end collision warning system for cars, a Bayesian approach combined with signal detection theory shows that the posterior probability of a collision situation given a warning is surprisingly low because the base rate of collision situation is so low (Parasuraman et al., 1997). This analysis shows that the selection of a detection threshold should consider the base rate; otherwise, the relatively high rate of false alarms could undermine driver acceptance.

More generally, calculating the expected value of manual and automatic control provides a rigorous means of selecting the best alternative (Sheridan and Parasuraman, 2000). In the simplest case this involves comparing the expected value of the operator and automation response to a binary failure state—a system is either operating normally or it has failed. The expected-value calculation combines the benefits and costs of four general responses to the system: a true

positive, a true negative, a false negative, and a false positive. The expected value of the automation and the expected value of the operator response depend on the costs of being wrong and the benefits of being correct, together with the prior probabilities of the failure and the probabilities of the automation and operator being wrong and correct. If the expected value for automatic control is greater than the expected value for manual control, automation should be implemented. A similar analysis shows that the time-dependent value of automation makes it reasonable to give the automation final authority in some situations, such as in guiding the pilot to make go/no go decisions in aborting a takeoff (Inagaki, 2003). A similar analysis might help designers balance the information-processing demands of feedback regarding automation behavior with the time demands of the situation. Experiments assessing human interaction with automation should consider this calculation in defining experimental conditions, defining the reward structure, and interpreting the participants' behavior (Bettman and Payne, 1990; Payne et al., 1992; Meyer, 2004); otherwise, it is impossible to differentiate automation bias from eutactic behavior.

An expected-value analysis provides a way to formalize the cost–benefit analysis that might otherwise be guided by the qualitative Fitts list heuristics. Although it promises to precisely quantify otherwise ambiguous decisions, estimating the numbers required to support the calculations can be a challenge. The costs and probabilities of rare, catastrophic events are notoriously difficult to estimate. More subtly, operator performance may affect the prior probabilities of events such that good operators experience fewer failures than do poor operators. In this situation, the automation will perform more poorly for better operators (Meyer and Bitan, 2002). Although precise probabilities and values may be difficult or impossible to estimate, such an approach is quite useful even if only relative benefits and costs of the automation and operator can be estimated (Sheridan and Parasuraman, 2000).

Simulation can also guide designers to consider the costs and benefits of automation more thoroughly. A simulation of a supervisory control situation shows that well-adapted operators are sensitive to the costs of engaging and disengaging automation (Kirlik, 1993). This simulation analysis identifies how the time costs of engaging the automation interact with the dynamics of the environment to undermine the value of the automation. A similar analysis argues that designers must make the normative strategy less effortful than competing strategies if operators are to use automation effectively (Todd and Benbasat, 2000). More generally, simulation models that capture the human performance consequences of different levels of automation reliability, and the environmental constraints are needed to support design. For example, a connectionist model of complacency provides a strong theoretical basis that accounts for empirical findings (Farrell and Lewandowsky, 2000). Cognitive architectures such as ACT-R also offer a promising approach to modeling human–automation interaction (Anderson and Libiere, 1998). Although ACT-R may not be able to capture the full complexity

of this interaction, it may provide a useful tool for approximating the costs and benefits of various automation alternatives (Byrne and Kirlik, 2005).

## 5 EMERGING CHALLENGES

Substantial progress has been made regarding how to design automation to support people effectively. However, continuous advances in software and hardware development combined with an ever-expanding range of applications make future problems with automation likely. The following section highlights some of these emerging challenges. The first is the demands of managing a new type of automation, *swarm automation*, in which many semiautonomous agents work together. The second is the implication of automation in large interconnected networks of people and other automated elements, where issues of coordination and competition become critical. Automation in this environment requires considerations beyond those of the typical single operator interacting with one or two elements of automation. The third is the introduction of automation into daily life: specifically, automation in the car. These three examples represent some of the challenges associated with new types of automation, new types of human–automation organizations, and new application domains.

### 5.1 Swarm Automation

*Swarm automation* is an alternative approach to automation that may make it possible to respond to environmental variability while reducing the chance of system failure. These capabilities have important applications in a wide range of domains, including planetary exploration, unmanned aerial vehicle reconnaissance, landmine neutralization, or even data exploration, where hundreds of simple agents might be more effective than a single complex agent. Biology-inspired roboticists provide a specific example of swarm automation. Instead of the traditional approach of relying on one or two larger robots, they employ swarms of insect robots as an alternative (Brooks et al., 1990; Johnson and Bay, 1995). The swarm robot concept assumes that small machines with simple reactive behaviors can perform important functions more reliably and with lower power and mass requirements than can larger robots (Beni and Wang, 1993; Brooks and Flynn, 1993; Fukuda et al., 1998). Typically, the simple programs running on an insect robot are designed to elicit desirable emergent behaviors in the swarm (Sugihara and Suzuki, 1990; Min and Yin, 1998). For example, a large group of small robots might be programmed to search for concentrations of particular mineral deposits by building on the foraging algorithms of honeybees or ants.

In addition to physical examples of swarm automation, swarm automation has potential in searching large complex data sets for useful information. For example, the pervasive issue of data overload and the difficulties associated with effective information retrieval suggest a particularly useful application of swarm automation. Current approaches to searching large complex data sources, such as the Internet, are limited. People are

likely to miss important documents, disregard data that represent a significant departure from initial assumptions, misinterpret data that conflict with an emerging understanding, and disregard more recent data that could revise interpretation (Patterson, 1999). These issues can be summarized as the need to broaden searches to enhance opportunity to discover highly relevant information, promote recognition of unexpected information to avoid premature fixation on a particular viewpoint or hypothesis, and manage data uncertainty to avoid misinterpretation of inaccurate or obsolete data (Woods et al., 1999). These represent important challenges that may require innovative design concepts and significant departures from current tools (Patterson, 1999). Just as swarm automation might help explore physical spaces, it might also help explore information spaces.

Managing swarm automation requires a qualitatively different approach than that of more traditional automation (Lee, 2001). Swarms of bees and ants, in which many simple individuals combine to behave as a single entity, provide some useful insights into the characteristics of swarm behavior and how they might be managed (Bonabeau et al., 1997). A defining characteristic of swarm behavior is that it emerges from parallel interaction between many agents. For example, swarms of bees adjust their foraging behavior to the environment dynamically in a way that does not depend on the performance of any individual. A colony of honeybees functions as a large, diffuse, amoeboid entity that can extend over great distances and simultaneously tap a vast array of food sources (Seeley, 1997). Direct control of this emergent behavior is not possible. Instead, mechanisms influencing individual elements of the swarm indirectly influence swarm behavior. Two particularly important mechanisms are positive feedback and random variation. Positive feedback reinforces existing activities, and random variation generates new activities and encourages adaptation (Resnick, 1991). One way that positive feedback and random variation combine to influence behavior is through *stimergy*, in which communication and control occur through a dynamically evolving structure. Through stimergy, social insects communicate directly through the products of their work (e.g., the bees' honeycomb and the termites' chambers). A specific example of stimergy is the pheromone trail that guides the self-organizing foraging behavior of ants. Stimergy in foraging behavior involves a trade-off of speed of trail establishment and search thoroughness; A trail that is more quickly established will sacrifice the thoroughness of the search. Stimergy represents a powerful alternative to a static set of instructions that specify a sequence of activity. Parallel interaction between many agents, positive feedback, random variation, and stimergy make it possible for many simple individuals to produce complex group behavior (Bonabeau et al., 1997). However, such control mechanisms may be difficult for operators to understand.

The concept of hortatory control describes some of the challenges of controlling swarm automation. Hortatory control applies in situations where the system being controlled retains a high degree of autonomy and operators must exert indirect rather than direct control (Murray and Liu, 1997). Interacting with swarm automation requires people to consider swarm dynamics independent of the individual agents. In these situations it is most useful for the operator to control parameters affecting group rather than individual agents and for the operators to receive feedback about group rather than individual behavior. Swarm automation has great potential to extend human capabilities, but only if a thorough empirical and analytic investigation identifies the display requirements, feasible control mechanisms, and range of swarm dynamics that can be comprehended and controlled by humans.

## 5.2 Management of Complex Networks of Operators and Automation

As automation becomes pervasive, it creates complex networks of increasingly tightly coupled elements. In this situation, the appropriate unit of analysis may shift from a single operator interacting with a single element of automation to that of multiple operators interacting with multiple elements of automation. Important dynamics can only be explained with this more complex unit of analysis. More so than single-operator situations, in these highly coupled systems, poor coordination between operators and inappropriate reliance on automation can degrade the decision-making performance and lead to catastrophes (Woods, 1994). As an example, the largest power grid failure in the nation's history occurred on August 14, 2003. In this failure, the flow of approximately 61,800 MW of electricity was disrupted, leaving 50 million customers from Ohio to New York and parts of Canada without power. An important contribution to this event was a lack of cooperation between two regional electrical grid operators that monitor the same region. These operators manage the flow of the electricity from suppliers to distributors. Poor communication and a failure to exchange detailed information on their operations prevented them from understanding and responding to changes in the power grid. Similar failures occur in supply chains as well as petrochemical processes, where people and automation sometimes fail to coordinate their activities.

Supply chains represent an increasingly important example of multioperator multiautomation. A supply chain is composed of a network of suppliers, transporters, and purchasers who work together, usually as a decentralized virtual company, to convert raw materials into products for end users. The growing popularity of supply chains reflects the general trend of companies to move away from vertical integration, where a single company converts raw materials into products for end users. Many manufacturers increasingly rely on supply chains; a typical U.S. company purchases 55% of the value of its products from other companies (Dyer and Singh, 1998). Efficient supply chains play a critical role in maintaining the economic health of the U.S. economy.

However, supply chains suffer from serious problems that erode their promised benefits. One is the *bullwhip effect*, in which small variations in end-item demand induce large-order oscillations, excess inventory, and backorders (Sterman, 1989). This effect can have enormous consequences on a company's efficiency and value. As an example, news reports of supply chain

glitches associated with the bullwhip effect resulted in abnormal declines of 10.28% in companies' stock price (Hendricks and Singhal, 2003). Automation that forecasts demands can moderate these oscillations (Lee and Whang, 2000; Zhao and Xie, 2002). However, people must trust and rely on that automation, and substantial cooperation between supply chain members must exist to share such information.

Another major problem facing supply chains is the breakdown in cooperation as relationships between members of a supply chain devolve through an escalating series of conflicts that has been termed a *vicious cycle* (Akkermans and van Helden, 2002). Such conflicts can have dramatic negative consequences for a supply chain. For example, a strategic alliance between Office Max and Ryder International Logistics devolved into a legal fight in which Office Max sued Ryder for $21.4 million and then Ryder sued Office Max for $75 million (Handfield and Bechtel, 2002). Beyond the legal costs, these breakdowns can threaten competitiveness and undermine the market value of the company (Dyer and Singh, 1998). Vicious cycles also undermine information sharing, which can exacerbate the bullwhip effect. Even with the substantial benefits of cooperation, supply chains frequently fall into a vicious cycle in which poor cooperation leads to further poor cooperation. Trust between people plays a critical role in developing and sustaining cooperative relationships. People must trust each other to share information, and this trust can be undermined if poorly managed automation of one supply chain member compromises the success of another.

The bullwhip effect and vicious cycles and other supply chain problems reflect the influence of inappropriate actions at the local level that drive dysfunctional network dynamics. These effects are unique to highly coupled networks and require a unit of analysis that goes beyond the single person interacting with a single element of automation. As exemplified by the bullwhip effect and vicious cycles, the problems of supply chain management reflect generic challenges in using decentralized control to achieve a central objective. Decentralized networks promise efficiency and the capacity to adapt to unexpected perturbations, but their complexity and inefficient information sharing can lead people to respond to local rather than global considerations. Automation can alleviate the tendency for attention to local goals to magnify a small disturbance into a widespread disruption, or properly designed, it may alleviate this tendency. However, too little or too much trust in automation leads to inappropriate reliance, which can induce dysfunctional dynamics, such as the bullwhip effect and vicious cycles (Lee and Gao, 2006).

Other domains share the general promise and pitfalls of modern supply chain management. For example, power grid management involves a decentralized network that makes it possible to supply the United States efficiently with power, but it can fail catastrophically when cooperation and information sharing break down (Zhou et al., 2003). Similarly, datalink-enabled air traffic control makes it possible for pilots to negotiate flight paths efficiently, but it can fail when pilots have trouble anticipating the complex dynamics of the system (Olson

and Sarter, 2001; Mulkerin, 2003). Also, grid computing makes its enormous computing power available for use by many independent agents, but it can fail if load balancing and job scheduling do not consider global considerations (Lorch and Kafura, 2002; Chervenak et al., 2003). Overall, technology is creating many highly interconnected networks that have great potential but that also raise important concerns. Resolving these concerns depends on designing effective multioperator, multiautomation interactions.

### 5.3  Driving and Roadway Safety

Much of the existing research on automation has focused on operators of large complex systems for which expensive automation has been practical to develop. As computer and sensor technology becomes more affordable, automation will become more common in systems encountered in day-to-day life. Automation for cars and trucks is an example of automation that will touch the day-to-day lives of many people. Vehicle automation may touch more peoples' lives and have a greater safety consequence than any other type of automation. In the United States alone, people drive over 2 trillion miles a year in cars and light trucks (Pickrell and Schimek, 1999). The safety consequence is equally impressive. Over 6 million crashes kill approximately 42,000 people each year and result in an economic cost of over $164 billion per year (Wang et al., 1999). Motor vehicle crashes are also the leading cause of workplace injuries, being responsible for 42% of work-related fatalities (Bureau of Labor Statistics, 2003). Automation in cars and trucks, like that of increasing automation in other parts of daily life, has the potential to influence the safety and comfort of many people.

Functions that vehicle automation might support range from routing and navigation to collision avoidance and vehicle control (Lee, 1997; Young and Stanton, 2007). Table 2 shows some of the many examples of current and potential types of vehicle automation. Currently, examples include navigation systems that use GPS data and electronic map databases that give drivers turn-by-turn directions. Also, adaptive cruise control uses sensors and new control algorithms to extend cruise control so that cars slow down automatically and maintain a safe distance from the car ahead. Many vehicles even have a system that uses sensor data (e.g., airbag deployment) to detect a crash, calls for emergency aid, and then transmits the crash location using the car's GPS. The potential of automation to enhance the safety and comfort of drivers is substantial.

Designing automation to support driving confronts many of the same challenges as those found with automation in other domains. Sensor imperfections and complexity of the driving environment make adaptive cruise control and collision warning systems fallible. Recent studies suggest that adaptive cruise control may induce complacency and the potential of overtrust. Specifically, many drivers intervene too slowly to prevent a collision when the adaptive cruise control fails to brake (Stanton et al., 1997). Behavioral adaptation also threatens to undermine the safety benefits of automation. Automation aimed to enhance safety, such as an ABS,

**Table 2 Automation for Driving and Other In-Vehicle Technology**

| General Functions | Specific Examples |
|---|---|
| Routing and navigation | Trip planning, multimode travel coordination and planning, predrive route and destination selection, dynamic route selection, route guidance, route navigation, automated toll collection, route scheduling, posttrip summary |
| Motorist services | Broadcast services/attractions, services/attractions directory, destination coordination, delivery-related information |
| Augmented signage | Guidance sign information, notification sign information, regulatory sign information |
| Safety and warning | Immediate hazard warning, road condition information, aid request, vehicle condition monitoring, driver monitoring, sensory augmentation |
| Collision avoidance and vehicle control | Forward object collision avoidance, road departure collision avoidance, lane change and merge collision avoidance, intersection collision avoidance, railroad crossing collision avoidance, backing aid, vehicle control |
| Driver comfort, communication, and convenience | Real-time communication; asynchronous communication; contact search and history; entertainment and general information; heating, ventilation, air conditioning, and noise |

*Source*: Adapted from Lee and Kantowitz (2005).

has not produced the expected safety benefits because drivers with an ABS tend to change their driving behavior and follow more closely (Sagberg et al., 1997). A similar response may occur with collision warning systems that aim to give drivers advance notice of impending collisions. Such systems may lead some drivers to think they can safely engage in distracting activities, such as reading or watching DVDs, while driving. Understanding how to develop vehicle automation to enhance safety such that behavioral adaptation does not erode its benefits is a critical challenge.

Another challenge that confronts the design of vehicle automation is the potential for driver confusion in the face of many poorly integrated systems. Similar problems of automation coordination and integration have occurred with maritime navigation aids (Lee and Sanquist, 2000), flight management systems (Sarter and Woods, 1995), and medical devices (Cook et al., 1990a). Already, early examples of vehicle automation show the substantial confusion and frustration associated with poorly integrated systems, such as the recent controversy

and confusion regarding the 700 features of the BMW iDrive (Norman, 2003). Forward object, road departure, lane change, and intersection collision warning systems may all populate the car of the future, and identifying which warning has been activated may be a challenge for drivers. To avoid such confusion requires a design approach that considers the overall driving ecology and the information needed to negotiate it rather than an approach focused on sensor technology and arbitrarily defined collision types.

Unlike operators of automation in domains such as aviation and process control, drivers do not receive specific training on how to operate particular features of their car. In addition, drivers belong to a very heterogeneous group that spans a wide range of age, experience, and goals for driving. The difficulty of providing systematic training for automotive automation and the diversity of drivers make it likely that many drivers will misunderstand and misuse vehicle automation. Drivers misunderstand even a simple system, such as an ABS, and benefit from training on how to use it (Mollenhauer et al., 1997). More complex systems such as adaptive cruise control may confuse drivers, particularly as they move from a vehicle they are accustomed to driving to one they are not (e.g., a rental car). Ensuring that all drivers are properly trained is much more difficult than ensuring that process control operators or pilots understand the automation they manage. Automation that affects day-to-day life, such as vehicle automation, faces the particular challenges of being understood and used appropriately by a highly diverse array of potential users.

## 6  AUTOMATION—DOES IT NEED US?

The Luddites faced the prospect of automation changing their lives, and we face a similar prospect today. Increasingly sophisticated automation makes it possible to replace the human in many situations, and the situations in which humans outperform automation are diminishing rapidly. Although the need for human adaptability, creativity, and flexibility makes complete automation of most systems infeasible, the increasing capability of automation may eliminate even these reasons to include human operators. Soon, automating based on the criterion of whether the human or machine is better suited to perform a task may be irrelevant. This situation requires a deeper consideration of the purpose of technology (Hancock, 1996). Although automation allows people to avoid dangerous and unpleasant situations, unrestrained automation may eliminate activities that provide intrinsic enjoyment and purpose to life (Nickerson, 1999). Ironically, automating everything that is technologically possible or even everything that enhances system efficiency and safety may have the unanticipated effect of diminishing the lives of the people that automation should ultimately serve. Like the Luddites, we may ultimately need to confront the issue of whether automation needs us. "At least we have it in our power to say no to new technology, or do we?"(Sheridan, 2000, p. 203).

# CHAPTER 60

# HUMAN FACTORS IN MANUFACTURING

**Dieter Spath, Martin Braun, and Katrin Meinken**
**Fraunhofer Institute for Industrial Engineering**
**Stuttgart, Germany**

## 1 MANUFACTURING

### 1.1 Basic Definitions

*Manufacturing* is a human-driven transformation process. Using energy and manpower, this process creates consumer goods of economic value from naturally or rawly produced materials (Westkämper and Warnecke, 2002). The manufacturing area is more and more moving away from force-focused physical activity in favor of cognitive control activity. The main challenges coming with this change will be addressed in this contribution regarding the ergonomic work design.

Manufacturing is a part of production which has a major function in enterprises. It includes the tasks of production, assembly, logistics, planning, control, maintainance, and quality management. Additionally human resource management needs to be considered. Comprehensive production contemplation refers not only to technological and organizational aspects but also to the work's social and cultural values. The production process can only run optimally if integration of these factors has been achieved (Spath, 2003).

### 1.2 Historical Overview of Production Engineering

Three "industrial revolutions" characterize the historical development of production engineering (see Figure 1):

- During the *first industrial revolution*, power machines were developed. Characteristic for this period is the aspect of energy conversion.

- During the *second industrial revolution*, the organization of production was at the forefront. As far as organizational work measures, time became a most important production factor.

- During the *third industrial revolution*, information technology and automation were developed. Characteristic for this era is the application of information.

### 1.2.1 Early Industrialization

For decades production systems have been influenced by the "principles of scientific management" of Taylor (1911). Taylor examined the effects of monetary incentive systems and work division on performance. The basic assumption was that the average worker is motivated to work efficient mainly by financial aspects. This assumption leads to a consequent division of manual and mental work. In this way, the production system became independent from the know-how of the skilled worker. Complex tasks divided into sufficiently small subtasks could be done by almost everyone. This division of work called for responsible management, which today is still an influential characteristic of many businesses. The most important characteristics of the Tayloristic work structure are:

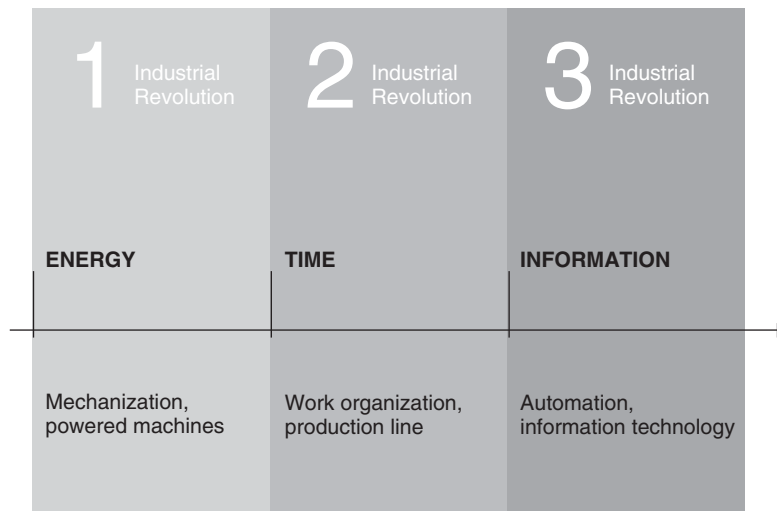
- Division of planning and implementing tasks
- Individual incentives (e.g., piece wage)
- Hierarchical system


**Figure 1**  History of industrial development.

- Low work content
- Low skill levels
- "One best way" for every work sequence

It was not until the middle of the twentieth century that there was a gradual turn from the Taylorism division-of-work structure. In the 1960s, team work was used in place of these concepts. Team work calls for the individual to strive toward autonomy and self-realization.

