The finding that the majority of the technicians that removed oxygen canisters from ValueJet airplanes as part of the overhaul of these aircraft were not SabreTech personnel is particularly relevant to this discussion as this work arrangement can easily produce an inadequately informed organizational culture. It is also not surprising that management would be insensitive to the implications of outsourcing on worker communication and task performance, and focus instead on the cost reduction benefits. As Peters and Peters (2006) note: "Outsourcing can be a brain drain, a quality system nightmare, and an error producer unless rigorously and appropriately managed" (p. 152).

Finally, any discussion on organizational culture, especially within the context of risk management, would be remiss not to include the idea of a *safety culture* (Reason, 1997; Vicente, 2004; Glendon et al., 2006). A number of the elements required for the emergence of a safety culture within an organization have already been discussed with regard to IRSs (Section 5.4). Reason cautions, however, that having all the necessary ingredients of a safety culture does not necessarily establish a safety culture, and the perception by an organization that it has achieved a respectable or first-rate safety culture is almost a sure sign that they

are mistaken. This warning is consistent with one of the tenets of resiliency: as stated by Pariès (2006), "the core of a good safety culture is a self-defeating prophecy."

### 6.1 *Columbia* Accident

The physical cause of the *Columbia* space shuttle accident in 2003 was a breach in the thermal protection system on the leading edge of *Columbia*'s left wing about 82 s after the launch. This breach was caused by a piece of insulating foam that separated from the external tank in an area where the orbiter attaches to the external tank. However, the *Columbia* Accident Investigation Board's (2003) report stated that "NASA's organizational culture had as much to do with this accident as foam did," that "only significant structural changes to NASA's organizational culture will enable it to succeed," and that NASA's current organization "has not demonstrated the characteristics of a learning organization" (p. 12).

To some extent NASA's culture was shaped by compromises with political administrations that were required to gain approval for the space shuttle program. These compromises imposed competing budgetary and mission requirements that resulted in a "remarkably capable and resilient vehicle," but one that was "less than optimal for manned flights" and "that never met any of its original requirements for reliability, cost, ease of turnaround, maintainability, or, regrettably, safety" (p. 11).

The organizational failures are almost too numerous to document: unwillingness to trade off scheduling and production pressures for safety; shifting management systems and a lack of integrated management across program elements; reliance on past success as a basis for engineering practice rather than on dependable engineering data and rigorous testing; the existence of organizational barriers that compromised communication of critical safety information and discouraged differences of opinion; and the emergence of an informal command and decision-making apparatus that operated outside the organization's norms. According to the *Columbia* Accident Investigation Board, deficiencies in communication, both up and down the shuttle program's hierarchy, were a foundation for the *Columbia* accident.

These failures were largely responsible for missed opportunities, blocked or ineffective communication, and flawed analysis by management during *Columbia*'s final flight that hindered the possibility of a challenging but conceivable rescue of the crew by launching *Atlantis*, another space shuttle craft, to rendezvous with *Columbia*. The accident investigation board concluded: "Some Space Shuttle Program managers failed to fulfill the implicit contract to do whatever is possible to ensure the safety of the crew. In fact, their management techniques unknowingly imposed barriers that kept at bay both engineering concerns and dissenting views, and ultimately helped create 'blind spots' that prevented them from seeing the danger the foam strike posed" (p. 170). Essentially, the position adopted by managers concerning whether the debris strike created a safety-of-flight issue placed the burden on engineers to prove that the system was unsafe.

Numerous deficiencies were also found with the Problem Reporting and Corrective Action database, a critical information system that provided data on any nonconformances. In addition to being too time consuming and cumbersome, it was also incomplete. For example, only foam strikes that were considered in-flight anomalies were added to this database, which masked the extent of this problem.

What is particularly disturbing was the failure of the shuttle program to detect the foam trend and appreciate the danger that it presented. Shuttle managers discarded warning signs from previous foam strikes and normalized their occurrences. In so doing, they desensitized the program to the dangers of foam strikes and compromised the flight readiness process. Although many workers at NASA knew of the problem, in the absence of an effective mechanism for communicating these "incidents" (Section 5.4), proactive approaches for identifying and mitigating risks were unlikely to be in place. In particular, a proactive perspective to risk identification and management could have resulted in a better understanding of the risk of thermal protection damage from foam strikes; tests being performed on the resilience of the reinforced carbon–carbon panels; and either the elimination of external tank foam loss or its mitigation through the use of redundant layers of protection.

## 6.2 Deepwater Horizon Accident

On April 20, 2010, an explosion occurred on the Deepwater Horizon, a massive oil exploration rig located about 50 miles south of the Louisiana coast in the Gulf of Mexico. The rig was owned by the drilling company Transocean, the world's largest offshore drilling contractor, and leased to the energy company British Petroleum (BP). This accident resulted from a blowout—an uncontrolled or sudden release of oil or natural gases—of an oil well located about a mile below the surface of the sea. The explosion and ensuing inferno resulted in 11 deaths and at least 17 injuries.

The rig sank to the bottom of the sea and in the process ruptured the pipes that carried oil to the surface, ultimately leading to the worst oil spill in U.S. (and probably world) history and causing significant economic and environmental damage to the Gulf region. Because the pressure at the well site is more than a ton per square inch, recovery from the failure needed to be performed remotely. At the conclusion of the writing of this chapter, which occurred on the 80th day of the oil spill, BP had finally appeared, following a series of highly publicized failed attempts, to successfully cap the leak streaming from the blown well. The evidence accumulated by this time seemed to indicate that it was a complex combination of factors that led to this accident.

In these rigs the first line of defense is the blowout preventer (BOP), a stack of equipment about 40 ft high that contains hydraulic valves designed to automatically seal the wellhead during an emergency. However, workers on the Deepwater Horizon were not able to activate this equipment. The failure of the fail-safe BOP has garnered a tremendous amount of attention as it represents the ultimate (and single) defense against onrushing oil and gas when an oil rig loses control of a well.

The key device in the BOP is the blind shear ram. In the event of a blowout, the blind shear ram utilizes two blades to slice through the drill pipe and seal the well. However, if one of the small shuttle valves leading to the blind shear ram becomes jammed or leaks, the ram's blades may not budge, and there is evidence that there was leakage of hydraulic fluid in one or more of the shuttle valves when the crew on the rig activated the blind shear ram (*New York Times*, 2010a).

This vulnerability to the fail-safe system was known within the oil industry and prompted offshore drillers, including Transocean, to add a layer of redundancy by equipping their BOPs with two blind shear rams. In fact, at the time of the Deepwater Horizon accident 11 of Transocean's 14 rigs in the Gulf had two blind shear rams, as did every (other) oil rig under contract with BP (*New York Times*, 2010a). However, neither Transocean nor BP appeared to take the necessary steps to outfit Deepwater Horizon's BOP with two blind shear rams. Transocean stated that it was BP's responsibility, based on various factors such as water depth and seismic data, for deciding on the BOP. BP's position was that both companies needed to be involved in making such a determination, as the decision entailed consideration of contractor preferences and operator requirements.

The problem with assuring the reliability of these devices appears to extend across the entire oil industry and includes the whole process by which federally mandated tests on BOPs are run and evaluated. One study that examined the performance of blind shear rams in BOPs on 14 new rigs found that 7 had not even been checked to determine if their shear rams would function in deep water, and of the remaining 7 only 3 were found to be capable of shearing pipe at their maximum rated water depths. Yet, despite this lack of preparedness in the last line of defense against a blowout, and even as the oil industry moves into deeper water, BP and other oil companies financed a study in early 2010 aimed at arguing against conducting BOP pressure tests every 14 days in favor of having these tests performed every 35 days, which would result in an estimated annual savings of $193 million in lost productivity (*New York Times*, 2010a).

Irrespective of whether these required government tests indeed provide reasonable guarantees of safety, the federal Minerals Management Services (MMS), which at the time served under the U.S. Department of the Interior, issued permits to drill in deepwater without assurances that these companies' BOPs could shear pipe and seal a well at depths of 5000 ft. These regulatory shortcomings, which came to light following the Deepwater Horizon accident, led Ken Salazar, Secretary of the Interior, to announce plans for the reorganization of the MMS "by separating safety oversight from the division that collects royalties from oil and gas companies" (*New York Times*, 2010b). (The MMS has since been renamed Bureau of Ocean Energy Management, Regulation and Enforcement.)

There were also a number of indicators in the months and weeks prior to the Deepwater Horizon

accident that the risks of drilling might exceed acceptable risk boundaries. The crew of the Deepwater Horizon encountered difficulty maintaining control of the well against "kicks" (sudden releases of surging gas) and had problems with stuck drilling pipes and broken tools, costing BP millions of dollars in rig rental fees as they fell behind schedule. Immediately before the explosion there were warning signs that a blowout was impending, based on preliminary evidence of equipment readings suggesting that gas was bubbling into the well (*New York Times*, 2010c). In fact, in the month before the explosion BP officials conceded to federal regulators that there were issues controlling the well, and on at least three occasions BP records indicated that the BOP was leaking fluid, which limits its ability to operate effectively. Although regulators (the MMS) were informed by BP officials of these struggles with well control, they ultimately conceded to a request to delay their federally mandated BOP test, which is supposed to occur every two weeks, until problems were resolved. When the BOP was tested again, it was tested at a pressure level 35% below the levels used on the device before the delay and continued to be tested at this lower pressure level until the explosion.