The complex nature of these challenges required appropriate work design strategies. Although numerous promising design concepts were developed, it is to be noted that the obtained findings were implemented only insufficiently.

### 1.2.2  Present Positions

Production engineering is significantly influenced by progressive technical development, dynamic market conditions, and individual values regarding his or her work. At the same time, the technical organisational and human factors influencing the production process are not seen as being isolated from each other but rather influence each other. The most important factors influencing production design will be discussed below.

***The Human***  Over the past few years, the application of flexible production systems has become more widespread as a result of small lot sizes and an increasing variety of products. A high level of mechanization as well as intense informational relationships is characteristic of flexible production systems. Modified working situations for the human arise: While physical load was at the foreground earlier in time, the human today has to face additional psychological stress (Braun, 2008). Examples are as follows:

- Maintenance and surveillance of large-scale plants with increasing complexity
- Attention when working with dangerous materials or during dangerous processes

- Exposure to industrial robots
- Working with computer networking systems
- Innovative information systems
- Management and leadership paradigms (e.g., management by objectives)

Despite the change in working conditions, physical strain still plays an important role. Physical strain results, for example, from the manual handling of loads, by unfavorable or forced body movements, and postures which can lead to health hazards.

Additionally, companies are confronted with the effects of demographic development, that is, a partially overaged population of workers. In the future production tasks will be predominantly carried out by older employees. Therefore, maintaining health and qualification is more important than ever (Kern and Braun, 2006).

***Market***  The buyer's market has confronted manufacturing businesses with new challenges. Product life cycles are shortened and the time to market is constantly decreasing. These factors cause increases in employees' complaints about time pressure and stress.

***Technology***  In manufacturing, increasing automation and use of efficient information technology (IT) are particularly important. The problem is how individual work can be designed through existing and developing technology operations. It is assumed that the planning and operation of production systems need a paradigm shift toward a balance between individual and technical factors (Bullinger, 2003).

### 1.2.3  Perspectives in Manufacturing

The market-driven development and introduction of new products are crucial in order to obtain competitive economic advantages. At the same time, increased efficiency must be promoted. These can be achieved by the strategies discussed below (Westkämper, 2004).

***Time to Market*** In order to attain and use innovations with the goal of having a timely advantage over competitors, the manufacturing processes must be effective. Methods and tools have to be supplied in order to reduce the time as well as the cost of development and planning (Spath et al., 2003). As seminal are regarded:

- The synchronization of product and production development
- The market orientation and objective orientation considering the entire process chain
- An optimization of product development at an early stage
- Integrated management systems for engineering and production, including generative processes for prototyping

***Flexible Enterprise*** Customer orientation is a strategic success factor. The fulfillment of customer demands and short supply of products are preconditions for a substantial economic benefit. In dynamic markets only a flexible and adaptive organization delivers justifiable economic results. Above all, the resources (i.e., manufacturing resources, employees, material) must constantly be adjusted to demand. Currently, reaction times are often in the middle range. Bureaucracy and long logistical routes hinder flexibility.

Short-term production structure flexibility can be achieved by production networks, self-organization, self-optimization, and the use of intelligent production methods. Buzzwords such as "agile manufacturing" characterize the discussion of product paradigms which cause a higher dynamic and flexibility.

### Performance and Precision in Manufacturing

Over the past few years, performance has improved in many areas of manufacturing technology. Starting points are the usage of information systems for process management, self-learning, quality control, just-in-time systems, and machine and system diagnostics. The development of materials, sensor systems, and actuating elements as well as the awareness of interactions between process parameters and achievable performance and precision is of significant importance. At a high technological and performance level significant time and cost savings can only be achieved by the cooperation of skilled individuals.

***Automation and Humanization*** The idea of full automated enterprises existed for years, inspired by the development of automation technology. The supply and disposal of workplaces with material and information processing from design to implementation were completely automated. These assumptions failed due to the high complexity of automated systems.

As a result, numerous enterprises changed their strategy by emphasizing the qualifications of employees. In this way, effective and increasing short-term performances could be achieved. At the same time, enterprises learned how to optimize operations and control processes by applying human resources better.

***Adaptive Production*** Not only is adaptive production affected by turbulences in the markets but also these turbulences should be used to develop a competitive advantage. Adaptive production systems have the following characteristics:

- Information, as a production factor, is becoming increasingly important.
- Economic growth is achieved more by system considerations than by individual optimization.
- Employee qualification development is becoming more important.
- Team work is being increased.
- The implementation and development of human resources become central issues.

## 1.3 Production Systems

*Production systems* were developed in order to deal with expected operational challenges. Their appearance is a result of an integrated industrial application of various methodical approaches.

### 1.3.1 Terms and Definitions

A *system* is an interrelated combination of elements or procedures which either exist in nature or are artificial. A system and its subsystems are confined by the system boundaries. Combinations and interactions within a system are usually described in a process-oriented manner.

Systemic design requires that elements and methods are connected to each other. Therefore, an optimal material and information flow is an important consideration. The output of one method serves as an input for the next method. Integrating material and information flow results in optimizing transfer processes concerning time and quality.

When dealing with production systems the individual, the organization, and the technology should be taken into consideration (Spath, 2003). Moreover various management concepts have been integrated (see Figure 2).

A production system covers at least the production process, which includes functions of planning, manufacturing and assembly, control, logistics, and quality control. These business processes are often expanded to integrate, for example, the acquisition process, the research and development process, and the sales process.

### 1.3.2 Design Principles

Production systems are adapted specifically to markets, products, technologies, and corporate cultures. The systematic application of design principles will ensure that all system elements fit together, resulting in a coherent system. Next we discuss the principles for designing production systems (Scholtz et al., 2003).

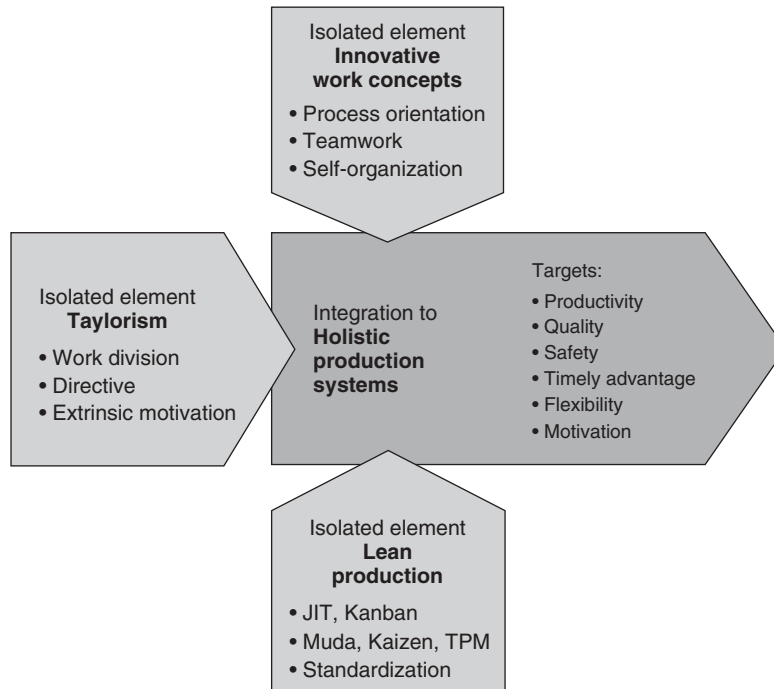
***Autonomous Teamwork*** Comprehensive and challenging tasks are often fulfilled best if the team is working autonomously. The team takes on planning tasks such as work distribution, the order in which assignments are processed, appointment compliance,


**Figure 2**  Development of integrated production systems (Korge and Scholtz, 2004).

acknowledgement of lot size per time unit, material disposition, and so on. In addition, they adopt tasks such as machine maintenance and repair, cleaning and transportation tasks, and quality control. Qualification activities ensure that group members are able to fulfill these tasks. Members more inefficient than others are not pushed to the edge in this system. The concept corresponds to a long-time existing demand to create working conditions which enhance an employee's development potential. Figure 3 illustrates a group working at an ergonomically and functional optimized workstation.

***Process Integration***  Process integration is defined as enabling the cooperation of production functions, which replaces the consideration of isolated functions. Process integration implies that production reacts to supply and demand. Information systems support process orientation (e.g., logistical tasks).

***Just in Time***  Just in time (JIT), that is, the concept of "timely delivery as required" is an essential part of process-oriented work. This concept is related to having limited storage capacity. Minimal capital is tied up for the storage of parts, and only the amount of product needed in one process step is provided in a specific time frame. The JIT concept includes the suppliers and only the required parts are produced at the right time in the desired quality and free of waste. The most important methods and concepts of JIT are:

- One-piece flow (piece production)
- Principle of "first in, first out (FIFO)"
- Small-sized transport equipment

**Figure 3**  Group work assembly operation at an ergonomically optimized workstation. (Courtesy of Fraunhofer IAO.)

- Rapid changeover
- Kanban

***Continuous Improvement Process***  The continuous improvement process (CIP) is a fundamental element of work organization. The attitude is to be always

in search of better problem solving. All workers are asked to supply ideas for the process improvement.

The concept of CIP originated in Japan where it is called "Kaizen," which means "getting good through a thousand little improvements." In contrast to the established employee suggestion system, CIP encourages all workers to make even minor recommendations. Basically, it is an attitude that directs employees to critically consider existing processes, analyze them, and find solutions. Improvements are communicated to all concerned.

CIP can be a fixed component in teamwork, for example, a quality circle. Mostly the employees are motivated by incentives to provide ideas. It is important to note that the improvement process might lead to disadvantages for the employees (e.g., job elimination). To motivate employees to participate in the CIP, they should be made aware that no disadvantages can arise from their participation. Therefore, the CIP should be aimed not at cost savings, personnel reduction, and work compression but at improved work organization, employee qualification, ergonomic work design, stress reduction, and so on.

***Professional Work Routines*** To maintain results from the CIP and to prevent, for example, the so-called brain drain, professional work routines are used. They define the manner and protocol by a work process is carried out. In this way professional work routines ensure a sustainable implementation of improvements.

Important concepts and methods regarding professional work routines are standardized working papers, standardized shift change, standardized equipment, standardized quality problem operations, and defined rhythms for preventive maintenance and documentation.

The standardization aims to improve the process management. It is wise to reduce the number of solutions to as few as possible. The necessary degree of flexibility with respect to the customer needs may not, however, be inadequately confined by standardized solutions.

***Target Management*** Target management means making agreements with individual employees or teams about the expected performance during a given period. After the given period, it is decided whether or not these goals have been reached. Many factors can be stipulated ahead of time, for example, the amount of revenue expected during a given period, the date until which a product is to be manufactured, and when an assignment has to be completed. Similarly, there are stipulations regarding employee performance, for example, in order to increase operational readiness. The extent and degree of the achieved objectives form the foundation for further personnel decisions, such as promotion prospects, transfers, and cancellations. In combination with performance management the target management forms an instrument for performance control. A main characteristic of target management is that employees decide nearly autonomously how to reach the goals.

Target agreements should be commonly developed to create mutual trust of the employee. The employee knows why reaching these goals is of importance for the business. Goals should not be inconsistent or too detailed; rather they should be important, plausible, and easy to evaluate.

***Robust Processes*** Robust processes aim to deliver products and benefits reliably and without errors (e.g., "zero-error goal") to the customer. This task can only be reached by a preventive quality policy. Preventive methods should help to identify and avoid errors before the start of production. By analyzing the source of the error and eliminating it, errors are prevented from reoccurring. Well-known robust process concepts and methods are the quality circle, account force diagram, marginal samples, quality alarm, machine breakpoint, total productive maintenance (TPM), poka yoke, failure mode and effects analysis (FMEA), and quality agreements.

## 1.4 Human Factors in Production

The significance of human factors can be appraised by the workers' contributions to the economic success of a businesss enterprise.

### 1.4.1 Economic Requirements

Businesses have an economic interest in keeping healthy, motivated, and qualified workers because they will have a positive effect on production efficiency. Frustrated, passive, or aggressive workers are less motivated and at the same time are susceptible to diseases. Diseases and accidents weaken an enterprise's productivity. Business surveys show a strong correlation between loss time and personnel costs. An appropriate compensation of absent personnel is in many sectors not possible without conflicts, which can lead to loss of flexibility, lack of quality, and production disruptions and in the end to assignment loss. In the course of flexible strategies and a decomposition of decreasing personnel compensation buffers, the economical consequences of absenteeism and insufficient employee engagement are becoming increasingly important (Braun, 2003).

### 1.4.2 Motives for Performance and Cooperation

Employees feel motivated to do good work if their personal interests agree with those of the company and their performance is acknowledged. If there is disagreement during the course of changing processes, resistance may develop. Resistance to change leads to considerable loss of performance and cooperation. As a result. managers of major enterprises expend between 50 and 80% of their working time to override internal constraints (Spath et al., 2003). A survey of approximately 2000 employees taken by Gallup (2010) in Germany shows that about 80% of those interviewed were insufficiently involved in their company. Approximately 70% of the interviewed employees lacked engagement and were passive when dealing with their managers. Fifteen percent of those interviewed were often aggressive toward their superiors, displaying this by poor productivity. Such negative attitudes resulted in:

- A high number of absences
- Readiness to leave the company as soon as an opportunity arises
- Nonexistent career intentions with current employer

- A bad attitude toward others
- A small chance of recommending the workplace to friends or relatives
- A small chance of recommending the product
- No enjoyment at work

As a result of lower productivity and high number of absences, the macroeconomic loss resulting from unengaged employees was over 10% of the yearly gross national product. Reasons for the lack of dedication are obscure expectations of managers as well as an insufficient acceptance. Also most interviewed employees had the feeling that their opinions and ideas were not acknowledged by their manager.

### 1.4.3 Focusing on the Healthy Individual

When discussing cooperation, flexible reaction, and innovation, the worker is irreplaceable due to his or her creativity and communicative capabilities. The employees' interest and will to change are essential factors for every increase in productivity. Many enterprises have recognized that healthy, qualified, and efficiency-motivated employees are one of their main assets.

Empirical comparative studies support that technology does not play such a meaningful role during the development of an enterprise. Actually, technology does not trigger innovations but merely expedites them (Collins and Porras, 1994). A successful enterprise has to ensure reliable orientation and demanding motivation for its employees during a change process. Experience has shown that problems such as motivation, engagement, and diversification are often solved when the work fits the preconditions of the human.

From the above-mentioned production concepts, it can be concluded that the process of making businesses automated and flexible requires consideration of human-oriented work design.

## 2 HUMAN-ORIENTED WORK DESIGN

### 2.1 Objective Target

The goal of human-oriented work design is to balance the strain of the worker. By doing this, human performance potential for the production of goods and services is utilized and it is balanced against the premature wear of performance capabilities. This involves the use of technical, medical, psychological, as well as social and ecological knowledge (Bullinger, 1994). It is to be noted that the scientific concepts of work design have been researched since the 1970s (Helander, 1995; Karwowski and Salvendy, 1998; Karwowski, 2001; Salvendy, 2006). Therefore it is supposed that the reader has sufficient knowledge of these human-oriented design concepts. Since their implementation is still of basic relevance, these concepts will be presented shortly within this chapter and referenced accordingly.

Human-oriented work design deals with the worker, the detection of his or her skills and abilities, and the analysis of variables that may influence performance. Further tasks concern the design of technical equipment and organizational structures used for work. The goal is optimal customization of equipment and structures to the workers' abilities and skills. This results from three operational and design approaches:

- Fitting the work to the human by designing working conditions
- Fitting the human to the work through qualification and job assignment
- Fitting the workers with each another; this can only indirectly result from organizational and technical work design

A five-stage target system is used for the design and evaluation of human-oriented work. The criteria are interdependent since criteria of lower levels must be achieved before criteria of higher levels can be applied. The criteria are (Luczak et al., 1987):

- *Without Damage*. Work has to be tolerable and free of damage. Also long-term effects have to be considered. The possible damage to workers during their lifetime must be assessed over a period of time. Work time, work intensity, and environmental conditions are particularly significant.
- *Feasibility*. Work tasks, particularly tool handling, must be feasible. Individual abilities and skills may lead to different kinds of strain. For this purpose, limits are generally established by human biomechanics or available mental capacity.
- *Reasonability*. Reasonableness is an individual factor which can only be answered by each employee. The individual experience, however, is related to the cultural environment and previous know-how. According to this criterion, workers should have some latitude over their work task design and work environment.
- *Satisfaction*. Work should be satisfying and supportive. Through work design this can be reached by considering the psychological and cultural environment. Here acknowledgment, motivation, reward, and superior leadership behavior are to be considered.
- *Social Compatibility*. Social compatibility means that the employees are involved in work design relating to their cooperative organization. Task-oriented work structures implement this criterion, particularly since the employees are involved in the work design process.

### 2.2 Humanization and Rationalization

Human-oriented work design similarly follows humanization and rationalization objectives. *Rationalization* describes the substitution of inherited procedures by using more practical and better thought-out procedures.

*Humanization* refers to the civilization and design of the workplace regarding the well-being of the worker. Work design follows both humanization and rationalization objectives of work systems. For this, it is necessary to find compatible conditions for both objectives (Kern et al., 2005).

In past years, under the premise of humanization, enterprises increased their efforts to accommodate the work organization to the growing demands of the individuals for larger task variety and self-organization. Thus the worker should be motivated by his or her work. As a result, enterprises hope for better product quality through a decline in absenteeism and fluctuation. Enterprises ultimately expect a better level of quality of their business processes.

## 2.3 Strategies of Human-Oriented Work Design

Focusing on the worker the following criteria should be implemented:

- Feasibility: anthropometrical, psychophysical, and biomechanical limits for short loading times
- Tolerability: physiological and medical limits for long loading times
- Reasonability: sociological, group-specified, and individual limits for long loading times
- Satisfaction: individual social–psychological limits with long and short valid times

These explanations make clear that the two first-mentioned criteria, feasibility and tolerability, are achieved by measures of engineering, while the other two criteria, reasonability and satisfaction, are achieved by psychological approaches. However, it has to be noted that both sets of approaches cannot be separated from one another.

When considering a manual assembly operation, feasibility limits arise for the worker which result from required movement speed and movement accuracy. In Figure 4 this situation is illustrated. At the point where the combination of the resulting work task's stress parameters does not lead to a feasible work situation, automation has to be implemented. Where work is achievable but not tolerable, the work content must be designed, that is, the work must be restructured. Ergonomically optimal conditions are aimed for where tolerable combinations exist.

The three design approaches differ when talking about humanization and rationalization. Thereby, the limit in which work is achievable but is not tolerable comprises most of the problems. The scheme also can be adapted to informational work.

### 2.3.1 Ergonomics

The aim of ergonomics is to protect the worker from impairments, especially by eliminating influences which constrain performance or cause physical damage. So far, good results regarding this task have been achieved. Particularly, anthropometric *workplace design* methods are very well engineered. Therefore, it is surprising to still find workplaces where important measurement questions remain unanswered. Computer-aided human models among others are installed for workplace design. These human models also include anthropometric and biomechanical modules and databases for posture evaluation (see Figure 5).

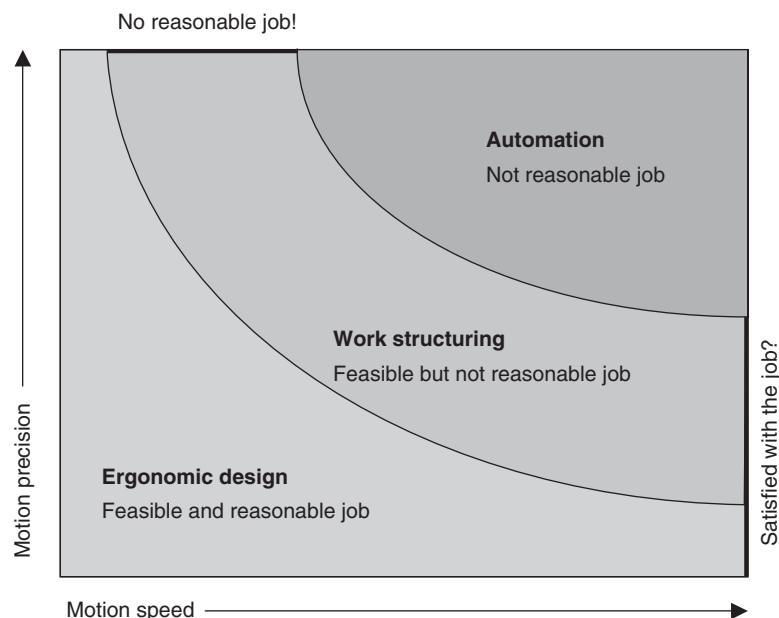

**Figure 4** Dimensions of work design strategies.

**Figure 5** Anthropometric workplace design using the virtual human model ANTHROPOS on a Picasso-3D-Projection System. (Courtesy of Fraunhofer IAO.)

*Product ergonomics* deals with ergonomic product design with respect to the task to be performed. This is particularly important for consumer products and when using hand-held tools in order to have optimal performance. In this case the ergonomic design complements the functional design (Bullinger, 1997).

Due to multiple requirements, ergonomic work design has become increasingly complex. This complexity can only be accomplished using an integrated method (see Figure 6).

Integration takes place in three dimensions: (1) Integration of requirements is comprised of all relevant design influence factors and requirements. (2) In methodological integration, it is essential to define and combine established procedures and methods during the design phases. (3) The process and communication for a design project will ultimately be adjusted in line with organizational integration.

### 2.3.2 Work Structuring

Work structuring involves the organization of work as well as their requirements so that the work contents comply with the capabilities and skills of the employees (Bullinger and Braun, 2001). The definition of work structuring allows different interpretations that are dependent on the objectives concerning humanization and rationalization, including:

- Solving economic problems (such as insufficient flexibility, poor production activity, lacking quality)
- Solving personnel problems (such as high numbers of fluctuation, lacking work morale, signs of dissatisfaction) Redesigning technical systems and the operational organization

At first glance, it appears as if economic and human problems are handled the same way. But an exact analysis of human-oriented problems shows that their removal also enhances performance. Therefore, human-oriented design measures always concern economic efficiency motives.

### 2.3.3 Automation

The goal of automation is to transfer functions done by humans to machines. The level of automation is measured by the number of functions previously performed by humans being done by machines. The prosperity in industrialized countries is due to the productivity increase through automation. This fact cannot be denied in the discussion about the consequences of automation. However, it accounts for the increasing need to work on solving automation-related problems.

Finding an automation strategy that is acceptable under human and economic aspects is difficult. The problem becomes clear once it is considered that, because of economic and technical reasons, automation

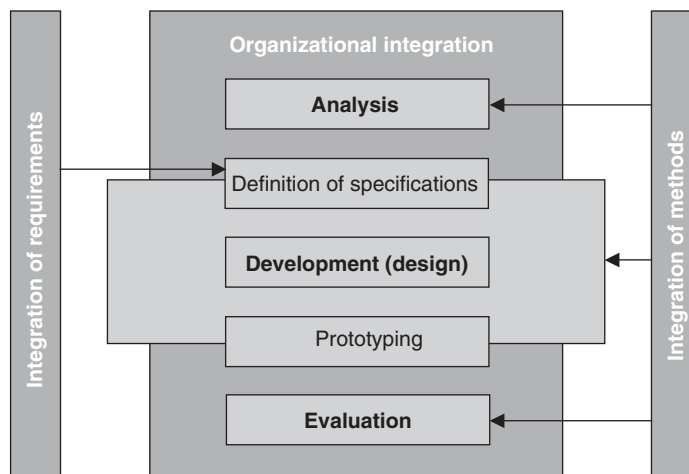

**Figure 6** Aspects of integrated ergonomic work design.

can only occur in a way that would make humans unnecessary. In many cases monotonous tasks remain for humans since machines can carry out the more complicated work with higher speed and precision. Also a workplace with ecological damage will expose humans to possible hazards.

It is obvious that an automation strategy has to consider the work structure. Thereby, the planning should emphasize the work structure while automation constitutes an alternative solution to the problem. This is away to avoid keeping undemanding tasks in highly mechanized structures.

Another basic requirement is to improve the automation technology in a way that workers are relieved from specific tasks, especially working in a straining environment. Using automated handling machines is an example. The effects of the humanization of automation are as follows (Spath et al., 2009):

- Disappearance of monotonous tasks
- Disappearance of heavy physical strain, resulting from unfavorable body position and exertion, for example, when lifting heavy loads
- Disappearance of unfavorable environmental influences, for example, through heat, filth, and noise
- Decline of accident risk

## 2.4 Work System Design

The systemic design approach was introduced in Section 1.1. To comprehend and design complex systems, the use of systemic models has proven valuable (Spath and Dill, 2002). Basic principles of systemic work design relating to complex production systems will be subsequently discussed.

### 2.4.1 Work System and Its Elements

The human, the workplace, the work environment, and the work organization all shape the production process. They are linked to each other in order to build the work system. This systemic model is able to provide systematization for analysis, planning, designing, and evaluation measures. It can be applied to an individual workplace (first-order work system) but also to a network enterprise (nth-order work system). The work system and its single elements as well as its related design approaches will be subsequently presented (see Figure 7).

Basic work system elements are:

- A *work task* is an assignment for humans to exercise a job which serves to achieve objectives. It illustrates the purpose of the work system. The work task is often referred as the target work result.
- *Tools* are equipment, machines, organizational tools, and so on, which are in any way involved in a work system in order to accomplish the work task. From a systemic point of view, tools are inactive elements.
- The *workplace* is a spatial area where one or more people are designated to accomplish a task.
- Physical, chemical, biological, social, and cultural conditions are identified by the *work environment*, which surrounds the workplace. These conditions influence the system behavior and the features of the elements.
- The *human* is the active element of the work system. It is only the human who is able to bring other system elements into action.

The traditional work system design methods are primarily oriented on isolated system elements. The

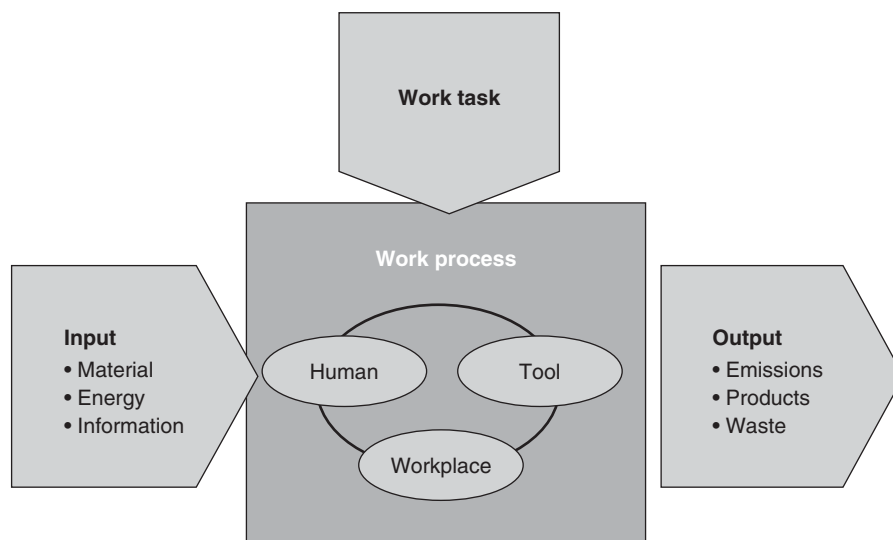

**Figure 7** Work system and its elements.

previous remarks make clear, however, that only integrative work design methods in a systemic context can lead to human-oriented and economic effective work systems.

### 2.4.2 Design Methods

Work system design aims for an optimal interaction of human, tools, and tasks. This goal is to be accomplished by consideration of the worker's capability as well as his or her individual and social needs. By minimizing impairments, human-oriented work design helps to continuously promote the worker's health and performance. Furthermore, to improve work system effectiveness, work design has the goal to increase efficiency and reliability by optimizing human–machine interfaces and by influencing the behavior at work.

In the following, starting with the system model, basic methods for work design will be presented. First, single work system elements will be considered. Subsequently, information on the design of the complete work system will be given. Thereby, the interaction of system elements is to be taken into consideration: The change of one element has an influence on all the other elements. Closer considerations of the presented methods are to be found in the literature (Helander, 1995; Luczak, 1998).

### 2.4.3 The Worker

The human, being the active element of the work system, holds particular importance. An effective work system is always a human-oriented system. In order to design a human-oriented system, basic function characteristics of the human must be identified. Here physical and mental dimensions are to be differentiated, even though these two dimensions are closely related to one another.

***Stress and Strain***   The simplified stress–strain model, presented in Figure 8, is an appropriate model to describe stress (i.e., workload), individual capabilities, and strain of the worker.

The term *stress* defines all external demands on humans resulting from the workplace, the work process, and all physical environmental influences. The term *strain* is defined as the reaction of the organism on stress which is affected by individual human characteristics.

**Figure 8**   Relationship between stress and strain.

The individual capability is the factor that combines stress with strain. Human physical and mental capabilities are, however, not constant variables but may change.

The total amount of human stress at work results from the level of stress as well as the duration of exposure. Stress is divided into stress that is measurable quantitatively and nonquantitavely. Quantitative stress can be measured by using physical methods. Nonquantitave stress can often only be described.

A direct strain measurement is not possible since every stress can result in a different strain with respect to different people. However, the analysis and quantification of strain are important so that:

- Work tolerability can be evaluated.
- (Durable) capacity limit values can be determined.
- Critical strain reactions can be avoided during work design.
- Physiologically adequate design of rest time is possible.

Strains can indirectly be measured by physiological parameters (e.g., frequency of heart beat, hormone concentration in blood), performance analyses, and subjective techniques (e.g., standardized questionnaires). The goal of human-oriented work design is to create an adequate balance between strain overload and underload.

***Capability and Motivation***   Physiological and psychological capacities define human capability (Luczak, 1998). Human capability fluctuates for each person and between individuals, increasing with training and declining with fatigue. An appropriate break design maintains the capability during work (Spath et al., 2003). Human motivation is no less relevant for efficient production. Even well-educated employees bring little added value when they are not willing to perform, that is, they are not motivated (see Section 1.4).

Numerous existing models describe capability and motivation. At this time, the psychological *theory of mental regulation of action* should be mentioned. This regulation theory predominantly relates to work tasks. Therefore, it refers to observable and conscious execution processes. Unconscious mental processes, for example, formation of opinion, remain unconsidered. The theory of mental regulation of action assumes that human action is target oriented, that it corresponds to external matters, involves social connections, and shows process characteristics. Consequently, the theory describes running processes of action, from setting the goal, and presumes an interaction of mental processes and observable activity. Hereby, two regulation procedures are differentiated, as shown in Figure 9 (Hacker, 1998):

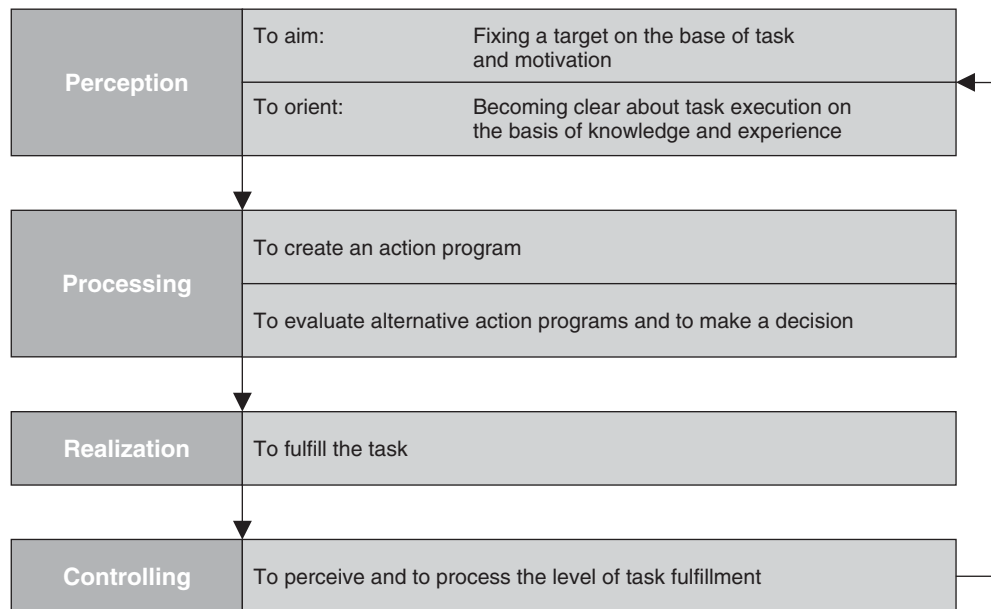
- Stimulus regulation, that is, it is determined when an action is conducted. Individual motives, attitudes, and preferences are the basis for these procedures.


**Figure 9** Structure of the mental process.

- Execution regulation, that is, it is determined how an action is done. Individual subgoals, mean-methods-choice, and execution control are the basis for these procedures.

According to this model, human action is a control circuit which is significantly influenced by motivation, knowledge, information, and experience.

The theory of mental regulation of action assumes that task requirements and stress are independent of one another. Psychological requirements should give the worker the possibility to independently decide goals and methods. The most important influencing factors are task variety and communication. Mental stresses at interfaces between the individual and the organization are defined as restraints. Regulation restraints describe discrepancies between working conditions and goal attainment as well as excessive demands, including time pressure and monotonous jobs.

This follows the simple realization that people who perform their work as a result of their inner motivation and conviction are considerably more productive than those who are only subjected to work. It shows that *motivation* is a deciding factor in the relationship between the individual and the work. Motivation is the sum of action, behavior, and behavioral tendencies. Contrary to the biological stimulus of humans, motivation and individual motives can be learned and respectively arranged in the socialization process. Therefore, for greater efficiency it is important to encourage employees.

Motivational theories only explain part of human behavior within the stimulus–reaction scheme. Because of their diffusion, the theories of Maslow (1987) and Herzberg et al. (1967) are mentioned.

Maslow (1987) established a hierarchy of individual requirements. A requirement level must be fulfilled for the next level of requirement to become relevant in terms of motivation. Thus, according to this theory, it makes little sense, for instance, to motivate the employee to self-realization using a general offer of further training when the security of their position (e.g., resulting from economic reasons) is not given.

Herzberg et al. (1967) differentiate between hygiene factors, whose nonobservance leads to work dissatisfaction, and motivators, whose compliance leads to work satisfaction, respectively motivation. Thus, poor internal enterprise politics lead to intense work dissatisfaction, while good internal politics prevent this from happening. This, however, does not conversely lead to work satisfaction. Acknowledgment from colleagues has strong motivating effects, but lack of acknowledgment does not necessarily lead to dissatisfaction.

For business practices, the following design concepts are derived from psychological theories:

- *Reduction of Time Constraints*. Using buffer banks between individual workstations, employees have the opportunity to work detached from the fixed-time work cycles.
- *Job Rotation*. The work content of individual jobs does not change, but employees exchange their workplaces systematically.
- *Job Enlargement.* The job content is increased. Employees are given more similar assignments of the same qualification level, leading to longer time work cycles.
- *Job Enrichment.* The job content is changed in a way that individual employees have a greater

task variety, resulting in higher qualification requirements.

- *Autonomous Team Work*. A job assignment is given to the work team. This assignment is separated into subtasks within the team. The team can organize the work itself within certain limits (i.e., time targets, technically marginal conditions). This type of work structuring offers a good chance for individual work design. However, it holds the risk of social conflicts arising within the group.

### *Consequences of Unbalanced Workload*

Fatigue, monotony, mental saturation, reduced vigilance, and stress are closely related to the problem of strain. These categories describe both a procedural happening and an internal condition of the human.

*Fatigue* describes stoppage of motivation, resulting from a continuous task performed over the course of hours up to a day. Considering the nature of the strain, it has to be differentiated between physical and psychological fatigue. Physical fatigue is attributed to displacement of the physiological–chemical balance of an organism. Psychological fatigue is an impairment of regulation. It is an aftereffect of psychologically demanding tasks which are characterized by information reception and processing. Monitoring, inspection, and control tasks, which are particularly found in process control, are mainly considered to be psychologically demanding tasks. For such tasks alertness adaptations and focus on defined task contents are typical. As a general rule, cognitively overstraining conditions bring sporadic functional ability and decreases in cognition, memory, and thinking. Fatigue-caused capability impairments can be temporarilyy eliminated by job rotation, environmental influences, or stimulants. They are completely eliminated only by sleep (Richter and Hacker, 1998).

*Monotony* is similar to fatigue but is generated by lack of stimulation or by conditions with minimal changes in stimulus structure. Symptoms of monotony are fatigue, sleepiness, aversion, and attention decline. The decrease in motivation and reaction ability associated with monotony is reflected by unsteady and decreasing performance. Monotony arises when the fulfillment of a job does not allow a complete solution and does not offer enough possibilities for a mental debate of the task [International Organization for Standardization (ISO) 10075; ISO, 1991].

According to ISO 10075, *mental saturation* is a condition of nervousness, restlessness. and intensely affective decline in an undemanding, repetitive task or situation. The concerned person perceives his or her job as being senseless; aversion and irritation are a result. The continuation of the task is carried out reluctantly. In the long run, psychological saturation leads to the employee's "internal termination" by refusing his or her own initiative and operational readiness. These sentiments are triggered by monotonous tasks which are under the employee's qualification level. Permanent troubles, unfulfilled needs, and unreached personal goals, however, also can lead to mental saturation.

*Diminishing vigilance* (also called hypovigilance) is a condition of reduced mental activation which results from little variation monitoring tasks. It is the consequence of qualitatively undemanding tasks with a highly passive work content, low amount of environmental stimulus, and lack of environmental diversification which result when concentrating on few inputs. The mental tension required for the deliberate balance of functional impairment with reduced vigilance presents an additional source of mental exhaustion. Hypovigilance systems, which recognize such conditions and support people accordingly, for example, by targeted activation, are being investigated and developed (Hagenmeyer, 2007).

Monotony, mental saturation, and diminishing vigilance resemble fatigue in that they result from an underdemand of human capability; they can be removed by expanding the task variety (Spath et al., 2003).

*Stress* is a condition of the organism which develops when the person has recognized that his or her well-being or integrity is in danger and he or she must use all available energy for self-defense (Cofer and Appley, 1964). All situations experienced as being unpleasant or threatening can trigger stress. At the same time, the amount of stress depends on the intensity and amount of time the person has been exposed to similar situations, the disposition, and the situational factors. The human is not able to support long-term stress. The physiological mechanism of stress reaction breaks down at the point when the stress factor cannot be removed by means of coping or avoidance for a short term. Long and continuous exposure to work-induced stress leads to excessively increased levels of alertness which do not sufficiently subside after work finishes. The consequences result in sleep disorders, impulse liability, and internal unrest. Long-term memory is weakened, and muscle activation including speech becomes aggravated. The responsiveness of perception is reduced. Consequences are erroneous actions, erroneous estimation, and anomiae.

### 2.4.4 Working Environment

Relevant factors of ergonomic working environment design are lighting, noise, mechanical vibrations, climate, harmful substances, and radiation. The sphere of influence for these factors is primarily in the direct environment of the workplace and in the used work tools. For example, the decrease in machine noise is primarily a constructive problem. Since the machine is, however, located at the workplace, its emission of sound also influences the quality of the workplace.

Some environmental factors are purposefully used for work design (see Figure 10). Others have undesirable effects. The goal is to reduce intensity, exposure time, and impact frequency in a way that avoids excessive strain. At the same time, eliminating all environmental influences can have disadvantageous consequences. As an example, psychic problems arise for inhabitants of apartments as a result of extreme isolation from outside noise. Complete elimination of noise and vibration emission while using an electrical razor irritates the user and might lead him to reject the product. In general,

| Environmental Factors | Potential desired effects | | Potential undesired effects | | | |
|---|---|---|---|---|---|---|
| **Legend:** ● Correlation ○ No correlation | Support of task operation | Well-being | Disturbance | Malfunction | Health damage | Bodily injury |
| Lighting | ● | ● | ● | ● | ○ | |
| Coloring | ● | ● | ○ | ● | | |
| Climate | ○ | ● | ● | ○ | ● | |
| Contact temperatures | | ● | ● | | | ● |
| Air/air quality | ○ | ● | ● | ○ | ● | |
| Noise | | ○ | ● | ● | ● | ● |
| Vibrations | | ○ | ● | ● | ● | ● |
| Acceleration forces | | | ● | ● | | ● |
| Moistness | | | ● | ● | ● | |
| Dirtiness | | | ● | ○ | ○ | |

**Figure 10** Environmental factors at the workplace and their effects (Bullinger, 1994).

environmental influences should not to be eliminated but be optimized.

The three environmental factors climate, noise, and lighting are most frequently identified as being problematic in manufacturing. These factors are discussed in the following.

**Lighting** Most human sensory perception happens over the visual canal. Appropriate lighting is required for visual information intake. By using appropriate lighting, performance and work safety can be enhanced and visual strain can be reduced.

Visual perception is directly dependent on light intensity. Therefore, light intensity must be adjusted to the visual task. Depending on the aging process, elderly people require more light in order to be able to carry out visual tasks precisely and rapidly. The work design must ensure that light intensity is sufficiently adapted to the conditions.

A visual object is only recognizable if it has a minimum contrast, that is, a luminous density difference within its environment. The capability to perceive contrasts depends on the object's size, luminous density, perception time, and level of adaptation. The higher the level of lighting, the greater the contrast has to be. If the contrast is too strong, then glare arises.