In April, prior to the accident, according to testimony at hearings concerning the accident and documents made available to investigators (*New York Times* 2010a, 2010b), BP took what many industry experts felt were highly questionable shortcuts in preparing to seal the oil well, including using a type of casing that was the riskier (but more cost-effective in the long term) of two options. With this option, if the cement around the casing pipe does not seal properly, high-pressure gases could leak all the way to the wellhead, where only a single seal would serve as a barrier. In fact, hours before the explosion, gases were found to be leaking through the cement that had been set by an oil services contractor (*New York Times*, 2010d).

BP has blamed the various companies involved in the sealing operation, including Transocean's oil rig workers, who BP claimed did not pump sufficient water to fully replace the thick buffer liquid between the water and the mud. This buffer liquid may have clogged the pipe that was used for the critical negative pressure tests needed to determine if the well was properly sealed. The resulting (and satisfying) pressure test reading of zero may have reflected a *false assumption error* arising from the failure to consider a side effect—in this case, that the reading was due to the pipe being plugged and not due to the absence of pressure in the well. Following the misinterpretation of these pressure tests, the rig workers began replacing drilling mud in the pipe to the seabed with water. The blowout and ensuing explosion occurred about 2 h later (*New York Times*, 2010a).

Because BP had hoped to use the Deepwater Horizon to drill in another field by March 8, there may have been incentives for them to proceed quickly, trading off thoroughness for efficiency (Section 6). By the day of the accident, BP was 43 days behind schedule, and based on the cost of $533,000 per day that BP was paying to lease the rig, this delay had incurred a substantial financial cost. However, accusations during hearings that many of the decisions by BP officials were intended to save BP money and time at the risk of catastrophe were denied by BP's chief executive officer (CEO), Tony Hayward, who repeatedly defended many of these decisions in testimony to the U.S. House of Representatives Energy and Commerce committee by indicating that they were approved by the MMS.

The changes in safety culture at BP that presumably came about under the leadership of Tony Hayward (who was appointed CEO in 2007), though laudatory, appeared to address mostly lower level system issues, such as exhorting workers to grasp banisters (*New York Times*, 2010e). BP's safety culture at the larger system level was apparently already set in place under Hayward's predecessor, John Browne, who had a reputation for pursuing potentially lucrative and technologically riskier ventures. Along the way there was BP's oil refinery explosion in Texas City, Texas, in 2005 in which 15 people died and 170 were injured. Organizational and safety deficiencies at all levels of BP were deemed the cause of the accident; subsequently, OSHA found more than 300 safety violations, resulting in a then record of $21 million in fines. OSHA inspectors revisited the plant in 2009 and discovered more than 700 safety violations and proposed an $87.4 million fine, mostly because of failures to correct past failures. A year after the Texas City explosion, BP was responsible for the worst spill on Alaska's North Slope, where oil leaked from a network of pipelines.

BP's near sinking of its offshore Thunder Horse platform was caused by a check valve that had been installed backward. Following costly repairs to fix the damage to that rig, more significant welding problems were discovered in the form of cracks and breaks in the pipes comprising the underwater manifold that connects numerous wells and helps carry oil back to the platform. It turns out that the construction of this production platform was severely rushed and, once at sea, hundreds of employees worked to complete it under severe time constraints while living in cramped chaotic conditions in temporary encampments aboard ships. Overall, this history of near misses, accidents, and problems did not appear to translate into lessons learned in the case of the Deepwater Horizon.

The label "organizational error" has sometimes been applied to companies that have experienced highly adverse or catastrophic outcomes that are linked to risky decisions influenced by financial incentives, scheduling setbacks, or other pressures. While some may object to this label, in reality this type of "error" is similar to that which might be committed by, for example, a physician who chooses to process more patients at the risk of increased carelessness in identifying and assessing critical patient information. With organizational error, however, it is group dynamics that play an important role, which can lead to flawed assessments of system vulnerabilities as these assessments can be easily biased by higher order goals such as the need for meeting deadlines (Haines, 2008). These assessments are also susceptible to behaviors such as coercion and intimidation that can prevail in group decision-making scenarios (Lehto and Buck, 2008).

As the many factors potentially related to the Deepwater Horizon accident are further examined for their authenticity and more details come to light, which decisions and incidents, or combinations thereof, that may have led to the accident will likely continue to be scrutinized. Lax federal regulation, pressure from shareholders, and the technological challenges of deepwater drilling will surely form the core of factors that played a role, but so will the role of the safety culture. The federal government may also need to rethink its strategies. The recent decision by the administration to open up more challenging offshore areas to drilling in the interest of increasing domestic oil production provides the incentive for aggressive oil companies to pursue riskier operations using "ultra-deep" platforms far more sophisticated than the Deepwater Horizon. Such government policies, however, put everyone at risk if there is no simultaneous effort to ensure appropriate regulatory oversight.

## 7 FINAL REMARKS

Human error remains a vast and intriguing topic. Some of the relatively recent interest in understanding and even predicting human error has been motivated by the possibility of finding its markings in the brain. For example, evidence from neuroimaging studies has linked an *error negativity*, an event-related brain potential, to the detection by individuals of action slips, errors of choice, and other errors (Nieuwenhuis et al., 2001; Holroyd and Coles, 2002), possibly signifying the existence of a neurophysiological basis for a preconscious action-monitoring system.

However, suggestions that these kinds of findings may offer possibilities for predicting human errors in real-time operations (Parasuraman, 2003) are probably overstated. Event-related brain potentials may provide insight into attentional preparedness and awareness of response conflicts, but the complex interplay of factors responsible for human error (Section 2.1) takes these discoveries out of contention as explanatory devices for most meaningful types of errors. Moreover, the practical utility of such findings is highly questionable given the complexity, and thus uncertainty associated with the actual environmental conditions in which humans operate as well as the uncertainty inherent in psychophysiological measures and their subsequent analyses (Cummings, 2010).

Often, one hears of the need for eliminating human error. This goal, however, is not always desirable. The realization that errors have been committed can play a critical role in human adaptability, creativity, and the manifestation of expertise. The elimination of human error is also inconceivable if only because human fallibility will always exist. Even if our attention and memory capabilities could be vastly extended, either through normal evolutionary processes or technological tampering, the probable effect would be the design and production of new and more complex systems that, in turn, would lead to more complex human activities with new and unanticipated opportunities for human error.

In no way, however, should such suppositions deter the goals of human error prediction, assessment, and reduction, especially in complex high-risk systems. As a start, system hardware and software need to be made more reliable; better partnerships between humans and automation need to be established; barriers that are effective in providing detection and absorption of errors without adversely affecting contextual and cognitive constraints need to be put in place; and IRSs that enable organizations to learn and anticipate, especially when errors become less frequent and thus deprive analysts with the opportunity for preparing and coping with their effects, need to become more ubiquitous.

Organizations also need to consider the adoption of strategies and processes for implementing features that have come to be associated with *high-reliability organizations* (Section 6). In particular, emphasis needs to be given to the development of cultures of reliability that anticipate and plan for unexpected events, try to monitor and understand the gap between work procedures and practice (Dekker, 2005), and place value in organizational learning.

The qualitative role of HRA in PRAs (Section 4) also needs to be strengthened. It is not hard to imagine a third generation of approaches to HRA that focuses more on ways of analyzing human performance in varying contexts and can more effectively assess the contribution of a wide variety of human–system interactive behaviors to the creation of hazardous conditions and system risks. These advances in HRA would depend on continued developments in methods for describing work contexts and determining the perceptions and assessments that workers might make in response to these contexts.

Where relevant, these methods also need to be integrated into the conceptual, development, and testing stages of the product and system design process. This would enable designers to become better informed about the potential effects of design decisions, thus bridging the gap between the knowledge and intentions of the designer and the needs and goals of the user.

Problems associated with performance failures in work operations have traditionally been "dumped" on training departments. Instead of using training to compensate for these problems, it should be given a proactive role through the use of methods that emphasize management of task activities under uncertainty and time constraints and the development of cognitive strategies for error detection (Kontogiannis and Malakis, 2009); give consideration to the kinds of cues that are necessary for developing situation awareness (Endsley et al., 2003) and for interpreting common-cause and common-mode system failures; and utilize simulation to provide workers with extensive exposure to a wide variety of contexts. By including provisions in training for imparting mental preparedness, people will be better able to anticipate the anomalies they might encounter and thus the errors they might make (Reason and Hobbs, 2003).

However, perhaps the greatest challenge in reducing human error is managing these error management processes (Reason and Hobbs, 2003)—defense strategies need to be aggregated coherently (Amalberti, 2001). Too

often these types of error reduction enterprises, innovative as they may be, remain isolated or hidden from each other.

# CHAPTER 27

# MANAGING LOW-BACK DISORDER RISK IN THE WORKPLACE

**William S. Marras**
**Biodynamics Laboratory**
**The Ohio State University**
**Columbus, Ohio**

## 1 INTRODUCTION

Low-back disorders (LBDs) resulting in low-back pain (LBP) are common experiences in life. Although LBDs appear to occur more frequently as one ages, it does not need to be an inevitable result of aging. There is also abundant information about the work related-ness of LBD. Both the physical as well as organizational/psychosocial aspects of work have independently been associated with higher rates of LBDs. At a superficial level these findings may appear to represent a paradox relative to LBD causality, and there has been significant debate about the contribution of work factors compared to individual factors in defining risk. However, for most of us these factors coexist and are for the most part inexplicably linked.