Direct glare results from directly glancing at a luminous source. Here the absolute light density value is often too high (e.g., when looking at the sun). Reflex glare is a result of luminous source reflections on reflective surfaces. Light density differences, which are too large in the visual field, that is, intense contrasts, lead to relative glare. Furthermore, relative glare causes eye strain which results from adaptation.

The contrast depends on the surface condition of the observed object, angle of light, and distribution of light density. Good contrast reproduction is achieved by dimmed material surfaces and by laterally arranged lighting above the workplace. The direction of light, especially at workplaces with visual display units, is important so that reflections do not occur on the visual display.

In practice, for lighting design the following are helpful:

- Adequate level of light intensity
- Harmonious distribution of light intensity
- Glare limitation
- High contrast reproduction
- Proper direction of light
- Accurate amount of shadiness
- proper lighting color and appropriate color reproduction
- High degree of energy efficiency

**Noise** Within the variety of physical environmental factors appearing as strain variables for the worker, noise is the most significant. In the last decades, noise

has become a public problem due to the high numbers of compensable occupational illnesses as a consequence of long-lasting noise exposure and emerging noise-induced hearing loss.

Continual loss of hearing results from recurring noise exposure or in rare cases from short exposure of high noise levels. Mental reactions such as disturbance and annoyance can already be observed at low noise pressure levels. These reactions mainly depend on the position of the concerned person to the origin of noise and his or her momentary disposition (e.g., mood and tension). At approximately 65 dB, there are reactions of the vegetative system, for example, a change in breathing rate. An irreversible effect on hearing loss is not excluded when noise exceeds 85 dB. Hearing loss makes it difficult to sense acoustic signals and speech. This can lead to higher accident risk and changes in behavior toward fellow workers.

Sound emissions and their effect on people are directly related. The effect of noise on people is assessed by the noise rating level of an 8-h work shift.

The goal of ergonomic work design is to prevent the development of noise. Basic *primary* measures are preferred in order to reduce noise. These measures prevent noise from developing, for example, by using electrical motors instead of pneumatics. Since these measures often have constructive machine and equipment demands, they are particularly considered during production planning and related machine construction; in ongoing production, primary measures are usually very expensive. In this case *secondary* measures, which prevent sound spread, are aimed for. For instance, noisy machines can be grouped in a separate space or machines can be encapsulated. *Tertiary* measures such as ear plugs should be used when all technically possible and economically justifiable efforts concerning noise reduction did not lead to a noise level below 85 dB.

***Climate***   Climate is an important environmental factor at the workplace. Its importance is a result of multiple interactions with the human. In fact, the number of workplaces under extreme climatic conditions has declined (e.g., foundry). But in the field of workplace design calls for a comfortable climate are increasing and ergonomic recommendations and rules are necessary.

Climate is not a consistent dimension; rather it is a generic term influenced by air temperature, humidity, air movement, and thermal radiation.

The various climate factors are integrated into one variable by a cumulative climate indicator. The principle of the cumulative climate indicator is based upon different combinations of three variables: air temperature, humidity, and air movement.

In principle, the human body tries to establish equilibrium between body heat and external climatic influences. The goal of this regulation is to maintain the normal temperature of approximately $37°C$ related to a certain level of comfort. Within low environmental temperatures, the lack of warmth is balanced by an increase of body temperature. Within a higher environmental temperature, the body tries to eliminate excess warmth in the environment by transpiration.

In the production environment *temperatures* between $-50°C$ and $+50°C$ can be found, whereas workplaces with more extreme thermal radiation (e.g., a foundry) are not considered. This climate variety underlines the need for adequate climate design.

For the climate assessment, subjective influence variables beyond those relating to environmental climate are also considered. Among these variables are clothing and work intensity as well as the condition and constitution of each person. In the assessment of climate comfort it should be considered that individual differences in climate perception can arise: For example, in a survey of normally clothed office workers ($n = 1296$), a majority of those surveyed felt a temperature of approximately $21°C$ to be neither too cold nor too warm. This is also considered to be a state of neutral temperature. The interesting result of the survey was that only 20% of those surveyed found this temperature to be too warm and approximately 20% too cold. Consequently, a significant portion of those surveyed were dissatisfied with the climate (Fanger, 1972). Thus, climate sensation is highly individual, whereas on average summer high temperatures are felt to be more pleasant than those in winter.

Ultimately, climate design should strive to create damage-free, better executable, and in general achievable conditions. During ideal conditions, however, a comfortable climate is established when body heat balance turns out to be neutral.

### 2.4.5   Tools

In principle, a tool is differentiated in the hand side and the work side, whereas ergonomics has its focus on the hand side.

A deductive approach (i.e., from the general to the specific) works best when designing an ergonomic hand side. Inductive approaches that start with decisions about shape are usually doomed to fail or require extensive reworking, which is time consuming and expensive. Ergonomic products are optimized for the human user, taking individual abilities and skills into account, helping to prevent one-sided stress during work and increase efficiency.

The relevant measured variables on the hand and work sides of a tool affect:

- Body position, posture, and range of motion
- Hand position, grip type, and connection type
- Handle shape, dimensions, material, and surface
- Function direction and force direction
- Accuracy, movement speed, and resistance

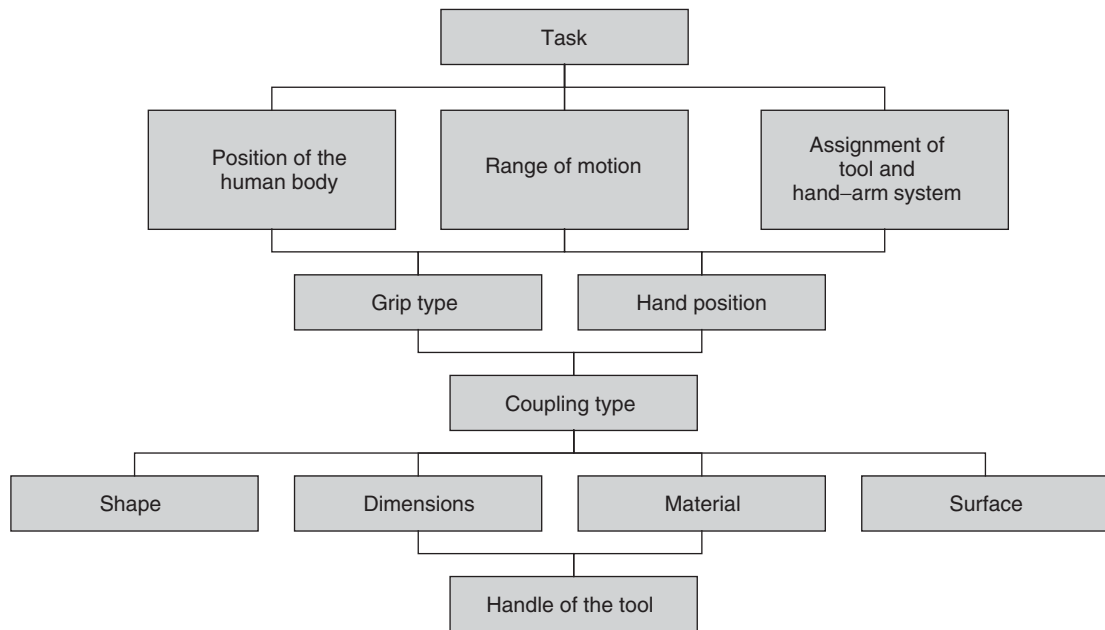
A systematic approach is essential to ensure that these variables are implemented into the design process in the right amount and order. The design process starts with the consideration of the task, that is, the examination of working conditions. Only after further detail analysis do design parameters (i.e., shape, dimensions, material, and surface) actually become part of the process (see Figure 11).


**Figure 11** Algorithm for the design of work tools (Bullinger, 1994).

In this way, tool handle design becomes a creative and analytical process instead of a purely technical and aesthetic task. The procedure conforms to classical scientific engineering methods, which may also be complemented with usability engineering practices (Meinken et al., 2008).

### 2.4.6 Workplace Design

A basic requirement for the use of manpower is an ergonomic workplace. Workplaces which are arranged ergonomically inadequate not only affect occupational safety and health but also limit effective assignment.

Because musculoskeletal diseases cause the most illness-related absences from work, it is important that special attention be paid to workplace design with respect to dimensions and forces.

The advantages of workplaces designed ergonomically can be assessed directly and indirectly. Processing time is decreased and number of absence is reduced. Both human body dimensions and physical forces are main aspects of ergonomic work design.

Human body dimensions are especially important as here the minimal values are not always as fundamentally decisive as physical strength.

***Anthropometry*** Anthropometry is the scientific approach of the different human body dimensions and their exact determination. Since everybody has different anthropometric values, the only way to create an ergonomically correct and efficient working environment is to adjust workplaces individually. The most important criteria for determining workplace dimensions are shown in Figure 12.

Human physical measurements vary. Therefore, defining an "average human" is not applicable as designs often have to accommodate both the smallest and largest users. If designs were based on average dimensions, half of the population would be worried about hitting their heads on doorframes, while the other half would fear not being able to reach an emergency power switch in the event of an accident. The definition of upper and lower limits for broad population groups has proven to be a good feasible method. This consideration leads to the term "percentile."

The customary limits for the adjustment area of an object, adapted to the human body, are the 5th and 95th percentile. Since the variance of the residual extreme groups is overproportionally large, 95% of the users can be addressed by only approximately one fourth of the entire variation range.

However, when using anthropometrical data, it should be kept in mind that it is gradually changing. The current acceleration phenomenon results in the fact that physical dimensions are slowly and continually increasing.

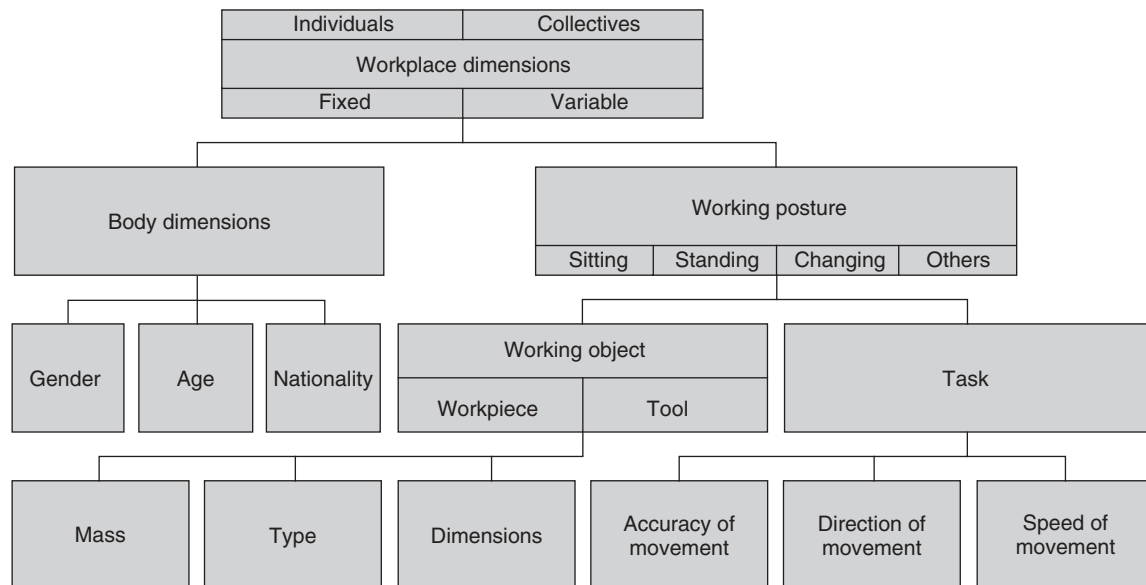
The action space for body parts is confined by the anatomically maximal rotary range, respectively displacement range and bent angles. Since details about optimal ranges and angles are required in the workplace design, the maximal action space plays a minor role in ergonomics. There are neutral positions between the extreme values, in which muscle activity as well as tendon and ligament strain is minimal. Muscle exhaustion is at its lowest level in these positions, which are generally considered to be subjectively comfortable but do not have to inevitably be in the respective centralized position.


**Figure 12** Factors of workplace measure specification (Bullinger, 1994).

This also applies to the visual space. The work process must be visually controlled and checked for nearly all tasks. Therefore, besides body position and body posture, the visual space parameters are important for workplace design.

***Dimensioning of Workplaces*** The nature of the work task primarily influences the choice of working height and the decision of whether to set up a sitting, standing, or sitting–standing workplace. In principle, minor motional limitations exist at a standing workplace. For this reason, great force development is possible. The sitting workplace is favorable for precisional work and reduces posture work. From a physiological viewpoint, the sitting workplace should be preferred to the standing workplace since work chairs corresponding to ergonomic requirements can reduce the number of continuous muscle contraction. Standing steady does not cause much muscle activity but does strain the ankles and affected tendons and ligaments, which can lead to increased blood pressure in the legs.

It should be noted that no standing or sitting posture can be comfortably maintained for a long period. Therefore, a workplace should be set up such that it is possible for the worker to alternate between sitting and standing (sitting–standing workplace). Thereby it is possible for the worker to have a balanced amount of movement which is more favorable for the human body than motionless forced posture. This fact is expressed by the ergonomic proverb "the most ergonomic (sitting) position is the next one."

Forced posture, however, results from:

- Not enough free space at the workplace (i.e., foot space, leg space)
- Unfavorable working height (i.e., height of chair, height of table)

- Unfavorable position of work objects (i.e., too large of a frontal or side displacement, too high or too low)
- Arrangement of work tools and manual controls far from the body
- Unfavorable position of displays
- Limited space of movement (e.g., projecting components of machinery)

A workplace adjusted to human dimensions is necessary in order to provide natural body posture and motion sequences during work.

Because of the multiple influencing factors to the dimensioning of workplaces, each respective method has a different relevance. Some methods are appropriate for a quick qualitative examination of workplaces, while others are complex and produce detailed results. An overview of methods and tools for workplace design is shown in Figure 13.

At this point two established methods are presented:

- *Calculation Using Body Measurement Charts.* Using body measurement charts, specific workstation measurements are defined whereby certain measures pertain to the 5th percentile (e.g., hand and foot operating space), whereas others pertain to the 95th percentile (open space for feet and knees). Summing up, it is necessary that a small person be able to reach all relevant elements, while a large person should have ample room and not hit anything at the same workplace.
- *Computer-Based Methods.* A variety of computer-aided design (CAD) system applications opens up a basis for efficient workplace design. In particular, variant designs and quick changes of particular components of a work system improve

| Influencing factors | Method/instrument | Workplace dimensions |

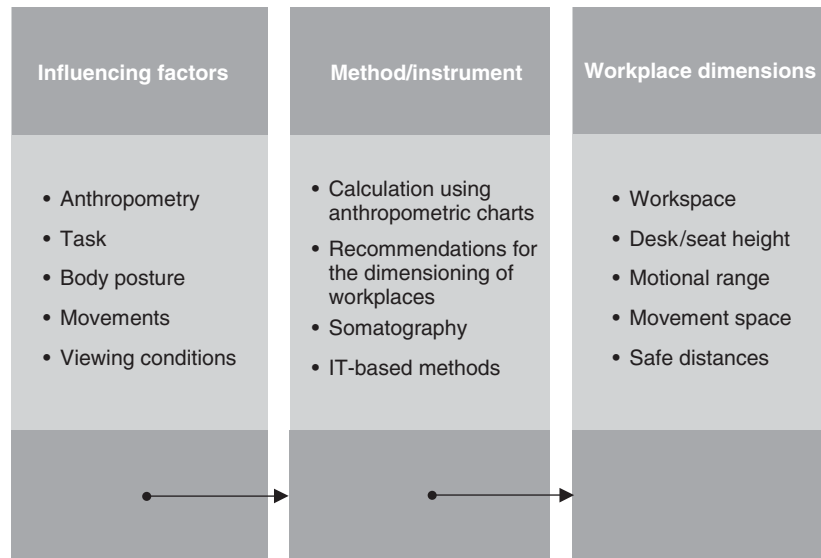

**Figure 13** Methods for workplace design.

the ergonomic design of the entire work system. Depending upon type and performance of available hardware and software, human models with different degrees of detail are available. Two-dimensional (2D) models, corresponding in principle to digital templates, are standard. On the other hand 3D human models such as JACK (Allbeck/Badler 2002) or RAMSIS [Forschungsvereinigung Automobiltechnik (FAT), 1995] allow a detailed ergonomic analysis of the entire workplace system (see Figure 14).

### 2.4.7 Manual Load Handling

Despite the handling technology application, heavy loads have to be moved often during manufacturing.

**Figure 14** IT-based workplace design using VirtualANTHROPOS. (Courtesy of Fraunhofer IAO.)

Here, back stress is so intense that serious health effects cannot be excluded: Acute limited functional impairments can appear (e.g., strained muscles and blockage of vertebrae joints while lifting loads). Furthermore, chronic impairments along with steadily increasing continuous medical conditions can appear (e.g., deteriorating intevertebral disks, expansion of ligaments, tendosynovitis, and muscle tension). These cause pain and often limit human flexibility. They can lead to longer periods of disablement [National Institute for Occcupational Safety and Health (NIOSH), 1994].

Strains are effectively reduced when constant or heavy lifting is avoided. This applies especially for young people (because of reduced strain capacity of the spine) and women (because of lower average strain capacity of the spine in comparison to men).

Where this is not possible, appropriate measures have to be taken on the basis of a work analysis in order to keep health hazards as low as possible. A variety of tested and proven methods are available in order to conduct an ergonomic assessment. These methods include operational terms and conditions and corresponding legal guidelines. Resulting measures to be taken can be carried out with the aid of technical, organizational, or individual means. Recommendations for the manual handling of loads are:

- Supply of appropriate work tools and utilities (lifting belts, lifting platforms, etc.)
- Opportunity that the load can be carried and transported close to the body
- Favorable load lifting, respectively depositing heights between 70 and 110 cm over the ground
- Adequate motional range for load handling
- Alternating between straining and relieving tasks
- Adequate relaxation time

Informing employees about the right way of lifting and carrying loads is necessary so that they can avoid health impairments. Here, information about straight posture of the spine is important leading to an equal distribution of the stress. Heightened strain on the spine results from the weight of the load; load distribution is uneven when the torso is bent. For this reason, the danger of intervertebral disk or vertebral body damage increases considerably.

### 2.4.8 Human–Machine Interface

All components of a work system for functional interaction between the human and technical system are defined by the term *human–machine interface*. Processes to be supervised and controlled by humans generate a multitude of information such as operating status or task conditions. Human receptors take in this information both directly and indirectly. This information is processed in the brain and is usually referred back to the process by an operation.

Information is transferred to the technical system in an operation by using either so-called actuator components or control elements (i.e., switches, levers, buttons) or by using complex informational input systems (such as speech input systems, graphic charts, and keyboards). The system can in turn communicate with the user by using visual, acoustic, or haptic modes of interaction. Today more and more automatic announcements and multi-/hypermedia systems are in use due to highly sophisticated language and image processing systems as well as highly effective data storage.

When designing the modes of interaction, the different individual attributes are to be considered: Human expectations are attributed to inherited or, in the technical and social environment, acquired behavioral stereotypes which are dependent upon certain population affiliations (e.g., left-handed people). These behavioral stereotypes are introduced into the work system as part of the individual's proficiency requirements. If one wants to use them during the task or at least respond to them, they must be considered during display and manual control design, that is, the display and manual controls must be designed compatibly.

Compatibility of informational input and output of work tools is accomplished when certain human expectations regarding spatial as well as mapping of dynamic procedures correspond. In the dynamic case, movement compatibility is of major importance. A well-known example is steering a vehicle. When turning the steering wheel right, the vehicle is expected to turn right; the same holds true for the converse.

In order to obtain an option and design of informational input and output elements customized to the work task, it is necessary to analyze the task. The arrangement and design of input and output media result from the work procedure.

In past years, during the course of increasing automation, a trend from manual tasks to control and monitoring tasks has appeared. Meanwhile, microcontrollers are being built into machines. For this reason, however, the mode of the human–machine interaction (HCI) is also

**Figure 15** Depiction of a typical process control workstation. (Courtesy of BKB Göppingen.)

changing. Classical machine interfaces, which mainly use discrete operating elements, are nowadays only found rarely. They are replaced by display screens on the machine as well as in control centers (see Figure 15). As a result of this, ergonomic software considerations (often referred to as HCI) are becoming increasingly important for the division of production. Thus, the design of information flow under cognitive considerations is still a challenge for HCI.

If in the past the human and machine were considered to be independent partners, now the human is seen as the central component of the human–machine system to which the machine is to be adjusted (Oborne and Arnold, 2001). Since the human, however, learns through interaction with the machine, the best possible mode of interaction is also changing constantly. It is here that the human–machine system is considered to be dynamic. "So the goal is to create supportive dynamic environments that enable individuals to work at their safest and most effective levels; not just to design the environment to fit the individual in some static sense" (Oborne and Arnold, 2001).

The central tool used to accomplish this goal is *usability engineering*. Lin et al. (1997) define usability as "the ease with which a . . . product can be used to perform its designated task by its users at a specific criterion." According to ISO (2006) 9241-110, four steps in the design process will ensure usability:

- understand and specify the context of use, which leads to
- specify the user and the organizational requirements, which leads to
- define product design solutions, which leads to
- evaluate the designs against the requirements.