When one steps away from the opinionated motivations behind many of the causal claims, it is clear that there is both a natural degenerative impact of aging upon the spine that is capable of leading to pain for some people. However, this degenerative process can be greatly accelerated through work exposure, thus leading to greater incidences of LBDs at the workplace.

This line of thinking suggests that one can never totally eliminate the risk of LBD in the workplace since a natural or base rate of LBDs would be expected to occur due to individual factors such as heredity and aging. However, through the proper design of work it is possible to minimize the additional (and often substantial) risk that could be offered through workplace risk factors. Therefore, this chapter will focus primarily upon what we now know about the causal factors leading to LBDs and LBP as well as how the workplace can be assessed and designed to minimize its impact on contributing to this additional workplace risk. Hence, this chapter will concentrate primarily upon the preventive aspects of workplace design from an ergonomics standpoint.

The science of ergonomics is concerned primarily with *prevention*. Many large and small companies have permanent ergonomic programs (processes) in place and have successfully controlled the risk as well as the costs associated with musculoskeletal disorders [Government Accountability Office (GAO), 1997]. Ergonomic approaches attempt to alter the work environment with the objective of controlling risk exposure and optimizing efficiency and productivity. Two types of risk control (interventions) categories are used in the workplace. The first control category involves engineering controls that physically change the orientation of the

work environment relative to the worker. Engineering controls alter the workplace and create a "smart" work environment where the risk has been minimized so that the work–person interface is optimal for productivity and minimal for risk. The second category of control involves administrative controls that are employed when it is not possible to provide engineering controls. It should be understood that administrative controls do not eliminate the risk. They attempt to control risk by managing the time of exposure to the risk in the workplace and, thus, require active management. Administrative controls often consist of rotation of workers to ensure that workers have adequate time to recover from exposure to risks through appropriate scheduling of non–risk exposure tasks.

While ergonomics typically addresses all aspects of musculoskeletal disorders as well as performance issues, this chapter will be limited to issues and principles associated with the prevention of LBDs due to repetitive physical work (not including vibration).

## 2   MAGNITUDE OF LOW-BACK PAIN PROBLEM AT WORK

Since most people work, workplace risk factors and individual risk factors are difficult to separate [National Research Council (NRC), 2001]. Nonetheless, the magnitude of LBDs in the workplace can be appreciated via surveys of working populations. Within the United States back disorders are associated with more days away from work than any other part of the body [National Institute for Occupational Safety and Health (NIOSH), 2000; Jacobs, 2008]. A study of 17,000 working-age men and women in Sweden (Vingard et al., 2002) indicated that 5% of workers sought care for a new LBP episode over a three-year period. In addition, they reported that many of these LBP cases became chronic. Assessment of information gathered in the National Health Injury Survey (NHIS) found that back

pain accounts for about one-quarter of the workers' compensation claims in the United States (Guo et al., 1995). About two-thirds of these LBP cases were related to occupational activities. Prevalence of lost-work days due to back pain was found to be 4.6% (Guo et al., 1999).

Recent efforts through the Bone and Joint Decade effort (Jacobs, 2008) have evaluated the burden of low-back problems on U.S. workers. This assessment reports that about 32% of the population reports pain that limits their ability to do work and 11% of workers report pain that limits their ability to do any work. Within these categories, 62 and 63% of workers, respectively, report low-back dysfunction as the limiting factor responsible for their work limitations. When work limitation due to back pain was considered as a function of gender, we see that more females report slightly more back pain than males. As shown in Figure 1, back pain that limits work or prevents one from working occurs more frequently as a function of age up until 65–74 years of age and then deceases slightly over the age of 75.

Certain types of occupations have also reported significantly greater rates of LBP. Reported risk was greatest for construction laborers (prevalence 22.6%) followed by nursing aides (19.8%) (Guo et al., 1995). However, a recent literature review (Hignett, 2008) has concluded that the annual LBP prevalence in nurses is as high as 40–50%. Figure 2 shows a summary of the distribution of lost-time back cases in private industry as a function of the type of work and the source of the injury based upon a NIOSH analysis of work-related LBDs (NIOSH, 2000). This figure suggests that the service industry followed by manufacturing jobs accounts for nearly half of all prevalence for occupationally related LBDs. The figure also indicates that handling of containers and worker motions or position assumed during work are very often associated with LBDs in industry. Therefore, these data strongly suggest that occupational factors can be related to risk of LBDs.

**Figure 1**   Age distribution and its relationship to work limitations.
**Figure 2** (*a*) Number and distribution of back cases with days away from work in private industry by industry division during 1997 (NIOSH, 2000). (*b*) Number and distribution of back cases with days away from work in private industry by source of the disorder during 1997 (Jacobs, 2008).

## 3 EPIDEMIOLOGY OF WORK RISK FACTORS

Numerous literature reviews have endeavored to identify specific risk factors that may increase the risk of LBDs in the workplace. One of the first attempts at consolidating this information was performed by the NIOSH. In this critical review of the epidemiological evidence associated with musculoskeletal disorders (NIOSH, 1997) five categories of risk factors were evaluated. This evaluation suggested that strong evidence existed for an association between LBDs and lifting/forceful movements and LBDs and whole-body vibration. In addition, the evaluation concluded that there was significant evidence establishing associations between heavy physical work and awkward postures and back problems. Additionally, insufficient evidence was available to make any conclusions between static work postures and LBD risk.

Independent methodologically rigorous literature reviews by Hoogendoorn and colleagues (1999) were able to support these conclusions. Specifically, they concluded that manual materials handling, bending and twisting, and whole-body vibration were all significant risk factors for back pain.

Numerous investigations have attempted to assess the potential dose–response relationship among work risk factors and LBP. In particular, studies have been interested in the existence of an occupational "cumulative load" relationship with LBD. Two studies (Kumar, 1990; Norman et al., 1998) suggested the existence of such a cumulative load –LBD relationship in the workplace, although Videman et al. (1990) suggested that this relationship might not be a linear relationship. Videman et al. found that the relationship between history of physical loading due to occupation (cumulative load) and history of LBP was "J shaped" with sedentary jobs being associated with moderate levels of risk, heavy work being associated with the greatest degree of risk, and moderate exposure to loading being associated with the lowest level of risk (Figure 3). Seidler and colleagues (2001) have suggested a multifactor relationship with risk in that the combination of occupational lifting, trunk flexion, and duration of the activities significantly increased risk.

Recent studies have been able to identify risk with high levels of sensitivity and specificity when continuous dynamic biomechanical measures are employed (Marras et al., 2010b, 2010c). These efforts indicated that collective exposure to dynamic sagittal bending moments above 49 N-m, lateral trunk velocities greater than 84.1 deg/s, and exposure to the moment occurring after the midway point of the lift (more than 47.6% of the lift duration) yielded a sensitivity of 85% and a specificity of 87.5% in its ability to identify jobs resulting in reduced spine function.

Studies have also implicated psychosocial factors in the workplace as work risk factors for LBDs (Bigos et al., 1991; Bongers et al., 1993; Hoogendoorn et al., 2000; Karasek et al., 1998; van Poppel et al., 1998). Studies have indicated that monotonous work, high perceived work load, time pressure, low job satisfaction, and lack of social support were all related to LBD risk. Yet, the specific relationship with LBD appears to be unclear. Davis and Heaney (2000) found that the impact of psychosocial factors was diminished, although still significant, once biomechanical factors were accounted for in the study designs.

**Figure 3** Relationship between risk of LBP and work intensity exposure.

Several secondary prevention investigations of LBD have begun to explore the interaction between LBDs, physical factors, and psychosocial factors. Frank and colleagues (1996) as well as Waddell (1992, 1999) have concluded that much of LBP treatment is multidimensional. Primary prevention epidemiological studies have indicated that multiple categories of risk, such as physical stressors and psychosocial factors, play a role in LBD risk (Krause et al., 1998). Tubach and colleagues (2002) have reported that low social support at the workplace and bending at work were strongly associated with extended work absence due to LBP.

Perhaps the most comprehensive review of the epidemiological literature was performed by the National Research Council/Institute of Medicine (NRC, 2001). This assessment concluded that there is a clear relationship between LBDs and physical load imposed by manual material handling, frequent bending and twisting, physically heavy work, and whole-body vibration. Using the concept of attributable risk (attributable fraction), this analysis was able to determine the portion of LBP that would have been avoided if workers were not exposed to specific risk factors. As indicated in Table 1, the vast majority of high-quality epidemiological studies have associated LBDs with these risk factors and as much as two-thirds of risk can be attributed to materials handling activities. It was concluded that preventive measures may reduce the exposure to risk factors and reduce the occurrence of back problems.

## 4 OCCUPATIONAL BIOMECHANICS LOGIC

While epidemiological findings help us understand what exposure *factors* could be associated with work-related LBDs, the literature is problematic in that it cannot prescribe an optimal level of exposure in order to minimize risk. The previous section concluded that moderate levels of exposure are least risky for LBDs; however, we do not know what, precisely, constitutes moderate levels of exposure. The National Research Council/Institute of Medicine's (NRC, 2001) review of epidemiological evidence and LBDs states that "epidemiologic evidence itself is not specific enough to provide detailed, quantitative guidelines for design of the workplace, job, or task." This lack of specificity results from a dearth of the

**Table 1 Summary of Epidemiological Evidence with Risk Estimates (Attributable Fraction) of Associations with Work-Related Factors Associated with LBDs**

| Work-Related Risk Factor | Attributable Fraction (%) Range |
|---|---|
| Manual material handling | 11–66 |
| Frequent bending and twisting | 19–57 |
| Heavy physical load | 31–58 |
| Static work posture | 14–32 |

continuous exposure measures. Most epidemiological studies have documented workplace exposures in a binary fashion where they document if a specific threshold of exposure has been exceeded. For example, many studies document whether workers lift more than 25 lb or not. Without continuous measures, it is impossible to ascertain the specific "levels" of exposure that would be associated with an increased risk of LBDs (NRC, 2001). In addition, from a biomechanical standpoint, we know that risk is a much more complex issue. We need to understand the load origin in terms of distance from the body and height off the floor as well as the load destination location if we are to understand the forces imposed on the body through the lifting task. Defining risk is most likely multidimensional. Hence, in order to more fully understand "how much exposure is too much exposure" to risk factors, it is necessary to understand *how* work-related factors interact and lead to LBDs. Thus, causal pathways are addressed through biomechanical and ergonomic analyses. Collectively, the biomechanical literature as a whole provides specificity of exposure and a promising approach to controlling LBD risk in the workplace.

Biomechanical logic provides a logic structure to help us understand the mechanisms that might effect the development of a LBD. At the center of this logic is the notion that risk can be defined by comparing the load imposed upon a structure with the tolerance of that same structure. As shown in Figure 4*a*, McGill (1997) suggests that, during work, the structures and tissues of the spine undergo a loading pattern with each repeated job cycle. When the magnitude of the load imposed upon a structure or tissue exceeds the structural tolerance limit, tissue damage occurs. The tissue damage might be capable of setting off the sequence of events that could lead to LBD. With this logic, if the magnitude of the imposed load is below the structural tolerance, the task can be considered free of risk to the tissue. The magnitude of the distance between the structure loading and the tolerance can be thought of as a safety margin. On the other hand, if the load exceeds the tolerance, significant risk is present.

Biomechanics reasoning can also be employed to describe the processes believed to be at play during cumulative trauma exposure. When exposed to repetitive exertions, one would expect the tolerance to be subject to degradation over time (Figure 4*b*). Yet, as the work is performed repeatedly, we would expect that the loading pattern would remain relatively constant, whereas with overuse we would expect the tolerance limit to drop over time. This process would make it more probable that the tissue load exceeds the tissue tolerance and trigger a potential disorder.

## 5 BIOMECHANICS OF RISK

There are numerous pathways to the pain perception associated with LBDs. These pain pathways are the key to understanding how tissue loading results in LBP. In addition, if one appreciates how pain is related to the factors associated with tissue loading, then one can use
**Figure 4** Biomechanical load–tolerance relationships. (*a*) When the tolerance exceeds the load, the situation is considered safe with the distance between the two benchmarks considered a safety margin. (*b*) Cumulative trauma occurs when the tolerance decreases over time.

this knowledge to minimize the exacerbation of pain in workplace design. Thus, this knowledge forms the basis of ergonomics thinking. One can quantitatively target the limits above which a pain pathway is initiated as a tolerance limit for ergonomic purposes. Although these pathways have not been explicitly defined, designing tasks relative to these general principles is appealing since they represent biologically plausible mechanisms that are consistent with the injury association derived from the epidemiological literature.

Three general pain pathways are believed to be present for the spine that may affect the design of the workplace. These pathways are related to (1) structural and tissue stimulation, (2) physiological limits, and (3) psychophysical acceptance. It is expected that each of these pathways have different tolerances to the mechanical loading of the tissue. Thus, in order to optimally design a workplace, one must orient the specific tasks so that the ultimate tolerances within each of these categories are not exceeded.

## 5.1 Relationship between Tissue Stimulation and Pain

There are several structures in the back that when stimulated are capable of initiating pain perception. Both cellular and neural mechanisms can initiate and exacerbate pain perception. Several investigations have described the neurophysiological and neuroanatomical origins of back pain (Bogduk, 1995; Cavanaugh, 1995; Cavanaugh et al., 1997; Kallakuri et al., 1998; Siddall & Cousins, 1997b). These pathways involve the application of force or pressure on a structure that can directly stimulate pain receptors and can trigger the release of pain-stimulating chemicals.

Pain pathways in the low back have been identified for pain originating from the facet joints, disc, longitudinal ligaments, and sciatica. Facet joint pain is believed to be associated with the distribution of small nerve fibers and endings in the lumbar facet joint, nerves containing substance P (a pain-enhancing biochemical), high-threshold mechanoreceptors in the facet joint capsule,

and sensitization and excitation of nerves in the facet joint and surrounding muscle when the nerves were exposed to inflammatory biochemicals (Dwyer et al., 1990; Ozaktay et al., 1995; Yamashita et al., 1996). The pathway for disc pain is believed to activate through an extensive distribution of small nerve fibers and free nerve endings in the superficial annulus of the disc as well as in small fibers and free nerve endings in the adjacent longitudinal ligaments (Bogduk, 1991, 1995; Cavanaugh et al., 1995; Kallakuri et al., 1998). Sciatic pain is thought to be associated with mechanical stimulation of some of the spine structures. Moderate pressure placed on the dorsal root ganglia can result in vigorous and long-lasting excitatory discharges that could easily explain sciatica. In addition, sciatica might be explained through excitation of the dorsal root fibers when the ganglia are exposed to the nucleus pulposus. Stimulation and nerve function loss in nerve roots exposed to phospholipase A$_2$ could also explain the pain associated with sciatica (Cavanaugh et al., 1997; Chen et al., 1997; Ozaktay et al., 1998).

Studies are demonstrating the importance of proinflammatory agents such as tumor necrosis factor alpha (TNF$\alpha$) and interleukin-1 (IL-1) (Dinarello, 2000) in the development of pain. Proinflammatory agents are believed to upregulate vulnerability to inflammation under certain conditions and set the stage for pain perception. Thus, it is thought that mechanical stimulation of tissues can initiate this sequence of events and thus become the initiator of pain. It may be possible to consider the role of these agents in a load–tolerance model where tolerance may be considered the point at which these agents are upregulated. A preliminary study (Yang et al., 2010) has demonstrated that loads on spine structures due to occupational tasks are capable of initiating such a chemical reaction.

This body of work is providing a framework for a logical link between the mechanical stimulation of spinal tissues and structures and the sensation of LBP that is the foundation of occupational biomechanics and ergonomics.

## 5.2 Functional Lumbar Spinal Unit Tolerance Limits

Individual structure tolerances within lumbar functional spinal units are often considered, collectively, as part of the structural support system. The vertebral body can withstand fairly large loads when compressed, and since the end plate is usually the first structure to yield, the end-plate tolerance is often considered as a key marker of spine damage leading to pain. A review by Jager (1987) indicated the compressive tolerance of the end plate reported in the literature can be large (over 8 kN), especially in upright postures, but highly variable (depending greatly on age) with some specimens indicating failure at 2 kN. Damage to human vertebral cancellous bone often results from shear loading and the ultimate strength is correlated with tissue stiffness when exposed to compressive loading (Fyhrie and Schaffler, 1994). Bone failure typically occurs along with disc herniation and annular delamination (Gunning et al., 2001). Thus, damage to the bone itself appears

to often be part of the cascading series of events associated with LBP (Brinkmann, 1985; Kirkaldy-Willis, 1998; Siddall and Cousins, 1997b).

There are several lines of thinking about how vertebral end plate microfractures can lead to low-back problems. One line of thinking contends that the health of the vertebral body end plate is essential for proper mechanical functioning of the spine. When damage occurs to the end plate, nutrient supply is restricted to the disc and this can lead to degeneration of the disc fibers and disruption of spinal function (Moore, 2000). The literature supports the notion that the disruption of nutrient flow is capable of initiating a cascading series of events leading to LBP (Brinkmann, 1985; Kirkaldy-Willis, 1998; Siddall and Cousins, 1997a, 1997b). The literature suggests that the end plate is often the first structure to be damaged when the spine is loaded, especially at low load rates (Brinkmann et al., 1988; Callaghan and McGill, 2001; Holmes et al., 1993; Moore, 2000). Vertebral end-plate tolerance levels have been documented in numerous investigations. End-plate failure typically occurs when the end plate is subjected to compressive loads of 5.5 kN (Holmes et al., 1993). In addition, end-plate tolerances decrease by 30–50% with exposure to repetitive loading (Brinkmann et al., 1988) and suggests the disc is affected by cumulative trauma. The literature suggests that spine integrity can also be weakened by anterior–posterior (forward–backward) shear loading. Shear limit tolerance levels beginning at 1290–1770 N for soft tissue and 2000–2800 N for hard tissue have been reported for the spinal structures (Begeman et al., 1994; Krypton et al., 1995).

Load-related damage might also be indicated by the presence of Schmorls nodes in the vertebral bodies. Some have suggested that Schmorls nodes could be remnants of healed end-plate fractures (Vernon-Roberts and Pirie, 1973, 1977) and might be linked to trauma (Kornberg, 1988; Vernon-Roberts and Pirie, 1973).