For monitoring tasks, constantly appearing in process control, a good interaction system design implies a significant safety aspect. Information must be taken and processed reliably according to its importance. For this purpose, the human must not be overstrained or unchallenged. In the worst case, a decrease in vigilance

can result from monotony when the user is not able to act quickly enough in an acute critical situation. As a result, more damages can threaten the human and environment. In addition to ergonomic design of modes of interaction, such as the geometric arrangement of display elements, vigilance management systems can bring an important safety contribution by detecting decreasing vigilance and warning the respective user, correspondingly by maintaining vigilance through appropriate activation.

## 3 DESIGN PRINCIPLES FOR MANUFACTURING SYSTEMS

So far, the manufacturing system, its elements, and the approved methods for ergonomic work design were introduced. These methods, however, correspond primarily to isolated elements of a work system. For the design of manufacturing systems, limitation to individual elements is not sufficient. In fact, systemic consideration is required, as it happens within an integrative design process. Design principles and measures of ergonomic and efficient manufacturing system development, whose conceptual basics were already named, will be subsequently presented.

### 3.1 From Execution- to Object-Oriented Work Content

Organizational production according to the principles of Taylorism leads to high division of work, which results in less work. As a result, employees only identify with the work and its results to a minor degree. Besides these human problems, the high division of work also leads to organizational problems resulting from a multitude of interfaces. An example of this is the sometimes troublesome adjustment of the cycle times.

*Team work*, embedded in decentralized enterprise structures, can serve as a solution to this problem. These groups are established according to the object principle. An example is the complete assembly of all attached parts and aggregates for a dashboard (object) of a car (product). In the further production process, the completely assembled dashboard is installed as a whole in the body work of the car.

This procedure generates small units. In addition, the scope of action and decision making for each worker expands and groups are able to manage and coordinate operating processes independently.

The object-oriented concept has most notably become accepted in the form of production and assembly insulars. Thereby, the team has the task of the entire production process, assembling a spectrum of particles. They also take on tasks from which the individual employee is excluded by the performance principle of Taylorism. The additional work content occurs as a result of:

- Job enlargement, by overtaking preliminary and downstream functions (e.g., material provision, examination of the particles)
- Job enrichment, by overtaking the production and preparing functions (e.g., setup and maintenance of installation, material disposition)

### 3.2 From One- to Multidimensional Work Qualifications

In the work system, complex work structures such as production and assembly insulars also require employee organizational skills aside from technical skills and abilities. These are needed since employees handle greater work content in terms of the scope of services and efficiency diversity within these production structures.

Cooperation within the group, however, also employs new demands on the cooperation and coordination capabilities of the individual. It is clear that the introduction and implementation of more innovative production structures with conventional, strongly subject-oriented training concepts on a wider basis are problematic since a sufficient number of qualified employees are not available right away. Here, a training concept is required for enterprises in order to provide technically well-trained employees with strong organizational and social skills.

### 3.3 From Fixed to Flexible Working Times

The reduction of working hours, mainly in industrial countries, calls for the development of more flexible work models so that the work time factor does not become a disadvantage for the enterprise. This results in pressure to use intensive production systems to remain competitive in the international market.

In the past few years, the following working hour designs in production are recognized:

- Flexible work time models
- Seasonalization of working time
- Working time differentiation (maintenance of preferably high working time volume for highly qualified employees, of whom not very many can be found in the job market)
- Part-time work
- Individualized working time models instead of collective working time models

Note that such flexible working time models must be attractive so that employees accept them, that is, the employees have to understand the advantages that arise from these models.

### 3.4 From Reactive to Preventive Work Design

Work design should protect employees from work-related risks. Therefore occupational health and safety (OHS) criteria have been established in enterprises. In the past, OHS predominantly focused on human protection from hazards. A reactive procedure, however, does not meet the requirements of a human-oriented work design. It has been recognized that the preventive dimension of OHS has to be strengthened, that is, the protection of humans' health is achieved through the avoidance and elimination of hazards before damage occurs.

Practice shows that the implementations of these conclusions are not yet adequate. This is mainly because hazard risks need to be identified in an early phase

of production system planning so that the human-oriented realization of the working system can be based on it. Otherwise, for economic reasons, the practical adjustment of ergonomic design measures might become impossible during the course of the project.

## 4 HUMAN RESOURCES MANAGEMENT

In this section, essential aspects of human-oriented work design are discussed in detail in human resource management perspectives. One focus of human resource management rests upon the accomplishment of demographic change challenges, which are related to measures of qualification and occupational health.

### 4.1 Accomplishing Sociodemographic Change

Sociodemographical development in nearly all industrial nations leads to a fractional increase in the elderly (worker) population. More dramatic than the decline in the absolute number of working people is the change in age composition as the number of younger workers slowly but continually decreases and the number of elderly people able to work will continue to grow in the coming years. With this in mind, there will be an increase in the average age of staff and shortages when recruiting a younger work force. Youth-centered enterprise principles, short-term success-oriented personnel policies, and general conditions that favor the retirement of older workers do not measure up to this development (Pack et al., 2000).

The age in professional life mostly becomes a problem when employees remain in stressful tasks for a long time and the required specific capability is used up to the point that individual resources do not satisfy the work requirements any more.

On-going physical and psychological stress in badly designed work systems is partly responsible for physical decline and decreasing cognitive flexibility. Thus, for example, a lack of physical demand resulting from unbalanced body posture such as continuously sitting while working leads to the reduction of physical ability efficiency and ultimately to the same result as capacity overload, namely musculoskeletal illnesses.

The condition of an employee's health is not primarily appropriated by their age but rather by the result of past work conditions. A reduction in older employees' work efficiency ability does not generally apply; it always refers to specific tasks and work requirements. For example, a machine operator with damaged intervertebral disks might no longer be able to operate a machine but might be able to work in administration.

There is no standard solution for designing age-based jobs, personnel placement, and work hours. The acceptable method for an enterprise depends upon specific initial conditions of the enterprise. In general, however, a basic sensibility toward the topic of age is important.

Age-based work design remains an illusion as long as production strategies exclusively aim for short-term economies of scale and profit increases. Indeed, such strategies cause long-term damage to the enterprises themselves, as misunderstood examples of *lean management* show. Here, the principally correct idea of reducing the number of hierarchal levels caused a number of personnel reductions that resulted in a massive lack of qualified employees (Kern and Braun, 2006).

In order to face the risks of sociodemographic change for performance and innovation ability, work design and human resource management have to be able to support employee psychological and physical capacity during their entire professional lifetime and open up a larger degree of specific capabilities for elder employees. During work design, it has to be considered that with any work, middle to long term, depending on requirements, the physical and psychological capacity derived through learning, training, and degradation processes can change. Therefore, work should be designed in a way that an assorted amount of body movement as well as varied mental specifications are required to accomplish assignments.

Effective age-based work design should be set up not only for elderly people, who are already concerned with performance limitations, but also for younger people so as to counteract health damages as early as possible. For this purpose, a rethinking of both employees and managers is necessary. Criteria for appropriate personal development processes should confirm that through different work specifications:

- New knowledge is gained.
- Developing fixations concerning health-damaging strain and stress situations are halted.
- New social configuration (work groups and the like) are experienced and thereby new social key qualifications are learned.
- Individual willingness and ability to deal with new working situations and requirements are supported.

### 4.2 Qualification

In manufacturing systems, knowledge represents an important resource for the production of goods and services. Knowledge and capability significantly influence the innovation power and competitiveness of an enterprise.

A superior target of operational qualification measures is the development of comprehensive decision-making and responsibility as a sum of technical, method, social, and self-competence. Standard knowledge is losing importance as a basis for operational decision making. In the course of further manufacturing procedures, operational decision making will be based upon prognosis and diagnosis, which enables development of professional decision-making strategies.

The required availability of task-specific decision making and responsibility within complex production systems places high demands on the qualification. According to this, qualification processes are geared to the premises of decentralized organizational concepts:

- Qualification increasingly takes place in open knowledge networks, which are marked by exchange of knowledge and experience.

- Qualification strategies are more and more based on short-term learning content and on the integration of learning and implementation phases.
- Qualification methods incorporate learners' self-organization, for example, by means of computer-aided self-learning phases.

While in traditional qualification strategies knowledge is taught "on stock" and is timely implemented and spatially separated, an up-to-date gain in competence is more and more task oriented.

Poor predictability of future qualification places increasing demands on the flexibility and rapidity of learning. Up-to-date qualification concepts abandon teaching the concepts completely but use only elements of knowledge to develop of problem solution strategies, enabling the learner to reflect on new problems. A dynamic knowledge transfer is requested on the one hand by the increasing amount of required knowledge during the course of one's professional life and on the other hand by the short-lived validity of knowledge. It appears that specific professional knowledge becomes old relatively quickly and life-long learning is consequently becoming significantly more important. On-the-job training as a supplement to vocational training has become the norm.

### 4.3 Occupational Health Prevention

#### 4.3.1 Stress Situation

Considering all chances of innovative work structures, their negative effects on the employees' health situation cannot be overlooked. Increasing requirements on time and local flexibility as well as increasing performance demands are only a few effects of the structural change. Hereby, mental stress and chronic illnesses step into the forefront. These factors can lead to loss in human performance.

In past years mental health disorders are becoming common among workers. More than half of employees in the European Union complain about physical health damages caused by work (see Figure 16). In Germany, losses resulting from work-related health disorders are estimated to be over three billion Euros a year; stress resulting from work is the cause of 7% of early retirements. The most common causes of underperformance and absences are related to mental disorders (WHO, 2000).

In the workplace, the mental health and well-being of employees gain importance as resources worthy of being sustained and protected.

#### 4.3.2 Definition of Health

Traditional diction defines health as the absence of illness. According to timely understanding, health includes the goals of competence development as well as broad physical, mental, and social well-being (WHO, 1986). Health includes the ability to define and pursue individual long-term targets, the ability to adapt to changing environmental conditions, and the ability to take part in such changes. Therefore, a healthy person is target oriented and someone who actively acts within his or her world and develops further. Health relies on personnel and organizational resources. Occupational health is a precondition of coping with work challenges as well as a result of adequate working conditions.

#### 4.3.3 Prevention Strategies

For a long time occupational health prevention was primarily determined by the defense of acute risk hazards, that is, accidents at work, as well as by the impact of individual stress and illness factors with a definite effect on health. In addition to these risks, it is important to focus on the complex correlations of work factors and health effects. These complex correlations do not comply with the prototype of the specific cause–effect relationship. They can only be controlled by detailed regulations in a limited way. Furthermore, the health resources concept sets priorities by abandoning a risk-oriented approach (Braun, 2003).

Requests for occupational health prevention are the stabilization, that is, the enhancement of physical and mental health resources, as well as the mobilization of individual capabilities. Physical and mental resources should be developed in order to be able to cope with health disorders (see Figure 17). In addition to avoiding illness caused by work, the stabilization of health with respect to potentially illness-causing influences and

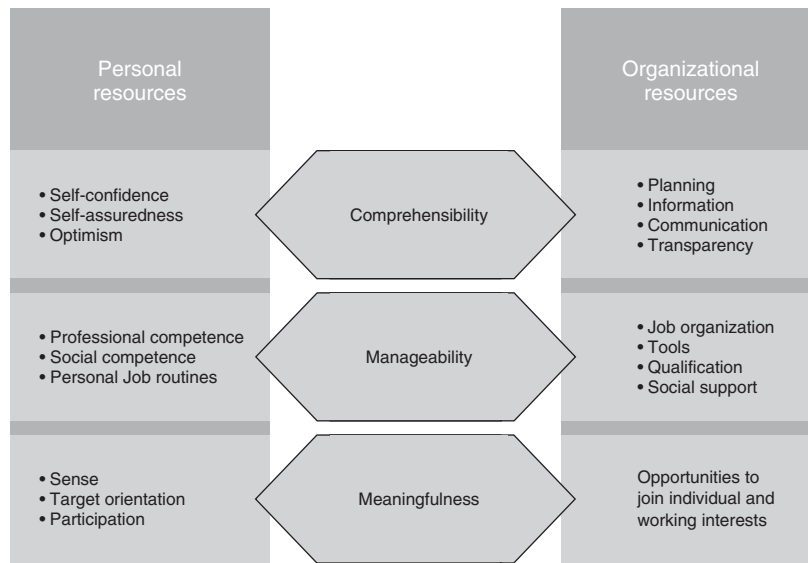
**Figure 16** Health problems caused by work. Fraction of complaints per 100 employees surveyed in countries in the European Union. (Data from European Foundation, 2005.)


**Figure 17**   Organizational and personal health resources according to the coherence model by Antonovsky (Spath et al., 2003).

premature weakening processes caused by work are considered.

The resource-oriented definition of the health concept focuses on the human ability for competence development as a basis for health. According to this, health prevention is aimed at enabling humans to have greater self-responsibility for strengthening their health and, moreover, to qualify them for this. Advancement of work satisfaction and social well-being, resulting from cooperation possibilities and a positive setup of the operational environment, come into central focus.

## 5   CONCLUSION

In past years, production enterprises made numerous efforts to increase their performance, efficiency, and flexibility and thereby satisfy market demands. Fundamental characteristics of manufacturing concepts are business process design and team work. Despite great endeavors and obvious success, a number of deficiencies still emerge as a closer look at manufacturing processes and results shows, for example, long cycle time and time of delivery.

In view of the obvious limits of technology-oriented strategies, it has been recently recognized that the targeted success in manufacturing can only be reached through the integrated actions of the human, technology, and organization. Production systems integrate elements of the organization of assembly, process, work, quality control, and continuous improvement, which for a long time have been only considered isolated, as one system. Design principles, methods, and tools have to be integrated into the production system. Nevertheless the established methods of human-oriented work design

have to be regarded as a necessary requirement for economic success.

One aspect that is critical for success is the development of production systems "from the operational practice." An efficient production system can only be realized when considering the specifications of the enterprise. Understanding the business culture and human values make up the specific requirements for successful implementation. It is necessary to involve all participants, to identify good practices, and to make this the business standard. In this way, the system is comprehensible and practicable for all participants.

The comprehension of human success factors such as qualification, information, and participation is of particular importance. On the one hand, this calls for meaning, commitment, and readiness to take on responsibility, and, on the other hand, it results in win–win situations as well as in leadership through personal commitment.

In the past, manufacturing enterprises have primarily relied upon quantitative or "hard" success factors. They are comprehensible by means of strategy papers, plans, organization charts, job descriptions, operating instructions, and target systems. Currently, a tendency toward a stronger emphasis on qualitative or "soft" success factors can be seen which are geared to the conditions of the worker. These factors include abilities, values, cultures, and participation. The soft success factors are often impossible to be described definitively. Although these soft factors rather remain latent, they crucially affect the performance of businesses, as numerous examples document: These companies are very successful in relation to economic efficiency and competitive ability, customer satisfaction, and employee health.

In view of the multiple business influences it is obvious that restructuring measures and technological advantages are no longer sufficient for maintaining the enterprise's competitiveness. Ultimately, the healthy, motivated, and qualified human generates distinctive and, hence, decisive competitive products and services. Consequently, human factors remain a focus of business enterprise strategies.

# CHAPTER 61

# HUMAN FACTORS AND ERGONOMICS IN AVIATION

**Steven J. Landry**
**School of Industrial Engineering**
**Purdue University**
**West Lafayette, Indiana**

## 1   INTRODUCTION: BRIEF HISTORY OF HUMAN FACTORS PROBLEMS IN AVIATION

Aviation is inherently a complex sociotechnical system. It involves the operation of numerous interacting vehicles by human operators within a complex system managed by other human operators. The performance of those human operators is tightly coupled to the safety and performance of the individual vehicles and the overall system. As such, human factors problems and the solutions to those problems have been of paramount importance to the air transportation system.

Overall, this chapter focuses on the principles that have been developed with respect to aviation, how those principles have been applied, and what challenges lie ahead. These principles and their application are described starting in Section 2, which describes principles related to the flight deck. Section 3 describes principles associated with air traffic control, and Section 4 describes principles associated with maintenance and safety management. Section 5 describes emerging issues, and Section 6 summarizes what we have learned and what future issues are appearing on the horizon.

Understanding these principles, however, requires an understanding of their genesis. In this section, a brief historical review of the problems that precipitated the need for these principles is provided. That review is, as is the case in aviation, notably driven by fatal accidents. Due to, in part, the complexity and safety criticality of aviation, change does not occur easily—it often takes catastrophe to push system managers to make large changes.

In addition, aircraft themselves are quite robust to failure. Serious aviation accidents are astonishingly rare; of those, accidents in which the pilots had no ability to save the aircraft are a small minority. In many cases, a properly designed system with a properly trained pilot would have been sufficient to save the aircraft.

In covering such principles, however, several aspects of human factors in aviation are not covered here. In particular, except for the principles related to circadian rhythms, the human factors of passenger travel in aviation, including the design of aircraft to improve passenger travel, are not discussed. (It is, however, a notable development that the Boeing 787 aircraft has incorporated features, such as daylight-simulating lighting and a lower cabin altitude, designed to improve passenger comfort.) Also, the human factors of the job of the flight attendant and that of the "ground side," such as passenger loading, baggage handling, aircraft marshalling, refueling, and deicing, are not discussed.

For a discussion of the human factors of passengers and principles for the cabin crew, see Hawkins (1987). Numerous texts that discuss ergonomics, including this handbook, exist and the principles within those texts can be applied to the ground side and passenger cabin. Notably, the Federal Aviation Administration (FAA, 2007) has published a manual for airport operations human factors, and some specific aspects have been investigated in more detail (e.g., Korkmaz et al., 2006). A description of the principles for the layout of passenger terminals, along with a good description of airport ground-side operations, is found in Kazda and Caves (2007).

### 1.1  First Flight–1940

In 1903 the Wright brothers took what is generally considered to be the first piloted, powered, and sustained flight. Aviation advanced rapidly, with Orville Wright living to see the dawn of supersonic jet propulsion aircraft.

Numerous problems, most related to the design of the vehicle itself, had to be overcome to allow for this rapid advancement. Safety became a paramount concern, with pilot errors a notable cause of crashes [National Advisory Committee for Aeronautics (NACA), 1921]. With the use of aircraft in two world wars, the performance of the vehicle and the pilot were also of great interest to researchers and engineers. One example of this is the identification of the problem of "situation awareness" by Oswald Boelcke, a World War I ace, who indicated that "the pilot must acquire the habit of 'taking in' unconsciously the general progress of the whole multi-aircraft dogfight going on around the individual combat in which the pilot will become involved ... [so that] no time [is] wasted in assessment of the general situation after the end of an individual combat (Hacker, 1984, p. 1)."

In recognition of the great promise of aviation, the United States founded NACA in 1915. NACA became a repository for worldwide aviation research for several decades.

### 1.1.1  NACA: Early Work on Human Factors

At NACA, several problems were identified early on in the development of aviation. The physiology of flight, including altitude sickness, became an issue as aircraft began to be operated at altitudes above 10,000 ft. A NACA report relayed the results of tests in pneumatic chambers by German researchers who found that severe symptoms, including unconsciousness, manifest themselves above 6500 m (NACA, 1921). (It is now known that altitude sickness can manifest itself as low as 2500 m.)

Hersey described challenges with instrumentation. Specifically, Hersey noted that pilots' use of instrumentation can be inappropriate, where important but poorly designed instruments may be ignored, and unimportant but salient instruments capturing the attention of the pilot. More generally, Hersey wrote that, "the reaction of the aviator to his [sic] instruments has to be considered ... [the instruments] must be ... readily intelligible to the pilot (and) must not make an appreciable demand on his [sic] time or attention" (Hersey, 1923, p. 482).

Researchers also identified that the challenge of interpreting instruments is compounded by the workload and time pressure experienced by the pilot. It was clear that instruments must be made for "the easiest possible reading and manipulation ... (due to) the extremely short time at the disposal of the pilot for adjustment (NACA, 1921, p. 5)."

Pilot error was very clearly a large source of serious accidents. In a 1924 report, errors in piloting were the largest single cause of serious accidents, with nearly two thirds of such accidents associated with pilot error during training and one third of such accidents in civil flying (Devaluez, 1924). A similarly large percentage (54%) of accidents were attributed to pilot errors in a slightly later study of accidents in French aviation (Brunat, 1927). Generally, these accidents were not viewed as a problem of the interaction of pilot and vehicle but, as is common today as well, are attributed to poor piloting skills and judgment. The suggested remedy for such problems was viewed to be training and selection, rather than better design of the vehicle and its instrumentation.

### 1.1.2  Equipment: Instrumentation and Automation

At *Concours de la Sécurité en Aéroplane* in France in 1914, Lawrence Sperry and his assistant, Emil Cachin, flew by the air show crowd utilizing a new device, a gyroscopic stabilizer, with their hands in the air to demonstrate that they were not touching the controls. (The gyroscopic stabilizer had previously been invented by Herman Anschütz-Kaempfe and manufactured by the Sperry Gyroscope Company for use on large naval vessels; see Hughes, 1971.) On a second pass, Cachin stood on the wing, with Sperry again holding his hands in the air; on the third pass both men stood on the wings, with the pilots' seats empty.

This automation utilized a simple feedback control system, a concept which had existed for centuries but whose utility did not extend to aircraft until Sperry developed a relatively light gyroscopic device. The autopilot was operated by a simple switch, and its only function was to stabilize the three axes of the aircraft (pitch, yaw, and roll). Since then, autopilots have increased in complexity but have remained standard equipment on commercial and military aircraft. Not only has the design of autopilots and their operation been of interest to human factors engineers and researchers, but the methods developed to perfect control automation have been applied to try to model the human pilot.