Position or posture of the spine is also closely related to end-plate tolerance to loading. Flexed spine postures greatly reduce end-plate tolerance (Adams and Hutton, 1982; Gunning et al., 2001). In addition, trunk posture has been documented as an important consideration for occupational risk assessment. Industrial surveillance studies by Punnett et al. (1991), Marras et al. (1993a, 1995), and Norman and colleagues (1998) have all suggested that LBD risk increases when trunk posture deviates from a neutral upright posture during the work cycle.

It also appears that individual factors also influence end-plate integrity. Most notably, age and gender appear to greatly influence the biomechanical tolerance of the end plate (Jager et al., 1991) in that age and gender are related to bone integrity. Brinkmann et al. 1988 have demonstrated that bone mineral content and end-plate cross-sectional area are responsible for much of the variance in tolerance (within 1 kN).

There is little doubt that the disc can be subject to damage with sufficient loading. Disc herniations occur frequently when the spine is subject to compression and positioned in an excessively flexed posture (Adams and Hutton, 1982). In addition, repeated flexion, even under

moderate compressive loading conditions, can produce repeated disc herniations (Callaghan and McGill, 2001). Under anterior–posterior shear conditions avulsion of the lateral annulus can occur (Yingling and McGill, 1999a, 1999b). The torsion tolerance limit of the disc can be exceeded at loads as low as 88 N-m in an intact disc and 54 N-m in the damaged disc (Adams and Hutton, 1981; Farfan et al., 1970). When the spine is loaded in multiple dimensions simultaneously, risk also increases. The literature indicates that when the spine assumes complex spinal postures such as hyperflexion with lateral bending and twisting, disc herniation is increasingly likely (Adams and Hutton, 1985; Gordon et al., 1991).

Disc tolerance can also be associated with diurnal cycles or time of day when the lifting exposure occurs. Snook and associates (1998) found that flexion early in the day was associated with an increased risk of a LBP report. In addition, Fathallah and colleagues (1995) found similar results reporting that risk of injury was greater early in the day when disc hydration was at a high level. Therefore, the temporal component of risk associated with work exposure must be considered when assessing risk.

This brief review of the spine's tolerance limits indicated that the tolerance limits of the functional lumbar spinal unit vary considerably. Adams et al. (1993) describe a process where repeated vertebral microfractures and scarring of the end plate can lead to an interruption of nutrient flow to the disc. This process can result in weakening of the annulus that can result in protrusion of the disc into the surrounding structures. In addition, the weakened disc can result in spinal instability. The end plate and most of the inner portions of the annulus are not capable of sensing pain. However, once disc protrusion and/or disc instability occurs, loads are transmitted to the outer portions of the annulus and surrounding tissues. These structures are indeed capable of sensing pain. In addition, inflammatory responses can occur and nociceptors of surrounding tissues can be further sensitized and stimulated, thus initiating a sequence of events resulting in pain. Quantitative ergonomics approaches attempt to design work tasks so that spine loads are well within the tolerance limits of the spine structures.

While a wide range of tolerance limits have been reported for the functional lumbar spinal unit, most authorities have adopted the NIOSH lower limit of 3400 N for compression as the protective limit for most male workers and 75% of female workers (Chaffin et al., 1999). This limit represents the point at which end-plate microfracture is believed to begin within a large, diverse, population of workers. Similarly, 6400 N of compressive load represents the limit at which 50% of workers would be at risk (NIOSH, 1981). Furthermore, current quantitative assessments are recognizing the complex interaction of spine position, frequency, and complex spine forces (compression, shear, and torsion) as more realistic assessments of risk. However, these complex relationships have yet to find their way into ergonomic assessments nor have they resulted in best practices or standards.

## 5.3 Ligament Tolerance Limits

Ligament tolerances are affected primarily by load rate (Noyes et al., 1994). Avulsion occurs at low load rates and tearing occurs mostly at high load rates. Therefore, load rate may explain the increased risk associated with bending kinematics (velocity) that have been identified as risk factors in surveillance studies (Fathallah et al., 1998) as well as injuries from slips or falls (McGill, 1997). Posture appears to also play a role in tolerance. While loaded the architecture of the interspinous ligaments can result in significant anterior shear forces imposed on the spine during forward flexion (Heylings, 1978). This finding is consistent with field observations of risk (Marras et al., 1993a, 1995, 1993b, 2000b; Norman et al., 1998; Punnett et al., 1991). Field observations have identified 60 N-m as the point at which tissue damage is initiated (Adams and Dolan, 1995). Similarly, surveillance studies (Marras et al., 1993a, 1995) have identified exposures to external load moments of at least 73.6 N-m as being associated with greater risk of occupationally related LBP reporting. Also reinforcing these findings was a study by Norman and colleagues (1998), who reported nearly 30% greater load moment exposure in those jobs associated with risk of LBP. In this study, mean moment exposure associated with the back pain cases was 182 N-m of *total* load moment (load lifted plus body segment weights).

Spine curvature or lumbar lordosis may also affect the loading and tolerance of the spinal structures. Findings from Canadian researchers have demonstrated that when lumbar spinal curvature is maintained during bending the extensor muscles support the shear forces of the torso. However, when the spine (and posterior ligaments) are flexed during bending significant shear can be imposed on the ligaments (McGill et al., 1994; McGill and Norman, 1987; Potvin et al., 1991). The shear tolerance of the spine can be easily exceeded (2000–2800 N) exceeded when the spine is in full flexion (Krypton et al., 1995).

As with most living tissues, temporal factors play a large role in recovery of the ligaments. Solomonow and colleagues have found that ligaments require long periods of time to regain structural integrity. During this recovery period it is likely that compensatory muscle activities are recruited (Gedalia et al., 1999; Solomonow et al., 1998, 1999, 2000, 2002; Stubbs et al., 1998; Wang et al., 2000), and these muscle activities can easily increase spine loading. Required recovery time has been estimated to be several times the loading period duration and thus may easily exceed the typical work–rest cycles common in industry.

## 5.4 Facet Joint Tolerance

The facet joints are capable of supporting a significant portion of the load transmitted along the spinal column. Therefore, it is important to understand the tolerance limits of this structure. Facet joint failure can occur in response to shear loading of the spine. McGill and colleagues have reported that much of the tissues that load the facets are capable of producing significant horizontal forces and thus place these structures at risk

during occupational tasks (McGill, 2002). Crypton et al. (1995) estimate a shear tolerance for the facet joints of 2000 N. These findings are consistent with industrial observations indicating that exposure to lateral motions and shear loading was associated with an increased risk of LBDs (Marras et al., 1993a, 1995; Norman et al., 1998). In addition, laboratory-based studies confirm that exposure to high lateral velocity can result in significant lateral shear forces in the lumbar spine (Marras and Granata, 1997a).

Torsion can also load the facet joints to a failure point (Adams and Hutton, 1981). Exposure to excessive twisting moments, especially when combined with high-velocity motions, have been associated with excessive tissue loading (Marras & Granata, 1995; McGill, 1991; Pope et al., 1986, 1987). Field-based studies have also identified these movements as being associated with high-risk (for LBP) tasks (Marras et al., 1993a, 1995; Norman et al., 1998). The load imposed upon the spinal tissues when exposed to torsional moments also depends greatly upon the posture of the spine, with greater loads occurring when deviated postures (from neutral) are adopted (Marras and Granata, 1995). The specific structure loading pattern depends upon both the posture assumed during the task as well as curvature of the spine since a great amount of load sharing occurs between the apophyseal joints and the disc (Adams and Dolan, 1995). Therefore, spine posture dictates both the nature of spine loading as well as the degree of risk to the facet joints or the disc.

## 5.5 Adaptation

An important consideration in the interpretation of the load–tolerance relationship of the spine is that of adaptation. Wolff's law suggests that tissues adapt and remodel in response to the imposed load. In the spine, adaptation in response to load has been reported for bone (Carter, 1985), ligaments (Woo et al., 1985), disc (Porter et al., 1989), and vertebrae (Brinkmann et al., 1989). Adaptation may explain the observation that the greatest risk has been associated with jobs involving both high loads and low levels of spinal load, whereas jobs associated with moderate spine loads appear to enjoy the lowest levels of risk (Chaffin and Park, 1973; Videman et al., 1990). Hence, there appears to be an optimal loading zone for the spine that minimizes risk of exceeding the tolerance limit.

## 5.6 Psychophysical Limits as a Tolerance Threshold

Tolerance limits used in biomechanical assessment of tissue are typically derived from cadaveric testing studies. While these mechanical limits for tissue strength are probably reasonable for the analysis of tasks resulting in acute-trauma-type injuries, the application of cadaver-based tolerances to repetitive tasks is less logical. Repetitive loading must consider the influence of repeated weakening of the structure as well as the impact of tissue repair. Since adaptation is a key distinction in living tissue, quantitative analyses of the load–tolerance relationship under repeated loading become problematic. Highly dynamic tasks may be difficult to characterize

through quantitative biomechanical analyses and their injury pathway may be poorly understood. Hence, there is a dearth of biomechanical tolerance limit data that describe how living tissues respond to such repeated loading conditions.