The autopilot is a somewhat rare example of a development that predated the problems that necessitated its use. Aircraft were considered generally stable and easy to fly for properly trained pilots (Warner, 1922a), and pilots and researchers did not see a substantial need or desire for an automatic pilot even almost a decade later (Warner, 1922b). However, much like driving a car, flying an aircraft requires constant vigilance, except that in an aircraft tracking must be done on the vertical axis as well as the horizontal axis and with respect to speed. Aircraft are also generally subjected to more substantial disruptions since their motion is easily disturbed by

changes in the wind. Because of this, it was clear from the very early days of flight that fatigue was a significant problem in controlling an aircraft on flights of even modest (1-h) duration (Devaluez, 1924). The autopilot would fill this need as flights grew in duration and as aircraft grew in complexity.

Along with the development of the aerodynamic and propulsion aspects of the aircraft, the development of instrumentation was considered crucial. A number of early studies were commissioned for the naming and taxonomy of instrumentation. From these papers, a number of human factors problems addressed or considered by early instrumentation were discussed, including:

- Ease of reading (Hersey, 1923)
- Errors in reading multiple-pointer round dials for altitude (Hunt, 1926)
- Trade-offs between space and usability (Subcommittee on Instruments, 1932)
- Spatial disorientation (Eaton, 1921)
- Usable and precise navigation and orientation instruments (Eaton, 1921)
- Use of vertical-scale instruments (Subcommittee on Instruments, 1932)
- Limits on the workload needed to interpret instruments (Subcommittee on Instruments, 1932)
- Discrete (vs. continuous) motion of instrument indicators (Subcommittee on Instruments, 1932)
- Arrangement of instruments, including Gestalt effects (Subcommittee on Instruments, 1932)
- Proper graduation and orientation of airspeed indicators (Beij, 1933)
- Visual field measurement and importance (Gough, 1936)
- Physical forces required to operate controls (Gough and Beard, 1936)
- Need for stall warning devices (Thompson, 1938)

Near the start of World War II, an aviation psychology research unit was established in England led by Sir Frederick Bartlett, and in the U.S., the National Research Council started a Committee on Aviation Psychology, led by Jack Jenkins (Roscoe, 1997a). These units focused much of their effort on pilot selection and training; they also were the first to deal with the problem of pilot error as a design problem instead of a personnel or training problem.

## 1.2 1950–1970

At the end of World War II, Lieutenant Colonel Paul Fitts edited a report commissioned by the Committee on Aviation Psychology that outlined the primary human factors challenges to aviation in 1951 (Fitts, 1951). Fitts was at the time leading a new research unit at Wright Field in Ohio on aviation psychology, which would produce a number of important results in aviation human factors. The report provides great insight into aviation problems at the beginning of the 1950s. As can be seen

from a comparison of the list generated by the Fitts panel, many of the problems identified prior to 1940 had not been satisfactorily addressed.

### 1.2.1 Fitts Panel

The Fitts (1951) report opens with a quote from a nineteenth-century textbook on applied mechanics which argues that the engineering of systems has largely focused on the machine and tools and ignored the operator, despite the operator being the most important part of the human–machine system. Morris Viteles, the Chairman of the Committee on Aviation Psychology, then states (p. iv):

> During the past decade, primarily in response to military requirements, there has been a growing withdrawal from this classical psychological viewpoint, and ever-increasing acceptance of the principle that "machines should be made for men; not men forcibly adapted to machines." This basic principle of "human engineering" is not new, particularly to industrial psychologists, although it has been consistently neglected, largely because engineers concerned with the development of the machine and scientists concerned with the individual who is to operate the machine have worked in almost complete insulation from one another. The resulting disregard of physiological and sensory handicaps; of fundamental principles of perception; of basic patterns of motor coordination; of human limitations in the integration of complex responses, etc. has at times led to the production of mechanical monstrosities which tax the capabilities of human operators and hinder the integration of man and machine into a system designed for most effective accomplishment of designated tasks.

The report then goes on to summarize the findings of the last several decades and to identify a long-range research program to address problems related to the navigation of aircraft in the air traffic system. The report may be unique in its scope and authority.

The report identified a number of human factors problems that needed to be solved, which will be numbered here so as to reference them in the remainder of the chapter. The problems identified include:

1. What is the proper role of humans in the air traffic system?
2. What tasks appear to exceed human capacities, either trained or untrained?
3. How do we measure human performance and behavior in the air traffic system?
4. How do we measure the information-handling capacity of pilots and controller, and how reliable are these measures?
5. What is the information-handling capacity of pilots and controllers?
6. What redundancy is needed in information presentation?

7. What information is needed by pilots and controllers, what is the required accuracy of that information, how much time do pilots and controllers have to use that information, and what actions or decisions do pilots and controllers make based on that information?

8. What are the relative advantages of single- versus multifunction instruments?

9. What is the best way to encode and present information on those instruments, including quantitative, spatial, status, and control information?

10. In what ways can communication be improved, including intelligibility, encoding, and the use of multiple modalities?

11. What variability, delay, and error can be attributed to the human operators in the air traffic system?

Over the next two decades, Fitts and a member of the review team named Stan Roscoe, among others, were instrumental in developing methods for evaluating flight deck and air traffic controller workload and performance. These efforts had a direct and substantial impact on the development of aircraft during the 1960s, including the Boeing 737, 727, and others.

### 1.2.2 Radar in ATC

The Fitts report also queried controllers about what equipment they would like to see adopted in the air traffic control (ATC) system. On the subject of radar, which had been developed in England during World War II and was being considered for use in the air traffic system, only 34% of the en route controllers desired such equipment. In 1951, aircraft were monitored by using flight status boards, on which the current and future (estimated) positions of aircraft, as reported by radio, were updated. Aircraft were separated based on the projected positions, but, with increasing air traffic, this method was becoming more and more difficult to apply effectively.

In 1956, two commercial aircraft, one a TWA Super Constellation and the other a United Airlines DC-7, collided over the Grand Canyon. Both aircraft were initially under the control of air traffic authorities, but, due to the need to fly around thunderstorms, the TWA flight requested, and was granted, visual flight rules, which meant the pilot was responsible for avoiding other aircraft. The TWA flight was struck by the DC-7 at 21,000 ft, disabling both aircraft and resulting in the death of all passengers and crew. This accident, in combination with several other collisions or near collisions, helped catalyze a radical change in the air traffic control system. Among the innovations mandated was the introduction of radar to monitor aircraft positions.

The introduction of radar is probably the single most radical change to have occurred in the air traffic control system to date. It fundamentally altered a controller's tasks and the nature of the controller's job and allowed for the introduction of a number of new technologies over the succeeding decades.

### 1.2.3 Altimeter Reading Problems/Design

Problem 9 on the Fitts report list was written broadly, but one of the specific problems in mind was almost certainly the difficulty in reading altimeters. Altimeters typically had multiple pointers on a single dial to indicate the hundreds, thousands, and (sometimes) ten thousands of feet. For example, in Figure 1, the altimeter shows an altitude of 10,180 ft.

The difficulty in reading such altimeters was the cause of two accidents in 1958 and was most likely a principal cause of two accidents between 1965 and 1967. The two crashes in 1958 involved aircraft carrying only crew. The 1965 accident involved a flight from LaGuardia Airport in New York to O'Hare Airport in Chicago. In that accident, a Boeing 727 crashed into Lake Michigan while on descent, killing 30. In 1967, a Caravelle was en route from Malaga, Spain, to London Heathrow, but descended slowly into trees in West Sussex, England, killing all 37 people on board. The accident report indicated the ease with which a pilot could mistake an indication of 6000 ft for one of 16,000 ft due to the lack of salience of the 10,000-ft pointer.

The solution to the problem, ultimately involving, in part, the vertical-scale instruments that had been under consideration since 1932, would also involve several of the other problems on the list. In particular, the salience of indications of problems would lead to the introduction of various types of alerting systems, which then spawned their own set of problems.

### 1.3 1970s — 1980s

From 1970 to 1990, the number of U.S. scheduled departures rose by 40%, from just over 5 million in 1970 to just under 7 million in 1990. During that same period, U.S. revenue passenger enplanements rose by 270%, from about 170,000,000 to 465,000,000. (European air

**Figure 1**  Three-pointer altimeter.

traffic rose in similar fashion.) This suggests that, in addition to an increase of 2 million flights, aircraft were larger and were carrying more passengers than ever before. The airspace was becoming more dense, and the consequences of accidents were growing.

Two other factors drove change in the air transportation system during the 1970s and 1980s. First, due to the Clean Air Act of 1970 in the U.S., which had followed earlier efforts in Europe such as the 1952 Clean Air Act in Britain, and the Arab Oil Embargo of 1973, airlines came to understand that new, more efficient aircraft were needed. Second, computing technology was being introduced in a form that would revolutionize instrumentation and which could be adopted for use in commercial aviation.

### 1.3.1 Elimination of Flight Engineer

As of 1970, all large commercial aircraft had three-person crews, which included a flight engineer, who was responsible for monitoring and controlling the fuel, pressurization, electrical, and hydraulic systems. The flight engineer was also expected to help troubleshoot any in-flight emergencies with the pilot. (The copilot would concentrate on flying the aircraft.) Due in part to advances in understanding and analyzing workload, and due in part to a desire to reduce salary costs for their client airlines, aircraft manufacturers began considering the possibility of reducing the crew size to two and eliminating the flight engineer.

This led to a great deal of human factors analysis and numerous hearings to resolve labor concerns. The general trade-off focused on two problems:

12. What is the relationship between flight deck workload and performance?
13. Does the ability to spread workload among three crew members overcome the additional interpersonal complexity of three-member teams?

The results of this analysis convinced regulators that two-person flight decks were no less safe than three-person flight decks. Boeing and Airbus, the two primary manufacturers of commercial aircraft, adapted the designs of their new aircraft and modified many older aircraft to eliminate the flight engineer position.

The pilots now became responsible for monitoring the automated systems using panels such as that shown in Figure 2. Although this potentially adds to the workload of pilots under some conditions, there have been no significant indications of safety problems related to the elimination of the flight engineer.

### 1.3.2 CRM

United Airlines Flight 173, A DC-8 en route from Stapleton Airport in Denver to Portland Airport, encountered unusual indications upon lowering the landing gear [National Transportation Safety Board (NTSB), 1979]. While the crew was troubleshooting the problem, the aircraft entered holding. Despite the relative simplicity of the problem—the gear problem was merely an indication problem—it would be nearly another

**Figure 2** Flight deck overhead panel showing systems controls. (This is a screenshot of copyrighted computer software; the copyright for the contents of the software is held by Level-D Simulations and Flight One Software, Inc.)

hour before the aircraft crashed due to fuel starvation. Although several queries and comments were made by the first officer and flight engineer about the fuel status, the captain did not appear to understand the actual fuel status. This accident highlighted a particular problem that had appeared to plague other incidents:

14. How do we ensure proper communication and coordination between crew members?

As a result of this incident, the NTSB recommended that all airlines ensure that crew members are trained in flight deck resource management. United Airlines complied, instituting a program in crew resource management (CRM) that was replicated by all other airlines and within the military. Good crew resource management is widely considered to be a significant factor in the relatively successful crash of a severely crippled DC-10 in Sioux City in 1989.

### 1.3.3 Alerting Systems

In an incident that presaged the crash of United 173, a Lockheed L-1011 aircraft, flying as Eastern Airlines Flight 401, encountered a similar problem with a landing gear indicator. The aircraft was placed on autopilot while troubleshooting occurred. However, during the troubleshooting the autopilot was inadvertently disconnected and the aircraft entered a very slow descent. Although an altitude warning was issued, it apparently was not heard due to fixation on the landing gear problem. In addition to the CRM-related problem, this accident highlighted a number of human factors issues related to automation and warning systems, including:

15. How do we ensure that pilots are aware of the status of the automation?
16. How do we ensure that alerts are sufficiently salient that pilots are aware of the situation?

This incident was one in a number of incidents that resulted in the introduction of new alerting systems onboard aircraft. In 1974, TWA flight 514 crashed on approach to Washington Dulles International Airport. This flight was one of the last in a series of "controlled flight into terrain" (CFIT) accidents that led to the requirement that commercial aircraft carry an operating ground proximity warning system. (That series of incidents included the 1970 crash of Southern Airways Flight 923, in which the Marshall University football team was killed.)

An encounter of a Lockheed L-1011 airliner with 152 passengers on board with "wind shear," a sudden shift in wind direction, speed, or both resulted in a crash that killed 135 people, including 1 person on the ground. This crash of Delta 191 in 1985 helped lead to the requirement for airliners to utilize wind shear detection systems.

Lastly, Aeroméxico Flight 498 collided with a general aviation aircraft approaching Los Angeles International Airport in August 1986. The crash claimed the lives of 82 persons and followed a number of in-flight collisions, including a very similar incident involving a Pacific Southwest Boeing 727 in which 144 persons died in San Diego, California, in 1978. These accidents led to the requirement that commercial aircraft be equipped with collision warning systems.

The introduction of multiple alerting systems, in addition to the numerous other alerting and status information displays in the aircraft, added complexity to the flight deck. With more alerting systems on board the flight deck, alerts were more likely to sound, even when unnecessary (false alarms), resulting in distraction to the pilots. In addition, aircraft malfunctions would sometimes result in a number of simultaneous alerts. While there have not been fatal accidents associated with these problems, they were listed as two of the primary factors in a number of incidents which are considered precursors to accidents (Rehmann, 1995). These two problems are:

17.  How do we design alerts so that pilots can properly prioritize actions when multiple alerts occur simultaneously?

18.  How do we design alerts so that they do not distract the pilot from higher priority duties?

### 1.3.4    Multifunction Displays

Cathode ray and computing technology enabled the replacement of single-sensor, single-instrument (SSSI) displays with multifunctional displays (MFDs). The adoption of MFDs was consistent with a number of human factors principles that arose from studying problems 8 and 9 but also added a new task to the flight deck—that of navigating through displays that now had *depth*. Moreover, controls for these displays had to be added. These two problems have close ties to usability research:

19.  What is the best design for controlling MFDs on a flight deck?

20.  What is the best interface design for MFDs on a flight deck?

These problems were somewhat unique to the flight deck due to the conditions on the flight deck, which include things such as that vision should be directed outside, there are a number of periods of very high workload, and both high- and low-frequency movement are prevalent.

### 1.3.5    Heads-Up Displays

The requirement for a good visual field outside the flight deck, the topic of earlier research, was present in commercial aircraft but was especially important in military aircraft. Early examples of information placed in the line of sight of the pilot such that the pilot could look through the information to the outside came in World War II when gun aiming was displayed on a transparent plate. (There were versions developed that projected information on the windscreen, but these were not adopted for use until after the war.)

In the 1950s, improvements were made to the projection of gun-sighting information on military aircraft. It was noticed that pilots could use the information to better fly the aircraft as well, so in the 1960s the information contained in the display was increased to include all the basic information. The symbology for this "heads-up display" (HUD), a name that distinguished the behavior of pilots from one who must look down to find the same information, was formalized by a French test pilot, Gilbert Klopfstein, in the 1960s and adapted during the 1970s for use as a primary flight instrument display (Deaton et al., 1989). However, research was needed to understand the HUD and how it differed from traditional instrumentation. In particular, the following problems were of interest:

21.  What effect does the use of a HUD have on flight performance?

22.  To what extent does the HUD improve detection of important environmental information external to the aircraft?

### 1.3.6    Communication

The deadliest accident in aviation history occurred in 1977 when two Boeing 747s, one with 396 persons on board and one with 248 persons on board, collided at a foggy Tenerife airport due to a fairly simple communication failure. The first aircraft, a KLM flight, mistook a route clearance as permission to take off while the second aircraft, a Pan Am flight, was still on the runway. The two aircraft collided, resulting in only 61 survivors, all of which were on the Pan Am flight. This accident highlights problem 10 on the Fitts panel list. As will be discussed, runway incursion incidents, primarily due to communications problems, continue to be one of the most vexing problems in air transportation.

23.  What principles should be used for communication between the different operators in the air traffic system?

## 1.4   1990s–Present

The last two decades have seen substantial changes to the system. The air traffic system has been undergoing modernization, as have the aircraft, with the introduction of new systems and with increasing reliance on automation and computing technology. These advances, however, have not come without difficulties.

### 1.4.1   Automated Collision Avoidance Systems

The danger of midair collisions reduced greatly after the introduction of radar at the end of the 1950s. Since that time, in the United States no two aircraft under radar control have collided. However, there have been collisions outside of the United States and near misses are not infrequent even within the United States.

To combat this danger, automated collision avoidance systems (ACASs) have been mandated on most commercial aircraft by national and international regulatory agencies. In actuality, the concept of an onboard collision avoidance system had been around since the 1950s as one response to the collision over the Grand Canyon in 1956. The systems were, for one reason or another, unreliable but continued to be developed and tested throughout the next decade (White, 1968).

It was not until the FAA focused researchers on systems that utilized the aircraft's transponder information, followed by the series of midair collisions mentioned above, that a system was actually developed and fielded (Kuchar and Drumm, 2007). Aircraft began flying with the systems in 1990.

However, aircraft have still collided, despite the presence of the system. These cases included problems with opaque failures of the system and with procedures for executing the resolutions of the system. In addition, it has been shown that pilots do not often comply with the resolution of the alerting system, which could be a precursor indication (Kuchar and Drumm, 2007). These problems can be summarized as follows:

24. What can be expected in terms of pilot response to a collision avoidance warning?

### 1.4.2   Mode Confusion and Envelope Protection

With new aircraft and with a two-person flight deck, autopilots were increasing in both capability and complexity. Autopilots were now capable of operating in numerous "modes" which do not have intuitive or salient differences but which can have profound consequences for the behavior of the aircraft.

In Toulouse, France, in 1994, a new Airbus A330 was being flight tested for certification of flight under engine failure conditions. The autopilot unexpectedly entered a mode where it attempted to capture the altitude input to it, which was 2000 ft, and pitched up to do so. The pilots were not aware of the mode and did not increase power or disconnect the autopilot until the aircraft had stalled. It crashed with no survivors.

A China Air A300 approaching Nagoya Airport in Japan, also in 1994, crashed after it inadvertently entered into a "go-around" mode. The pilots, not aware of the mode, attempted to continue the approach. With the autopilot and pilots fighting for control, the aircraft stalled and crashed, killing 264 persons.

More recently, two Bombardier Dash 8 aircraft have nearly crashed after their autopilots entered into modes other than those expected by the pilots. These incidents highlight a significant problem:

25. How do we design autopilots to prevent or minimize mode confusion?

### 1.4.3   AAS Failure in ATC

In the 1990s, the FAA contracted IBM to build an "advanced automation system" (AAS) to replace the aging automation infrastructure of the air traffic system. In addition to modernization, the system must have improved functionality and extensibility (Debelack et al., 1995). The procurement was terminated in 1994, and approximately $1.5 billion of the $2.6 billion invested was written off as a loss.

The program was criticized as overly ambitious; it tried to radically alter all aspects of the air traffic system nearly simultaneously. In addition, the program was caught in a nonterminating loop of specification and refinement. Since then, the FAA's approach has been to build and deploy smaller systems and capabilities in a more evolutionary approach.

### 1.4.4   Next-Generation Air Traffic

Recently, in response to projections of substantial delays in the air traffic system due to increasing demand in the face of static capacity, Europe and the United States have embarked on parallel plans to modernize the air transportation system. Implementation of changes suggested as part of these systems, while posing some technical challenges, will almost certainly hinge primarily on resolving a number of human factors issues. The systems proposed contain several significant changes, including:

- Trajectory-based operations—flying aircraft with respect to four-dimensional, three spatial dimensions plus time, trajectories
- Automated separation assurance—the allocation of the air traffic controller's primary function, separation assurance, to automation either on the ground or on the flight deck
- Increased coordinated information to pilots, controllers, and other stakeholders regarding weather and air traffic
- Robustness to disruptions such as weather and traffic congestion

These changes are expected to increase the capacity of the system to twice its current level or more. At the same time, the system must remain as safe or safer than the current system. This, however, poses a significant problem:

26. How do we predict the safety of a complex human-integrated system?

## 2  FLIGHT DECK HUMAN FACTORS

Much of the research and development in aviation human factors has been applied to the flight deck. Such work has been driven by the rapid expansion and advancement of flying in general, including commercially, where hundreds of millions of passengers are moved every year, and in the military, where the application of good human factors can make the difference between success and failure.

Substantial work has been done on the design and use of automation and the performance of the pilot reflecting human factors work that cuts across perception, information processing, decision making, workload, human error, usability, and physical ergonomics. The methods applied to study automation have included task analysis, modeling, information theory, control theory, and anthropometry.

### 2.1  Automation

Various types of automation have been introduced onto the flight deck. Perhaps the earliest forms of automation were autopilots, for control of the aircraft. These have proven highly successful. Next, various forms of information automation, mostly in the form of alerting systems, were deployed in response to a number of accidents. Lastly, decision support systems have been added to the flight deck.

#### 2.1.1  Control Automation

Autopilots have become an indispensable part of commercial flying. They allow for great reliability in maintaining the desired course, speed, and altitude and greatly assist in landing aircraft in very poor weather conditions. Overall, they relieve pilots of a great deal of workload. Autopilots, however, are not without problems, as indicated earlier. A number of principles have been developed based on research into these problems.

***Operators May Overrely on Reliable Automation***
Autopilots fit very clearly into the conception of a proper role for automation. Stabilizing an aircraft in the horizontal, vertical, and speed axes required extensive monitoring of these axes, a task for which humans are not well adapted, a finding which is well documented in the human factors research literature (Sheridan, 2002). Allocating this task to automation, then, should improve overall performance. For the tasks of stabilizing the axes of the aircraft, this is clearly true.

However, the humans would then have to monitor the automation, which was very reliable. Again, human vigilance is generally poor for such tasks. When such automation fails, the humans must detect and resolve the issues, problems that contributed to the L-1011 crash mentioned earlier. Research has led to the following principle:

***If Automation Has a Multiplicity of Modes, the Current Mode and Its Implications Should Be Transparent to the Operator***  The problem of mode confusion, as mentioned, is relatively recent. Generally, mode confusion occurs when the operator's

mental model is not coincident with the behavior of the system (Bredereke and Lankenau, 2005). In advanced, multimode automation, the operator must be provided with sufficient information to easily determine the mode in which the system is operating and must understand the consequences of being in that mode. Some of the mode problems that resulted in accidents were a consequence of subtle, easily confused cues as to the mode of the aircraft or even of opaque implications of being in a particular mode.

Better feedback alone, however, is generally not sufficient. In addition to having sufficient feedback, overcoming mode errors appears to involve training, workload management, and perhaps the use of multiple modalities (Sarter and Woods, 1995).

In general, although the problem is understood, the solution to the problem is not yet entirely clear. Complications in solving this problem include workload, vigilance, and the dynamic nature of mental models.

***Periods of Automatic Control Reduce the Operator's Situation Awareness***  Situation awareness (SA) refers to the pilot's knowledge of that information that is necessary for good performance. SA, whose measurement is discussed in a subsequent section, includes the knowledge of the status of important elements, knowledge of the meaning of that status, and knowledge of the future implications of that status (Endsley, 1995). SA has been extensively applied to aviation, where the concept has been discussed since the World War I (Hacker, 1984), although research on the topic did not occur until the 1980s.

The emphasis on situation awareness has grown in concert with the increase in information available to pilots and controllers and as automation further displaces the human operators from the work. As operators are removed from the task, they have been shown to lose situation awareness and performance declines (Endsley and Kiris, 1995). This tendency can be mitigated by either keeping the operator involved manually in the task or periodically allocating manual control to the operator.

#### 2.1.2  Information Automation and Systems

In addition to control automation, systems to support the information needs of pilots and controllers have been introduced. These include the provision of status information through single- and multiple-function displays and alerting systems.

One of the earliest problems to be considered by researchers involved information displayed on gauges. These issues included how to display the information, the arrangement of the displays, and whether to integrate information.

***Digital Displays Are Preferred When the Specific Reading Needs To Be Identified; When Precision Is Not Required, Fixed-Scale Displays with Moving Pointers Are Better***  Researchers have found that, when the precise numerical value is required from an instrument, digital displays are better than dial-type displays (Simmonds et al., 1981). In such cases, it is necessary to ensure that the display of the value

is of sufficient duration to allow the operator to read the value.

In other cases, dial-type displays are generally better. A number of subprinciples for these displays have been found (Sanders and McCormick, 1993), including that having the pointer move over a fixed scale is generally better than having the scale move against a fixed pointer unless the entire scale cannot be displayed; the movement should be consistent with the physical interpretation of the scale, such as vertical motion being presented on a vertical scale (Roscoe, 1968); multiple pointers on the same scale are generally not desirable and can result in reversal errors, as was the case with the altimeter-misreading accidents mentioned (Heglin, 1973); and for qualitative or check-reading instruments, where the precise value is not necessary, analog displays with the grouping and orientation designed to be consistent with a strong Gestalt, such as at the 9 or 12 o'clock position, produced the best performance (Dashevsky, 1964). Vertical scales are particularly effective for qualitative reading (Elkin, 1959), and performance can be enhanced by using color or coded markings that have intuitive meaning to the operator (Sabeh et al., 1958).

### Primary Flight Instruments Should Be Arranged in a "T" in the Center of the Pilot's Visual Field

A number of studies, primarily by Fitts, utilized eye tracking to determine where to position particular instruments. It was found that certain instruments, specifically the artificial horizon, the navigation display, the altimeter, and the airspeed indicator, were accessed the most, and best performance was obtained by positioning them directly in front of the pilot almost at eye level (Cole et al., 1954; Fitts et al., 1950). These studies led the Civil Aeronautics Board, whose name would later change to the FAA, to require a "basic T" arrangement for these instruments on all flight decks [Civil Aeronautics Board (CAB), 1953]. This original list included the vertical speed indicator and flight path deviation, which were later dropped from the list, although they still generally appear in the basic T arrangement.

### Place Related Information in Close Proximity to Allow for Easier Integration

Additional eye movement studies were conducted to examine whether certain pieces of information were "linked" or somehow related to one another. Information on separate instruments but which were closely related should be located next to one another whenever possible (Chapanis, 1959). Automation has since been developed roughly around this principle to help lay out instrument panels (Mendel and Sheridan, 1986; Pulat and Ayoub, 1979).

In general, locating information together when such information must be integrated is considered consistent with the "proximity compatibility principle" (Wickens and Carswell, 1995). In addition to locating related information proximally, the principle also covers cases in which the display has multiple, related pieces of information on it, such as the common integration of altitude and vertical speed on the same instrument. Multifunction displays are typically designed to be compatible with the proximity compatibility principle,

as one display usually only contains, on one screen, related information.

### MFDs Should Have Proper Organization and Minimal Depth

MFDs, although satisfying the proximity compatibility principle, could potentially suffer from poor organization (Seidler and Wickens, 1992). In addition, because the content of MFDs can be controlled manually or by computer, the display may have multiple pages (i.e., depth). If such a display is poorly organized, does not comply with usability guidelines, or has too much depth, the pilot could become lost while navigating the display pages (Allen, 1983; Francis, 2000; Schneiderman, 1998). Moreover, the operation of the display may require the pilot to have their head down, that is, not looking outside, which is generally considered poor practice.

### Operators May Not Be Able to Extract More Than Four to Six Distinct Pieces of Information from a Display

Miller (1956) roughly identified the number of objects one can keep in short-term memory as being approximately 7, although how to interpret this number has been the subject of some debate (Cowan, 2000), and clustering of related information can result in an apparently much larger set of information. When relating this to a pilot or controller's attention and processing of a visual scene, there is substantial debate, but it seems as if a similar number can be extracted (VanRullen and Koch, 2003).

The literature to support this principle is not settled. In general, operators likely quickly obtain a general but not detailed representation of a scene, then focus on specific items of interest (VanRullen and Thorpe, 2001). As each item of interest is focused on, its representation is suppressed in subsequent processing for a short period of time (Tipper and Driver, 1988).

### The Time Sequence of Operator Attention to Display Information Can Be Modeled as a Function of Expected Value, Including Salience, Effort, Expectancy, and Value

The factors that influence where attention is applied include size, color, and salience. A recent model applied to flight decks has found very good correspondence between predictions of areas of eye fixations and assessments of the salience and value of the information, of the effort needed to move to that fixation location, and the expectancy of what the pilot perceives is necessary (Horrey et al., 2006; Wickens et al., 2003).

### Minimize Clutter or Provide Decluttering Capabilities

While this may seem intuitive, some complexity has been identified with respect to the concept of clutter. In general, the response time of operators when given a stimulus that is "cluttered" by proximate non-stimulus items is longer than when the clutter does not exist (Eriksen and Eriksen, 1974). On displays with a great deal of information, pilots have been found to take longer to locate an item and may be unable to find items at all (Wickens, 2003). In addition, subjective ratings of complex instruments very often include criticisms of excessive clutter (Abbott et al., 1980).

However, clutter can come in more subtle forms. On an instrument, when given a particular task goal, one can identify "stimulus" versus nonstimulus items. However, it is, in general, difficult to know a priori how to categorize information in this way. In addition, operators have been found to be capable of extracting information effectively from extremely complex displays under some conditions (Landry et al., 2007).

HUDs represent an interesting case of clutter. On traditional instruments, additional symbology placed on the display can create clutter. On a HUD, either the symbology or the environmental information being viewed by the pilot through the HUD could be considered clutter. Research has suggested that this type of clutter does not affect pilot performance for nominal events (Levy et al., 1998; Ververs and Wickens, 1998) but may affect them for unexpected events (Wickens and Long, 1995).

***When Displaying Spatial Relationships, the Display Should Be Consistent with the Perceived Information in the Environment and Should Have Movement Consistent with a Person's Mental Model of the Motion of Elements in the System*** One of the concerns of instrument designers in the 1950s was related to the artificial horizon or "attitude indicator" (ADI). This instrument shows the orientation of the aircraft with respect to horizon, including the pitch and bank of the aircraft. (An example is shown in Figure 3.) Specifically, the instrument has a depiction of the horizon, with an overlay of aircraft wings.

Some designs for this instrument had a fixed earth depiction and the wings moved relative to that fixed earth, while others had fixed wings and the earth moved relative to the wings. These two depictions conflicted variously with the idea of either compatible motion or

**Figure 3** Attitude indicator.

pictorial realism, principles which had been developed for the general design of spatial instruments (Roscoe et al., 1981). While researchers found a compromise design and eventually demonstrated an improvement in performance using it (Beringer et al., 1975; Fogel, 1959), it was never implemented due to the strength of the legacy of the existing instruments. A number of accidents have been tied to this problem (Bryan et al., 1954; Roscoe, 1997b).

Also consistent with these principles is the idea that navigation problems are largely representational and they are more effectively solved by "distributing" some cognition to the environment. That is, some of the cognition needed to accomplish the task should be integrated into the display and not be required of the operator (Norman, 1993; Zhang and Norman, 1994). As such, good displays should eliminate the need for operators to perform complex calculations in their head. From this, one can understand why map-type displays are much more useful for navigation than instruments that only show relative position from a known location.

## 2.2 Performance

Operator performance is typically one of the primary measures for human factors researchers. As such, methods for evaluating, modeling, and predicting performance are extremely useful for system design and analysis.

### 2.2.1 Control-Theoretic Approaches

***Human Operators May Be Best Modeled as an Integrated Part of the System*** The mathematics of control systems and their reliability have advanced substantially over the decades since the first autopilot. Control theory allows for keen insight into the expected operating behavior of the system in which a feedback control system is embedded. The transfer functions of control systems provided an understanding of whether the system is *stable*, that is, that its outputs are always bounded for a given input.

In the 1950s and 1960s substantial effort was put into trying to determine the closed-loop transfer function of the pilot, such as is shown in Figure 4*a*. However, McRuer (McRuer and Graham, 1965) discovered that, while a general transfer function for the pilot could not be found, the transfer function for the pilot–aircraft system *combined*, as shown in Figure 4*b*, was fairly simple—the system, with the pilot controlling it, responded to an error by integrating the error with a certain amount of delay and gain.

While this result may not seem overly profound, the general concept is extremely important. As stated by Sheridan (Gerovitch, 2003):

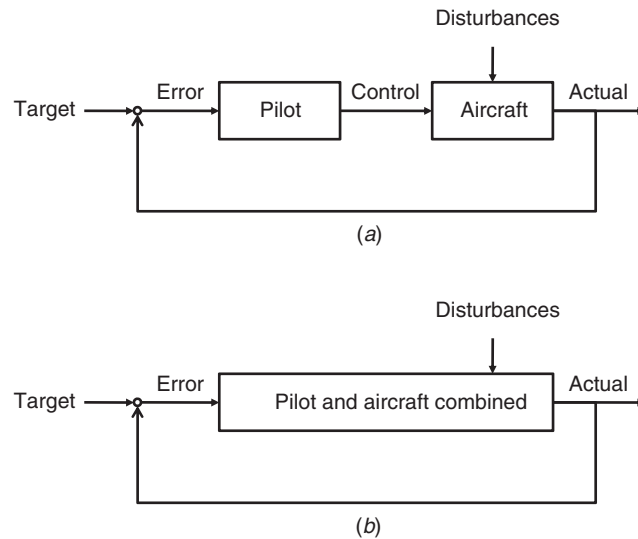
> In 1957–60, [a] man named Duane McRuer, got a bright idea that the human really was so adaptable that he or she could adapt to different types of dynamic systems, and the right way to model the human was to model the whole closed loop: the human and the airplane, or whatever system he was controlling, together as a single entity. This was a great insight.


**Figure 4** (*a*) Closed-loop system with pilot as controller; (*b*) closed-loop system with pilot embedded in system.

Subsequently, control theory was applied to more complex tasks than simply tracking one axis, as was done in the McRuer work. This led to "optimal control models" of human responses (e.g., Kleinman et al., 1970). These, however, were difficult to apply to realistic problems of any substantial complexity, and work along this track in aviation has not progressed significantly since the 1970s.

### 2.2.2 Alerting System Response

The number of alerting systems on board aircraft has steadily increased over the decades since the first retractable landing gear, which most likely precipitated the first alerting system, that for warning of the landing gear not being safely deployed or stowed. A number of principles have been developed over the years with respect to alerting systems.

***Alerts Can Be Set Based to Warn of Noncompliance, to Warn of Exceeding Some Threshold of Risk, or to Control Some Performance Metric*** A number of aviation alerting systems base an alert on deviation of the aircraft from its expected behavior, usually subject to some buffer. An altitude alert is an example of this type of alert, where descending below or climbing above the altitude set into an altitude command window results in a tone indicating the deviation.

Another type of alerting system monitors the projected behavior of the system and warns based on the prediction that a hazard would be encountered if the no control is applied to the system. In such cases, the alert is, by definition, probabilistic. If the hazard cannot be avoided, the alert is not useful. Therefore, some threshold must be set for the alert to occur. That threshold may be based on a trade-off between certainty and time to respond (Hu et al., 2002; Kuchar and Carpenter, 1997) or may be based on ensuring that some avoidance

maneuver is available (Teo and Tomlin, 2003). Because the system is probabilistic, there are false alarms, where the hazard would not have occurred had the alert not been given, missed detections, where the hazard did not sound but should have, and even induced hazards, where the hazard occurred only because the alert sounded.

Yang and Kuchar (2002) have suggested that alert thresholds can be set to control a specific performance indicator of the system, such as a minimum rate of missed detections or a maximum rate of false alarms. Such systems directly control the performance criteria of interest, rather than requiring them to be computed as is the case with other types of alerts.

***Excessive False Alarms Can Result in Disuse of the System*** Initial implementations of the Ground Proximity Warning System (GPWS), which warned of impending collision with the ground, were prone to false alarms. The alert would sound, even though the hazard did not exist. Moreover, there were a number of cases where the GPWS was ignored despite the hazard existing—a number of controlled flight into terrain (CFIT) accidents occurred as a result.

The incidence of CFIT, even with the GPWS alerting the crew, was troubling. Why would the crew ignore an alert that was informing them of probably the most hazardous situation?

One explanation was that the aircrews had lost their trust in the system due to the high rate of false alarms. That is, the system had "cried wolf" too often and it was no longer being listened to by the aircrew (Bliss et al., 1995). This effect has been found empirically to be affected by workload and the use of redundant information (Bliss and Dunn, 2000; Selcon et al., 1995).

### 2.2.3 Naturalistic Approaches

There is a belief among a number of human factors researchers that the behavior of the operator cannot be

extracted from the environment in which the operator is performing the task. That is, the person's behavior is inextricably linked to the specifics of the situation—it is embedded. Under such a view, the types of analyses, and even the units of analysis, change.

One such view holds that work is "situated" and that the work and how it is done will change and also that the use of the system will be altered by being present in the work environment (Suchman, 1987). In another view, decision making cannot be viewed abstractly from the exact conditions under which the decisions are made by the person, either due to framing issues (Gigerenzer and Goldstein, 1996) or due to the complexity of the environment (Klein et al., 1993). These views have been applied to aviation.

***Analysis of Work Should Contain an Appreciation for the Context in Which the Work Is Conducted*** There are sufficient safeguards built into aviation operations so that simple slips or lapses are unlikely to cause errors; instead, decision errors in aviation tend to be cases where the operator's intent itself is incorrect due to a mistaken interpretation of the environment. Such errors can be viewed in the context of naturalistic decision making, where a true understanding of the mistake can only be obtained by understanding the totality of the circumstances in which the pilot was immersed. Such problems have been found in a majority of cases where crew errors were a causal factor (Orasanu and Martin, 1998; Simpson, 2001).

### 2.2.4 Workload, Vigilance, and Situation Awareness

Workload and vigilance have been significant concerns in aviation since its inception. Situation awareness is a topic that has only been addressed more recently. General principles of workload, vigilance, and situation awareness, as applied to aviation, are presented here.

***Workload Should Be Kept at Moderate Levels for Best Performance*** For most complex tasks, performance has been shown to be poor at both low workload levels, where vigilance is low, and high workload levels, where the operator has difficulty in completing tasks (Hancock et al., 1995).

This simple guideline is effective but may be overly simple. Workload is a general term and has been shown to have somewhat independent aspects of mental workload and physical workload (Hart and Staveland, 1988). Perceptions of workload can also be influenced by time pressure and performance. Moreover, in aviation workload is often dynamic, with periods of high workload interspersed with periods of very low workload.

This latter concern is being addressed by the concept of adaptive or adaptable function allocation, where "adaptive" refers to function allocations controlled by automation and "adaptable" refers to function allocations controlled by the human operator. This concept is discussed further in Chapter 59.

***Crew Vigilance Is Poor for Monitoring Reliable Systems*** Failures of vigilance, particularly for

monitoring automation, have been found to be a significant source of aviation incidents (Malloy and Parasuraman, 1996). Moreover, such vigilance problems seem to occur on either end of the workload spectrum—too little workload or too much workload.

In general, however, research into vigilance has had little impact on the aviation system (Wiener, 1987). Aircrews continue to fail to monitor, such as a recent incident in which an aircraft overflew its destination by 150 miles before air traffic controllers could reach the aircrew on the radio. The crew was reportedly distracted and failed to notice they were not descending toward their destination.

This problem is still significant. Proposals for the next-generation system include substantially more automation and yet do not propose a specific task for the human operators. It is inferred that humans will monitor such automation, despite the findings regarding how poor humans are at such a task.

***Design to Maximize Situation Awareness*** Situation awareness, when viewed as a product of a process of situation assessment, is heightened when the operator is significantly involved in the task. Specifically, when human operators are asked to monitor automation performing a task instead of performing it themselves, their situation awareness suffers (Adams et al., 1995; Endsley and Kaber, 1999). This finding corresponds well to the idea that direct experiences result in deeper cognitive processing and are recalled more easily (Craik and Tulving, 2004).

One part of situation awareness relies on effective perception of information present in the environment. Reducing irrelevant information can improve such perception (Yeh et al., 2003). In addition, a thorough task analysis should be performed to ensure that the necessary information is available to the operator (Endsley et al., 2003; Kirwan and Ainsworth, 1992).

### 2.2.5 Flight Crew Interactions

Flight crews are essentially a team of individuals collaborating to enable the aircraft to reach its destination efficiently and safely. As with any team, the dynamics of interpersonal relationships can have a significant impact on performance.

***Although Ultimate Authority Rests with the Captain, All Flight Crews Should Feel Empowered to Identify Problems and Raise Concerns*** The principles of crew resource management, borne from accidents that may not have occurred if crew members had not deferred to the authority of the captain, insist on full participation of all crew members. Such principles can be particularly difficult to apply in cultures that value deference to authority but are critical to leveraging the expertise and simple redundancy of multiple crew members.

### 2.3 Fatigue and Circadian Rhythms

Aircraft on long flights typically cross numerous time zones, and both passengers and crew are exposed to an atmosphere equivalent in pressure to approximately

8000 ft altitude for nearly the entire duration of flight. These aspects mean that both passengers and crew members frequently suffer from fatigue and disruptions of their circadian rhythms.

The human sleep cycle is regulated by a number of factors, including internal brain processes and external factors such as lighting and the timing of meals. Inconsistencies between the expectations of the internal brain processes and these external factors can result in sleep disruptions, which in turn can result in fatigue.

Numerous remedies or mitigations have been suggested to treat the symptoms of these problems. A number of the factors known to help keep a regular circadian rhythm or to most quickly adjust a circadian rhythm include:

- Regular exercise
- A consistent routine
- Staying well hydrated
- Relaxation techniques such as meditation or reading
- Avoiding strenuous activity while your body adjusts to a new cycle
- Trying to remain exposed to sunlight during daylight hours and avoiding bright lighting at night
- Avoiding stimulants or depressants, such as caffeine or alcohol, if you know your sleep cycle will be disrupted
- Adjusting to the day–night hours as early as possible, including prior to leaving on the trip

In general, it is expected that, for each hour of time zone change, it will take about one day to adjust the internal clock. During the period of adjustment, fatigue is likely to occur. Fatigue has a number of effects on behavior and performance, including reduced vigilance, poor memory, scattered attention, and an increase in response time.

## 3 AIR TRAFFIC CONTROL HUMAN FACTORS

The job of air traffic controllers is highly manual. Their communication with each other and with pilots is through radio voice channels. They manually monitor a radar scope and project aircraft trajectories to detect potential problems. As a result, their performance has not been impacted by automation in the same way as it has for pilots, although under next-generation air traffic plans in Europe and the United States that may change.

### 3.1 Automating Air Traffic Control

As mentioned, air traffic control is highly manual. However, there are a few areas in which automation has been introduced. In general, controllers are, justifiably, highly conservative regarding changes to their displays and work practices, making the introduction of sophisticated automation difficult.