In circumstances where mechanical tolerances are not known, an alternative approach to establishing tolerance limits has been to use the psychophysical limit as a tolerance limit. Psychophysics has been used as a means of strength testing where subjects are asked to progressively adjust the amount of load they can push, pull, lift, or carry until they feel that the magnitude of the force exertion would be acceptable to them over an 8-h work shift. Work variables included in such evaluations typically include measures such as lift origin, height, load dimensions, frequency of exertion, push/pull heights, and carrying distance. These variables are systematically altered to yield a database of acceptable conditions or thresholds of acceptance that would be tolerable for a specified range of male and female workers. These data are typically presented in table form and indicate the percentage of subjects who would find a particular load condition acceptable for a given task. Snook and colleagues are best known for publishing extensive descriptions of these psychophysical tolerances (Ciriello et al., 1990; Snook, 1978, 1985a, 1985b, 1987; Snook and Ciriello, 1991). Table 2 shows an example of such data for a pulling task.

Very few investigations have reported whether the design of work tasks using these psychophysical tolerance limits results in a minimization of LBP reports at work. However, one study by Snook (1978) has reported that low-back-related injury claims were three times more prevalent in jobs exceeding the psychophysically determined strength tolerance of 75% of men compared with jobs demanding less strength.

## 5.7 Physiological Tolerance Limits

Energy expenditure limits can also be used as tolerance limits for those jobs where physiological load limits the workers' ability to perform the work. These limits are associated with the ability of the body to deliver oxygen to the muscles. When muscles go into oxygen debt, insufficient release of adenosine triphosphate (ATP) occurs within the muscle and prolonged muscle contractions cannot be sustained. Therefore, under these extremely high energy expenditure work conditions, aerobic capacity can be considered as a physiological tolerance limit for LBP.

The NIOSH has established physiological criteria for limiting heavy physical work based upon high levels of energy expenditure (Waters et al., 1994). These criteria established an energy expenditure rate of 9.5 kcal/min as a baseline for maximum aerobic lifting capacity. Seventy percent of this baseline limit is considered the aerobic tolerance limit for work that is defined primarily as "arm work." Fifty percent, 40%, and 33% of the baseline energy expenditure have been designated as the tolerance limits for lifting task durations of 1, 1–2, and 2–8 h, respectively. While limited epidemiological evidence is available to support these limits, Cady and associates (1979, 1985) have demonstrated the

**Table 2** Example of psychophysical table used to determine the acceptable load an individual is willing to accept. The table indicates the maximum amount of pull force acceptable for males and females under various conditions. From Stover H. Snook and Vincent M Ciriello, The design of manual handling tasks; revised tables of maximum acceptable weights and forced, Ergonomics, 1991, Vol. 34, No. 9, 1197–1213.

importance of aerobic capacity limits associated with back problems for firefighters.

## 5.8  Psychosocial Pathways

A body of literature has attempted to describe how psychosocial factors might relate to the risk of suffering a LBD. Psychosocial factors have been associated with risk of LBP in several reviews (Bongers et al., 1993; Burton et al., 1995) and some researchers have dismissed the role of biomechanical factors as a causal factor (Bigos et al., 1991). However, few studies have appropriately considered biomechanical exposure along with psychosocial exposure in these assessments. A study by Davis and Heaney (2000) demonstrated that no studies have been able to effectively assess both risk dimensions concurrently.

More sophisticated biomechanical assessments (Davis et al., 2002; Marras et al., 2000c) have shown that psychosocial stress has the capacity to influence biomechanical loading. These studies demonstrate that individual factors such as personality can interact with perception of psychosocial stress to increase trunk muscle coactivation and subsequently increase spine loading. Therefore, these studies provide evidence that psychosocial stress is capable of influencing LBP risk through a biomechanical pathway.

## 5.9  Spine-Loading Assessment

A critical part of evaluating the load–tolerance relationship and the subsequent risk associated with work is an accurate and quantitative assessment of the loading experienced by back and spine tissues. The tolerance literature suggests that it is important to understand the specific nature of the tissue loading, including the dimensions of tissue loading such as compression force, shear force in multiple dimensions, load rates, positions of the spine structures during loading, and frequency of loading. Hence, *accurate and specific* measures associated with spine loading are essential if one is to use this information to assess the potential risk associated with occupational tasks.

Currently, it is not practical to directly monitor the loads imposed upon living spine structures and tissues while workers are performing a work task. Alternatively, indirect assessments such as biomechanical models are typically used to estimate tissue loads. The goal of biomechanical models is to understand how exposure to external (to the body) loads results in internal (to the body) forces that may exceed specific tolerance limits. External loads are imposed on the musculoskeletal system through the external environment (e.g., gravity or inertia) and must be countered or overcome by the worker in order to perform work. Internal forces are supplied by the musculoskeletal structures within the body (e.g., muscles, ligaments) that must supply counterforces to support the external load. However, since the internal forces are typically at a severe biomechanical disadvantage (relative to the external moment), these internal forces can be very large and result in large force applications on spine tissues. Since these internal forces are so large it is extremely important to accurately assess the nature of these loads in order to appreciate

the risk of a musculoskeletal disorder. Several biomechanical modeling approaches have been employed for these purposes and these different approaches often result in significant different trade-offs between their ability to realistically and accurately assess spine loading associated with a task and ease of model use.

Early models used to assess spine loading during occupational tasks needed to make assumptions about which trunk muscles supported the external load during a lifting task (Chaffin and Baker, 1970; Chaffin et al., 1977). These initial models assumed that a single "equivalent" muscle vector within the trunk could characterize the trunk's internal supporting force (and thus define spine loading) required to counteract an external load lifted by a worker. These crude models assumed that a lift could be portrayed as a static equilibrium lifting situation and that no muscle coactivation occurs among the trunk musculature during lifting. The models employed anthropometric regression relationships to estimate body segment lengths representative of the general population. Two output variables were predicted that could be used in a load–tolerance assessment of work exposure. One commonly used model output involved spine compression that is typically compared to the NIOSH-established compression limits of 3400 and 6400 N. A second model output was population static strength capacity associated with six joints of the body. Specifically lumbosacral (L5/S1) joint strength was used to assess overexertion risk to the back. This model evolved into a personal computer–based model and was used for general assessments of materials handling tasks involving slow movements (that were assumed to be quasi-static) where excessive compression loads were suspected of contributing to risk. An example of the model program output is shown in Figure 5. Early field-based risk assessments of the workplace have used this method to assess spine loads on the job (Herrin et al., 1986).

As computational power became more available, workplace biomechanical models were expanded to account for the contribution of multiple internal muscle reactions in response to the lifting of an external load. The assessment of multiple muscles resulted in models that were much more accurate and realistic. In addition, the spine tolerance literature was beginning to recognize the significance of three-dimensional spine loads as compared to purely compression loads in characterizing potential risk. The multiple-muscle biomechanical models were capable of predicting spine compression forces as well as spine shear forces.

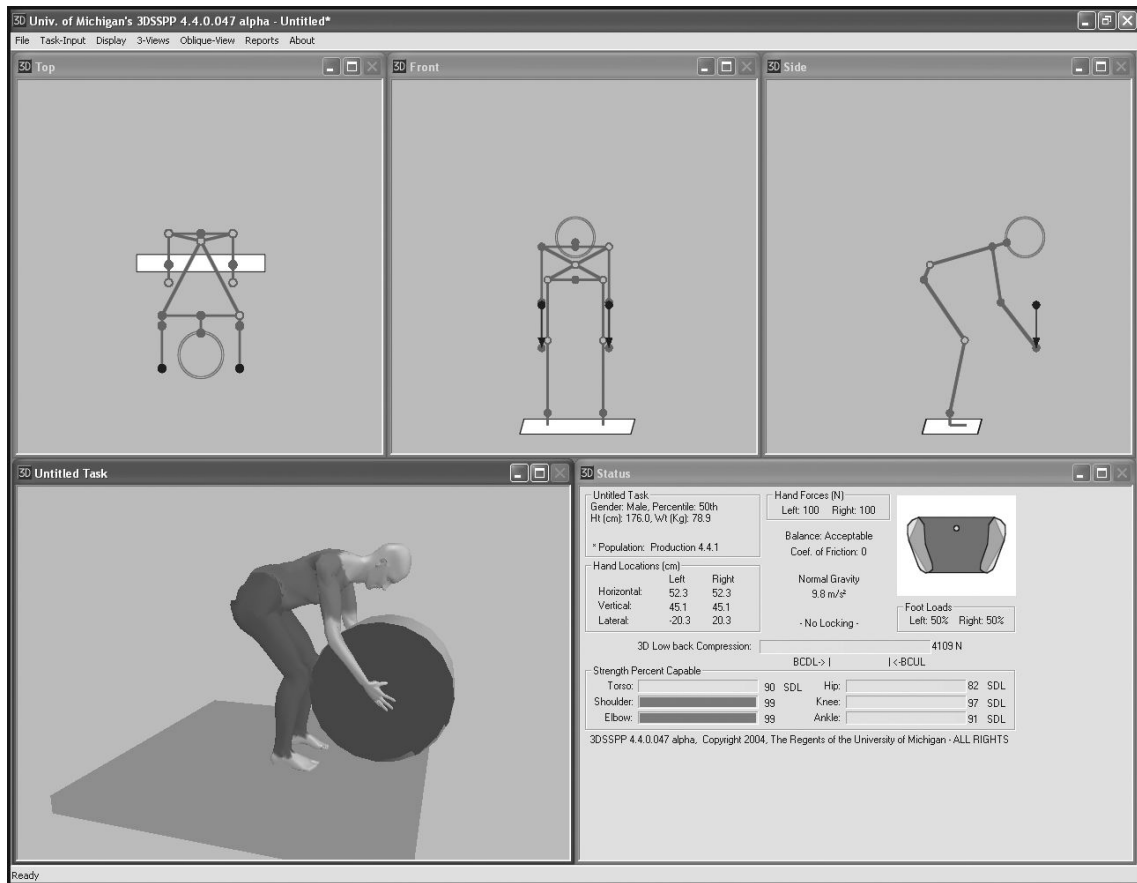
The first multiple-muscle system model was developed by Schultz and Andersson (1981). The model demonstrated how loads manipulated outside the body could impose large spinal loads upon the system of muscle within the torso due to the coactivation of trunk muscles necessary to counteract this external load. This model was able to predict asymmetric loading of the spine. Hence, the model represented an advancement in realism compared to previous models. However, the approach resulted in indeterminate solutions in that there were more muscle forces represented in the model than functional constraints available to uniquely solve


**Figure 5** Example of static strength prediction program used to assess spine load and strength requirements for a given task. (Courtesy of D. Chaffin.)

for the forces, so unique solutions were not apparent. Modeling efforts attempted to overcome this difficulty by assuming that certain muscles are inactive during the task (Bean et al., 1988; Hughes and Chaffin, 1995; Schultz et al., 1982). These efforts resulted in models that worked well for steady-state static representations of a lift but not for dynamic lifting situations (Marras et al., 1984).

Later efforts attempted to account for the influence of muscle coactivation upon spine loading under dynamic, complex lifting situations by directly monitoring muscle activity using electromyography (EMG) as an input to multiple-muscle models. EMG measures eliminated the problem of indeterminacy since specific muscle activities were uniquely defined through the neural activation of each muscle. Because of the use of direct muscle activity, these models were termed biologically assisted models. They were able not only to accurately assess compression and shear spine loads for a specific occupationally related movements (Granata and Marras, 1993, 1995a, 1999; Marras and Davis, 1998; Marras et al., 1998, 2001b; Marras and Granata, 1995, 1997b,

1997c; Marras and Sommerich, 1991a, 1991b; McGill, 1991, 1992a, 1992b) but also to predict differences among individuals so that variations in loading among a population could be evaluated (Granata et al., 1999; Marras et al., 2000c, 2000a, 2002; Marras and Granata, 1997a; Mirka and Marras, 1993) (Figure 6). These models were reported to have excellent external as well as internal validity (Granata et al., 1999; Marras et al., 1999c). The significance of accounting for trunk muscle coactivation when assessing realistic dynamic lifting was demonstrated by Granata and Marras (1995b). They found that not accounting for coactivation models could miscalculate spinal loading by up to 70%.

The disadvantage of biologically assisted models is that they require EMG recordings from the worker, which is often not practical in a workplace environment. Hence, many biologically assisted modeling assessments of the spine during work have been performed under laboratory conditions and have attempted to assess specific aspects of the work that may be common to many work conditions. For example, studies have employed EMG-assisted models to assess
**Figure 6** Biologically (EMG) assisted model used to evaluate spine loading during simulated work activities.

**Figure 7** Mean peak compression force as a function of lift asymmetry (clockwise (CW) vs. counterclockwise (CCW)) and hand(s) used to lift load. Results derived from EMG-assisted model simulation of tasks.

three-dimensional spine loading during materials handling activities (Davis and Marras, 2000; Davis et al., 1998a, 1998b; Marras and Davis, 1998; Marras et al., 2001b; Marras and Granata, 1997a). In addition, numerous studies have yielded information about various dimensions of lifting using biologically assisted models. Figure 7 illustrates the difference in spine compression as subjects lift with one hand verus two hands as a function of lift asymmetry (Marras and Davis, 1998). This assessment indicates that compressive loading of the spine is not simply a matter of load weight lifted. Considerable trade-offs occur as a function of asymmetry and the number of hands involved with the lift. Trade-offs among workplace factors were evaluated in a study

that assessed order-selecting activities in a laboratory setting (Marras et al., 1999d). Results from this study are shown in Table 3. This table highlights the interaction between load weight, location of the lift (region on the pallet), and presence of handles on spine compression (benchmark). The analysis indicates that all three factors influence the loading on the spine. Another study indicated the trade-offs between spine compressive and shear loads as a function of the number of hands used by the worker during the lift, whether both feet were in contact with the ground, lift origin, and height of a bin from which objects were lifted (Ferguson et al., 2002) (Table 4). Other studies have evaluated spine-loading trade-offs associated with team lifting

(Marras et al., 1999a), patient lifting (Table 5) (Wang, 1999), the assessment of lifting belts (Granata et al., 1997; Jorgensen and Marras, 2000; Marras et al., 2000d; McGill et al., 1990, 1994), and the use of lifting assistance devices (Marras et al., 1996). Efforts have also endeavored to translate these in-depth laboratory studies for use in the field through the use of regression models of workplace characteristics (Fathallah et al., 1999; McGill et al., 1996). In addition, biologically assisted models have been used to assess the role of psychosocial factors, personality, and mental processing on spine loading (Davis et al., 2002; Marras et al., 2000c).

In an effort to eliminate the need for biological measures (EMG) to assess muscle coactivity and subsequent spine loading, several studies have attempted to use stability as criteria to govern detailed biologically assisted biomechanical models of the torso (Cholewicki and McGill, 1996; Cholewicki et al., 2000b; Cholewicki and VanVliet, 2002; Granata and Marras, 2000; Granata and Orishimo, 2001; Granata and Wilson, 2001; Panjabi, 1992a, 1992b; Solomonow et al., 1999). This is thought to be important because a potential injury pathway for LBDs suggests that the unnatural rotation of a single spine segment may create loads on passive tissue or other muscle tissue that result in irritation or injury (McGill, 2002). However, nearly all of the work performed in this area to date has been directed toward static response of the trunk or sudden loading responses (Cholewicki et al., 2000a; Cholewicki et al., 2000b; Cholewicki and VanVliet, 2002; Granata and Orishimo, 2001; Granata et al., 2001; Granata and Wilson, 2001). Thus, these assessments may have limited value for the assessment of the most common workplace risk factors for LBP.

## 6 ASSESSMENT METHODS AND IDENTIFICATION OF LOW-BACK DISORDER RISK AT WORK

The logic associated with various risk assessment approaches has been described in previous sections. These approaches have been used to develop a rich body of literature that describes spine loading and subsequent risk in response to various work-related factors that are common to workplaces (e.g. one-hand vs. two-hand lifting). These studies can be used as a guide for the proper design of many work situations. However, there is still a need to assess unique work situations that may not have been assessed in these in-depth laboratory studies. High-fidelity spine-loading assessment techniques (e.g., EMG-assisted models) may not be practical for the assessment of some work situations since they require extensive instrumentation and typically require the task to be simulated in a laboratory environment. Therefore, tools with less precision and accuracy may be necessary to estimate risk to the spine due to the work. This section reviews the

methods and tools available for such assessments along with a review of the literature that supports their usage.

## 6.1 3DSSPP

The three-dimensional static strength prediction program (3DSSPP) has been available for quite some time. The logic associated with this approach was described previously. The computer program considers the load–tolerance relationship from both the spine compression and joint strength aspects. Spine compression is estimated with a linked segment–single equivalent muscle model and compared to the NIOSH-established compression tolerance limit of 3400 N.

Strength tolerance is assessed by estimating the joint load imposed by a task on six joints and comparing these loads to a population-based static strength database. This strength relationship has been defined as a lifting strength rating (LSR) and has been used to assess low-back injuries in industrial environments (Chaffin and Park, 1973). The LSR is defined as the weight of the maximum load lifted on the job divided by the lifting strength. The assessment concluded that "the incidence rate of low back pain (was) correlated (monotonically) with higher lifting strength requirements as determined by assessment of both the location and magnitude of the load lifted." This was one of the first studies to emphasize the importance of load moment exposure (importance of load location relative to the body in addition to load weight) when assessing risk. The study also found that exposure to moderate lifting frequencies appeared to be protective, whereas high or low lift rates were associated with jobs linked to greater reports of back injury.

One study used both the LSR and estimates of back-compression forces to observe job risk over a three-year period in five large industrial plants where 2934 material handling tasks were evaluated (Herrin et al., 1986). The findings indicated a positive association between the lifting strength ratio and back pain incidence rates. This study also found that musculoskeletal injuries were twice as likely when spine compression forces exceeded 6800 N. However, this relationship did not hold for low-back-specific incident reports. This study indicated that injury risk prediction was best associated with the most stressful tasks (as opposed to indices that represent risk aggregation).

## 6.2 Job Demand Index

Ayoub developed the concept of a sob severity index (JSI), which is somewhat similar to the LSR (Ayoub et al., 1978). The JSI is defined as the ratio of the job demands relative to the lifting capacities of the worker. Job demands include the variables of object weight (lifted), the frequency of lifting, exposure time, and lifting task origins and destinations. A comprehensive task analysis is necessary to assess the job demands in this context. Worker capacity includes the strength as well as the body size of the worker where strength is determined via psychophysical testing (as discussed earlier). Liles

and associates (1984) performed a prospective study using the JSI and identified a threshold of a job demand relative to worker strength above which the risk of low-back injury increased. These authors suggest that this method could identify the more high risk (costly) jobs.