### 3.1.1 Radar

Prior to radar, controllers updated aircraft positions and projections of position on a status board. Using this information, they could identify aircraft whose projections of positions were in conflict. Under such a control scheme, the deconfliction task was primarily a comparison task, where the controller simply needed to compare the positions and note any flights expected to reach common points and the same, or nearly the same, time.

Radar altered this task substantially. The task was now primarily a visual comparison, requiring a projection of the flight path of an aircraft while incorporating knowledge of the intent of the aircraft. (Intent can be inferred from the flight plan and other information.)

### 3.1.2 Flight Strips

***Electronic Representations Are Generally Inferior to the Physical Artifacts They Are Expected to Replace: It Takes Substantial Effort to Create a Suitable Replacement*** After the advent of radar, flight information was kept on specifically formatted strips of paper, called "flight strips." Flight strips would store basic routing and identification information, along with notes made by controllers about the flight. It would be physically handled by the controller in charge of the flight and, if possible, physically passed to the next controller to take charge of the aircraft. An example is shown in Figure 5. Flight strips would be held in an ordered "strip bay."

As automation was added to the air traffic system in the 1960s and 1970s, printers for these strips were also added, but little else was automated. Much of the information was still hand-written on the flight strips, and they were still physically handled by controllers. This physical possession, which was a highly salient cue for who was responsible for the aircraft, proved difficult to replace (Harper and Hughes, 1991).

For controllers, their situation awareness, or "picture," of the air traffic is of paramount importance (Whitfield and Jackson, 1983). The manual handling of flight strips, including the writing of notes, enhances situation awareness. Mediated interaction does not seem to provide the same level of situation awareness and has been heavily resisted by some air traffic controllers.

Flight strips are still used by controllers today, although an automated system, called the "User Request Evaluation Tool" (URET), provides an electronic version of the flight strip (Arthur and McLaughlin, 1998) in the United States, with similar systems having been developed in Europe (Berndtsson and Normark, 1999). URET is used as a flight strip replacement tool. As new controllers, more comfortable with electronic technology, enter the profession, it is expected that manually printed and handled flight strips will be entirely phased out.

### 3.1.3 Conflict Alert

***Not All Alerting Systems with High False-Alarm Rates Result in Underreliance*** One of the few alerting systems available to controllers is the "conflict alert" system. This system projects aircraft trajectories

**Figure 5**  Flight strip example.

and warns when a procedural separation violation is expected to occur within 3 min. Because the system uses simple dead reckoning to predict future positions, and because of the 3-min look-ahead time, false alarms occur frequently. Despite the high false-alarm rate, controllers still rely on the automation, defying the "cry wolf" effect found in other alerting systems prone to false alarms (Wickens et al., 2009).

If the conflict alert notification is ignored or if it does not occur and aircraft lose separation, the "operational error detection program" (OEDP) alert occurs. The OEDP results in an automatic data dump of information related to the occurrence, and the supervisor is notified. Typically, the controller is immediately removed from the position and is kept away from controlling operational traffic until remedial training occurs. Controllers can be fired or reassigned due to having excessive operational errors. Because of the seriousness of the occurrence of such operational errors, controllers routinely pad separation between aircraft to ensure the OEDP does not activate (Cotton, 2003).

Both conflict alert and the OEDP are fairly old technology. URET, in addition to being a flight strip replacement system, also has a "conflict probe" capability that can predict conflicts along the intended route of flight. Such a system would be less prone to false alarms than the conflict alert system.

### 3.1.4  Traffic Management Advisor

In the early 1990s, the National Aeronautics and Space Administration (NASA) adapted algorithms used in an aircraft's flight management computer to simulate the trajectories of all aircraft in an en route center. The resulting suite of tools, called the Center-TRACON Automation System (CTAS), could generate a prediction of an aircraft's arrival at a given point along its route of flight based on its flight plan, models of the aircraft type, airspace restrictions, winds, and a number of other factors.

From this, expected times of arrival for aircraft at their destinations could be generated. By applying separation requirements, a schedule of aircraft arrivals could be computed to coordinate the arrival of aircraft at a given destination. That coordination would be accomplished by displaying, to each controller involved in the control of the arriving aircraft, the amount of delay that controller was responsible for imparting to the aircraft.

The resulting system is called the Traffic Management Advisor (TMA). After an extensive set of human factors analyses on TMA, the system is in place in the air traffic control system today (Lee et al., 2000). Similar systems have been developed worldwide (Barco Orthogon, 2003; Ljundberg and Lucas, 1992; Nav-Canada, 2003; Robinson et al., 1997).

### 3.2  Conflict Detection and Resolution

A controller's primary function is to separate aircraft according to procedural rules. These rules are designed to ensure that collisions do not occur between aircraft, but they rely heavily on a controller's capability to detect potential problems and resolve them without creating additional conflicts. It has been proposed that, in future systems, automation may be used for this function. Such a shift would have profound human factors implications for the system, implications which are not yet known.

### 3.2.1  Principles for Manual Detection and Resolution

Currently, the process of detecting and resolving conflicts by controllers is manual. They must mentally extrapolate the trajectories of aircraft into the future and predict when aircraft will lose separation. Controllers are extremely adept at this task, but not much is known about exactly how it is done.

***Controller Ability to Predict Conflicts Appears to Be Influenced by the Geometry of the Encounter and by Gestalt Effects***  A number of factors have been shown to influence the detection of conflicts. In one study, novices were found to be influenced by the visual "cluster" of the aircraft, where such clusters were influenced by Gestalt factors of the traffic display (Landry et al., 2001). Specifically, if two conflicting aircraft were in the same visual cluster, as indicated by a high degree of transitions between them as compared to other targets, then the novices were more likely to detect the conflict than if they were in different clusters.

The geometric arrangement of the aircraft also influences whether a conflicting pair will be detected successfully. Specifically, the following factors seem to affect conflict detection performance:

- Speed differences, with larger speed differences having a negative effect on detection (Rantanen and Nunes, 2005)
- Aircraft pairs with acute angles of incidence that are harder to detect than those with obtuse angles (Remington et al., 2000)
- Aircraft pairs that are further from the point of intersection of their flight paths and thus are harder to detect as conflicts (Stankovic et al., 2008)

In general, it is believed that controllers consider three general factors: altitude, where co-altitude aircraft represent a higher risk; convergence of the flight paths; and speeds, where similar speed and distance from the convergence point would represent a higher risk. In general, however, little is known about the psychological processes involved in the controller's conflict detection task (Neal and Kwantes, 2009).

### 3.2.2 Principles for Automating CD&R

The automation of conflict detection and resolution will be extremely challenging from a human factors standpoint. Concepts for such automation include a centralized system, where ground-based automation provides CD&R, a fully decentralized and distributed system, where aircraft provide CD&R, or some combination of these concepts.

***Flight-Deck-Based CD&R Must Overcome the Natural Competition of Aircraft from Different Airlines and Not Impose Substantial Workload on the Flight Deck*** Currently pilots are responsible for the safety of the flight, including the prevention of collisions. However, their capability to do so is limited to tactical avoidance using visual means or mediated by a collision avoidance system. The full deployment of CD&R to the flight deck would necessitate that strategic considerations of traffic be incorporated into the decision making on the flight deck. Currently aircraft from different airlines compete with one another, calling into question their ability to impartially resolve conflicts.

Of particular concern would be the additional workload imposed on the flight deck. During the cruise portion of flight, workload is relatively low and most of the surrounding traffic is in level flight, simplifying CD&R. However, during the climb and descent phases, workload is very high in the flight deck, and the pilots' ability to perform CD&R may be limited.

***Ground-Based CD&R Cannot Be Supervised by a Controller, But Instead Must Be Capable of Graceful Reversion to Manual Control*** Above about 1.5 times the current level of traffic, controller performance drops precipitously (Prevot et al., 2008a). Under ground-based CD&R, traffic would be expected to be substantially above this level. With the accompanying loss in situation awareness, it is unlikely that controllers could successfully monitor a ground-based CD&R system.

In the case of failure of a ground-based CD&R system, backup systems must be capable of moving the system gracefully, and without controller intervention, from the high level of traffic controlled by automation back down to the level of traffic at which the controller is capable of performing the function. Moreover, the controller must be brought back into the loop while this reversion is occurring.

***A Mixed CD&R Must Provide Clearly Delineated Lines of Responsibility and Authority*** In a mixed environment, controllers or ground-based automation would have responsibility for certain aspects of CD&R, while pilots or flight deck automation would have responsibility for other aspects. Similar to an operator's interaction with automation, the authority and expected behavior of the system must be clear to the operators to avoid gaps in perceptions of responsibility.

## 4 AVIATION MAINTENANCE AND SAFETY MANAGEMENT

Apart from "pilot error," a catch-all phrase that includes mistakes resulting from poor human–machine system design, maintenance errors have caused a substantial portion of serious accidents. Recently, there has been a surge of interest in the human factors of maintenance in aviation.

Overall, analysis of the safety of the system has been reactive. When accidents occur, an analysis is done to determine the cause of the accident and remedies are suggested. In the last several decades, aviation regulators have begun using voluntary, anonymous reporting systems such as the Aviation Safety Reporting System (ASRS) in the United States. Such systems track *incidents*, which are situations perceived as hazardous by air traffic controllers or aircrews, but which did not result in an accident. Incidents are considered precursors to accidents, so identifying safety problems based on incidents may prevent accidents from occurring.

### 4.1 Maintenance

In 1927, Brunat (1927) indicated that a substantial fraction of deaths (5%) and injuries (19%) were due to maintenance problems. This compares well with a 1994 report in which 12% of accidents were due to maintenance problems (Marx and Graeber, 1994). (That is not to say there has not been improvement but merely that the relative percentage of accidents caused by maintenance has not substantially changed.)

Maintenance workers must contend with a number of issues, including poor documentation and procedures, fatigue due to shift work, and teamwork issues. In addition, aircraft are complex systems, requiring substantial expertise, and typically maintainers are experts on only one portion of the system. One study of maintenance errors examined the prevalence of

a number of contributing factors: fatigue, pressure, coordination, training, supervision, previous deviation, procedures, equipment, environment, and physiological factors (Hobbs and Williamson, 2003), which was crossed with the type of error committed, such as slip, violation, and perceptual error. Pressure was the leading contributing factor, and the leading type of error was memory lapse. However, many of the contributing factors and types of errors had a substantial percentage of occurrences attributed to them. A more recent report has added "group norms" to the conditions that may contribute to errors (Hobbs, 2008).

In general, little work has been done on the human factors of maintenance work, despite its apparent importance.

### 4.2  Safety

One of the significant challenges in modernizing the air traffic system is the requirement that safety be maintained at extremely high levels. Accident rates, in the number of accidents per flight hour, are in the range of one in every million flight hours. Keeping such a high level of safety is difficult and is compounded by the difficulty in applying traditional engineering methods to complex human-integrated systems. Because of this, human error analysis methods have been developed, although they also suffer from specific weaknesses. The concept of system safety has been applied, although primarily to understanding accidents that have already occurred. Most recently, the FAA has adopted a reporting system called the "safety management system" (SMS) to help track safety problems and identify precursors to accidents so that they can be prevented.

#### 4.2.1  Reliability Methods

***Probabilistic Methods Do Not Produce Reliable Estimates of Safety in Complex Human-Integrated Systems Because the Distributions of Failures Are Not Known***   Many engineering systems undergo reliability analysis based on a probabilistic analysis of the chance of overall system failure based on aggregations of the likelihood of failures of components or subassemblies and the relationship between those components, subassemblies, and the overall system (O'Connor, 2002). That is, one identifies how the failure of individual components relates to the failure of subassemblies, how the failure of subassemblies relates to the failure of higher level subassemblies, and so on, until the probability of failure of the overall system is quantitatively established. Fault trees are a common method used, whereas more complex systems are modeled using such methods as Petri nets or Markov chains (Rauzy, 2008; Schoenig et al., 2006; Volovoi, 2004).

However, such systems are unlikely to produce good estimates of failures in complex human-integrated systems. One reason for this difficulty is that the probability distributions that describe human failings are not known and are likely to be complex and sensitive to minor environmental variation. Moreover, most probability-based methods require an understanding of the dependency of component failures and work best when the failures of components are independent. It is

likely that human failures are highly dependent on the functioning of other components in the system.

#### 4.2.2  Human Operator Error Analysis Methods

***Human Operator Error Analysis Methods Can Be Used to Trace the Consequences of Specific Errors in a Human-Integrated System***   Human operator error analysis methods include process hazard analysis, root cause and barrier analysis, and failure mode and effects analysis (Dhillon, 2007). These methods, which rely on enumerating the various failures that can occur within the system, are most effective when attempting to control the consequences of specific, known human errors. Given a particular type of error, these methods allow for a complete tracing of the error through the system to identify the effect of the system. They also allow for an analysis of specific measures that can be applied to mitigate the consequences of those errors.

However, in these methods, failure to comprehensively enumerate failures can result in significant analysis errors (Johnson, 2007). Moreover, it is impossible to know whether the enumeration used is complete—there are no formal methods for establishing the completeness of the enumeration.

Additional difficulty is encountered when trying to use enumeration methods for predicting the safety of modified or new systems. For such systems, it is difficult to enumerate failures, as it is likely that previously unencountered failures will occur. In safety-critical systems such as the air transportation system, it is typically these difficult-to-identify errors that result in accidents.

#### 4.2.3  System Safety

***Safety Can Be Viewed from a Systems Perspective as the Ability Of Human and Automated Agents to Keep the System from Entering Unsafe States***   An alternative approach to safety analysis is the notion of "system safety" (Leveson, 2004). This approach views safety as a control problem, where one must ensure that agents in the system have sufficient control to prevent the system from entering states that are considered unsafe.

The approach has been almost exclusively applied to accident analysis using the "Systems-Theoretic Accident Model and Processes" (STAMP) approach. This method deconstructs an accident in terms of the features that allowed the system to enter the unsafe state. These features may be related to operators, procedures, regulations, mechanisms, or any combination.

The strength of this approach is the systemic view. It is consistent with the embedded view of human behavior adopted by such methods as naturalistic decision making, and avoids seeking a root or principal cause that tends to oversimplify accident analysis.

However, the method is retroactive. There is as yet few examples of its application as a proactive tool for predicting safety (Landry et al., 2010).

#### 4.2.4  Safety Mangement System

In 2006, the FAA introduced the "safety management system" (SMS). SMS is a framework to capture data on, and manage, safety in the air traffic system. SMS is

a set of processes designed to allow for the accounting and control of risk in aviation. It integrates safety within the management structure of the FAA, providing insight and data for decision making as well as a structure for review and response to safety problems.

With the introduction of SMS, the FAA has formalized processes for establishing safety policies, for the review and management of risk, for continuously evaluating the safety of existing and proposed structures, and for promoting safety.

## 5  EMERGING ISSUES IN AVIATION

Change is being impressed on aviation, a system generally reluctant to change. Technology, such as remotely piloted vehicles and satellite navigation, has been developed that is likely to have significant consequences for the air traffic system. New methods are needed to understand the impact of these new technologies, so that they can be implemented and expand the capacity and capability of the air traffic system.

### 5.1  Remotely Piloted Vehicles

Remotely piloted vehicles (RPVs), also known as uninhabited aerial vehicles (UAVs), are increasing rapidly in number and variety. RPVs, currently used mainly for military and intelligence purposes, are also being considered for a wider range of tasks, including private commercial interests.

This increasing use of RPVs is bringing a number of human factors issues related to the vehicles to the forefront. These issues can be generally grouped into control issues, interface and function allocation issues, and air traffic issues. The first two issues have combined with the less stringent manufacturing requirements to result in a high mishap rate for RPVs, while the latter issue has been a strong impediment to wider usage of RPVs.

### 5.1.1  RPV Control Issues

The control of RPVs differs from that of a conventional aircraft primarily in that (a) the visual field is mediated and (b) there is no vestibular or haptic cueing. (In some cases, a time lag is also present.) These aspects significantly complicate the control of the vehicle by reducing the amount of information available to the operator of the vehicle.

The variety of vehicles complicates analysis in that there are numerous types of vehicles, with very different dynamics and with different control systems. However, the loss of vestibular and haptic cueing is a substantial loss with respect to controllability—pilots can no longer feel things such as the effect of engines failing, of ice accumulation, or of an approach to stall. The delay between the haptic or vestibular cueing a pilot would normally receive and the detection of visual indications of such conditions is significant and will often be the difference between preventing an accident or not.

The mediated visual field restricts field of view and diminishes depth perception. These aspects impair an operator's ability to control the vehicle, particularly upon landing, when peripheral cues are especially valuable.

Some RPVs are operated remotely from takeoff to landing, while others may be launched and recovered visually. (This is particularly true of small, tactical RPVs.) There are substantial differences in the control problems experienced by operators who can see the vehicle; in particular, they often suffer from control reversal problems depending on the orientation of the vehicle with respect to their position.

In a larger sense, there are issues about the level of control that is appropriate for RPVs. Some RPVs are controlled in a fully manual sense, where the pilot's control actions directly move the control surfaces of the vehicle. In other cases, the pilots essentially program the vehicle's trajectory and do not directly control the vehicle's control surfaces. Each of these strategies has advantages and disadvantages, and it is not yet known under what conditions each may be desirable.

### 5.1.2  RPV Interface Issues

RPV interfaces vary widely and, because they are fairly new, do not always use consistent symbology or comply with standard human factors guidance. RPV operators are working with human factors engineers to improve symbology and display elements. However, the capability of providing better visual information to the pilot is limited by the bandwidth of the communications channel connecting the operator's station with the vehicle.

In addition, it is expected that operators may eventually be controlling multiple RPVs, especially once these systems achieve sufficient autonomy. In such a case, RPV operators may become supervisors of multiple semi-independent systems, with the attendant human factors problems associated with such supervisory control.

### 5.1.3  RPVs in the Airspace System

Currently, operating an RPV within the airspace system requires substantial effort and forethought. A waiver must be obtained from the national airspace authorities in most countries, a process that can take a substantial amount of time.

The main reason for this caution is that most vehicles are expected to be able to operate in a predictable manner, and, when losing contact with air traffic control, to be able to remain visually separated from other vehicles. RPVs have no effective equivalent to visual operations when the radio link to the vehicle is compromised. In such cases, the behavior of the vehicle is not considered sufficiently predictable and could therefore pose a substantial hazard to commercial air traffic.

Until RPVs can demonstrate sufficient predictability, it is unlikely that they will be allowed easy access into the airspace system. Even in countries that have lowered some restrictions on RPVs, they have done so only for small vehicles, those weighing just a few pounds, which, even if they were to collide with a manned vehicle, would be unlikely to produce significant damage.

### 5.2  Free Flight

In the 1990s, as satellite-based navigation became possible, it was envisioned that aircraft may be able to fly any desired trajectory as long as they could keep themselves separated from other aircraft. The concept was

dubbed "free flight" and spawned substantial research into the human factors implications of such a concept (e.g., see Bilimoria et al., 2003; Cotton, 2003; Eby et al., 1999; Johnson et al., 1997; Yang and Kuchar, 1997).

It has largely become apparent that uncontrolled flight will not be possible, although it may be possible in portions of the airspace. In such cases, the responsibility for separation assurance will be "distributed" to the flight deck. However, the implications of such concepts are not well known and demand additional human factors analysis.

### 5.3 Automated Conflict Detection and Resolution: Roles and Responsibilities

One of the primary reasons for automating conflict detection and resolution is to overcome the limitation of the controller, who is capable of handling only about 12–15 aircraft within the volume of airspace for which they are responsible. By automating conflict detection and resolution, it is expected that substantially more aircraft could be managed in the same volume. However, controllers will not be capable of controlling the resulting system, which means that they cannot identify automation mistakes and could not take over for the system should it fail. This raises substantial questions about just what controllers would do in a system where the conflict detection and resolution system was automated.

A number of possible operational concepts have been proposed (Dwyer and Landry, 2009; Krozel et al., 2000; McNally and Gong, 2007; Prevot et al., 2008a, 2008b). However, none of these concepts define a specific allocation of function between automation and human based on human factors principles.

### 5.4 System of Systems

The airspace system is made up of a large number of heterogeneous agents who are collaborating, in the sense of sharing the same goal; cooperating, in the sense of working together but toward idiosyncratic goals; and competing, in the sense of having mutually exclusive goals. Moreover, each of these heterogeneous agents exist within a system that could be analyzed and understood separately from the entire air traffic system, such as each aircraft or each airline.

The methods of analysis used for such individual systems, including pilots and controllers, do not seem fully sufficient. In a system as complex as the air transportation system, there are emergent features that can only be understood by taking a systems view and examining the interaction between the heterogeneous agents. New methods are needed to truly understand the behavior and performance of the human agents within the system.

## 6 FUTURE CHALLENGES AND CONCLUSIONS

A substantial amount of human factors research has been applied to the aviation system. Early research work centered on issues of display form and organization, with later work dealing with higher level cognitive issues such as situation awareness and function allocation. Since the early days of aviation, flight decks and air traffic control systems have grown in complexity and capability. Human factors principles have been needed to guide design and ensure the safety of the system as it evolves.

The future appears to be one of an increasing pace of change. If the vision of the U.S. and European plans for the next-generation air traffic system is realized, the system of 2040 is likely to be substantially different than the system of 2010. In order for that vision to be achieved, human factors researchers and engineers must meet the challenge to identify the proper allocation of function in a highly automated system and develop ways to define the safety of the resulting system.