## 6.3 NIOSH Lifting Guide and Revised Lifting Equation

The NIOSH has developed two lift assessment tools to help those in industry assess the risk associated with materials handling. The objective of these tools was to "prevent or reduce the occurrence of lifting-related low back pain among workers" (Waters et al., 1993). These assessments considered biomechanical, physiological, and psychophysical limits as criteria for assessing task risk.

The original tool was a guide to help define safe lifting limits based upon biomechanical, physiological, and psychophysical tolerance limits ((NIOSH, 1981). This method requires the evaluator to assess workplace characteristics. Based upon these work characteristics, the guide estimates that the magnitude of the load that must be lifted for spine compression reaches 3400 N [the action limit (AL)] and 6400N [the maximum permissible limit (MPL)]. From a biomechanical standpoint, the AL was defined as the spine compression limit at which damage just begins to occur in the spine in a large portion of the population. Based upon this logic, "safe" work tasks should be designed so that the load lifted by the worker is below the calculated AL limit. The AL is calculated through a functional equation that considers four discounting functions multiplied by a constant. The constant (90 lb, or 40 kg) is assumed to be the magnitude of the weight that, when lifted under ideal lifting conditions, would result in a spine compression of 3400 N. The four workplace-based discounting factors are (1) horizontal distance of the load from the spine, (2) the vertical height of the load off the floor, (3) the vertical travel distance of the load, and (4) the frequency of lifting. These factors are governed by functional relationships that reduce the magnitude of the allowable load (constant) proportionally according to their contribution to increases in spine compression. The MPL is determined by simply multiplying the AL by a factor of 3. If the load lifted by the worker exceeds the MPL, it is assumed that more than 50% of the workers would be at risk of damaging the disc. Under these conditions engineering controls would be required. If the load lifted is between the AL and the MPL values, then the task is assumed to place less than half the workers at risk. In this case, either engineering or administrative controls were permitted. If the load lifted is less than the AL, the task is considered safe. This guide was designed primarily for sagittally symmetric lifts that were slow (no appreciable acceleration) and smooth. Only one independent assessment of the guide's effectiveness could be found in the literature (Marras et al., 1999b). When predictions of risk were compared with historical data of industrial back injury reporting,

this evaluation indicated an odds ratio of 3.5 with good specificity and low sensitivity.

The most recent version of a NIOSH lifting guideline is known as the "revised NIOSH lifting equation" (Waters et al., 1993). The revised equation was developed with the intent of also including asymmetric lifting tasks as well as tasks with different types of coupling (handles) features in the assessment. The functional structure of the revised equation is similar in form to the 1981 guide in that it includes a load constant that mediates several work characteristic "multipliers." However, several differences are apparent between these two guides. First, the revised equation yields a recommended weight limit (RWL) (instead of an AL or MPL). If the magnitude of the load lifted by the worker is below the RWL, the load is considered safe. Second, the functional equation's load constant is reduced to 23 kg (51 lb) (from the 40 kg, or 90 lb, in the 1981 guide). Third, the functional relationship between the equation multipliers and the workplace factors is changed. Functionally, these relationships are slightly more liberal for the four factors in order to account for the lower value of the load constant. Fourth, two additional multipliers are included to account for task asymmetry and coupling. Once the RWL is calculated for a given workplace configuration, it is compared (as a denominator) to the load lifted by the worker to yield a lifting index (LI). If the LI is less than unity, the job is considered safe. If the LI is greater than 1, then risk is associated with the task. LI values above 3.0 are thought to place many of the workers at an increased risk of LBP (Waters et al., 1994). The equations that govern both the 1981 and 1993 versions of this guide are described in Chapter 12 of this handbook.

Two effectiveness studies have evaluated the revised equation. The first evaluation compared the ability of the revised equation to identify high- and low-risk jobs based upon a historical LBP reporting in industry (Marras et al., 1999b). This evaluation reported an overall odds ratio of 3.1. In-depth analyses indicated higher sensitivity than the 1981 guide but lower specificity. A second study assessed odds ratios as a function of the LI magnitude (Waters et al., 1999). LIs between 1 and 3 yielded odds ratios ranging from 1.54 to 2.45, suggesting increasing risk with increasing LIs. Conversely, when the LIs were over 3, the odds ratio was lower (odds ratio of 1.63), indicating a nonmonotonic relationship between the LI and risk.

## 6.4   Video-Based Biomechanical Models

Quantitative video-based assessments have been used to better understand the association of LBP risk with workplace factors. A study by Norman and colleagues (1998) employed a quasi-dynamic two-dimensional (2D) biomechanical model to evaluate cumulative biomechanical loading of the spine in 234 automotive assembly workers. The study identified four independent factors for LBP reporting. These factors consisted of integrated load moment (over a work shift), hand forces, peak shear force on the spine, and peak trunk velocity. The analysis found that workers exposed to the upper 25% of loading to all risk factors had about six times

more risk of reporting back pain than those exposed to the lowest 25% of loading.

### 6.4.1   Lumbar Motion Monitor Risk Assessment

The previously reviewed LBP risk assessment tools have not attempted to understand the role of motion in defining risk. We have known since the days of Sir Isaac Newton that force is a function of mass times acceleration. Hence, motion can have a very large influence on spine loading. Yet, most of the available assessment tools represent work tasks as static or quasi-static in their assessments.

The contribution of trunk dynamics combined with traditional workplace biomechanical factors contribution to LBP risk has been assessed by Marras and colleagues (1993a, 1995). These studies evaluated over 400 industrial jobs (along with documented LBD risk history) by observing 114 workplace and worker-related variables. Of the variables documented, load moment (load magnitude times distance of load from spine) exposure was identified as the single most powerful predictor of LBD reporting. The studies also identified 16 trunk kinematic variables that resulted in statistically significant odds ratios associated with risk of LBD reporting in the workplace. None of the individual kinematic variables were as strong a predictor as load moment. However, when load moment was considered in combination with three trunk kinematic variables (describing three dimensions of trunk motion) and an exposure frequency measure, a strong multiple logistic regression model that quantifies the risk of LBD risk (resulting from work design) was identified (odds ratio, O.R. = 10.7). This analysis indicated that risk was multidimensional in nature and that exposure to the combination of the five variables described LBP reporting well. This information was used to develop a functional risk model (Figure 8) that accounts for trade-offs between risk variables. As an example, a job that exposes a worker to a low magnitude of load moment can represent a high-risk situation if the other four variables in the model are of sufficient magnitude. Thus, the model is able to assess the interactions or collective influence of the risk variables. This model has been validated via a prospective workplace intervention study (Marras et al., 2000a). The risk model has been designed to work with a lumbar motion monitor (LMM) (Figure 9) and a computer program to document trunk motion exposure on the job.

When these conclusions are combined with the findings of epidemiological studies exploring the influence of nonneutral postures in the workplace (Punnett et al., 1991), a potential injury pathway is suggested. These studies indicate that as trunk posture becomes more extreme or the trunk motion becomes more rapid (during the performance of work) LBP reporting increases. From a biomechanical perspective, these results suggest that the occupational risk of LBD is associated with mechanical loading of the spine and indicates that when tasks involve greater three-dimensional loading the association with risk becomes much stronger.

Fathallah and associates (1998) evaluated data from 126 jobs to assess the complex trunk motions of groups
**Figure 8** Lumbar motion monitor (LMM) risk model. The probability of high-risk (LBP) group membership is quantitatively indicated for a particular task for each of five risk factors indicating how much exposure is too much exposure for a particular risk factor. The vertical arrow indicates the overall probability of high-risk group membership due to the combination of risk factors.

associated with varying degrees of LBP reporting. They found that groups with greater LBP reporting rates exhibited complex trunk motion patterns that consisted of high values of combined trunk velocities, especially

**Figure 9** LMM used to track trunk kinematics during occupational activities.

at extreme sagittal flexion. In contrast, the low-risk groups did not exhibit these patterns. This suggests that elevated levels of complex simultaneous velocity patterns along with key workplace factors (load moment and frequency) are correlated with increased LBP risk.

### 6.4.2 Dynamic Moment Exposure in the Workplace

Since earlier studies (Marras and Granata, 1995; Marras et al., 1993a) have shown that exposure to load moment is one of the best indicators of LBP reporting, a recent effort has investigated exposure to dynamic moment exposure and its relationship to decrements in low-back function. An ultrasound-based measurement device (Figure 10) was used to monitor dynamic load moment exposure in distribution center workers over extended periods throughout the workday (Marras et al., 2010a). This effort was able to precisely document the range of dynamic moment exposure associated with different types of work (Marras et al., 2010b). Assessment of these exposures relative to low-back function decrement risk indicated that lateral velocity along with dynamic moment exposure and timing of the peak load exposure allowed the identification of job characteristics leading to low-back dysfunction with excellent sensitivity and specificity (Marras et al., 2010c). This study demonstrates that with proper quantification of realistic (dynamic) task exposures and an appreciation for risk factor interactions, one can indeed identify the characteristics of jobs that lead to LBDs.

### 6.4.3 Workplace Assessment Summary

While there are many superficial reviews of the literature that have not been able to identify relationships between LBP and work factors, none of these studies have assessed quantitative studies of workplace exposure. Only with quantitative measures of the workplace can one assess "how much exposure is too much exposure." The studies described in this chapter are

**Figure 10** Moment monitor used to precisely measure exposure to dynamic load moments on the job.

insightful in that, even though some of these studies have not evaluated spinal loading directly, the exposure measures included can be considered indirect indicators of spinal load. Collectively these studies suggest that as the risk factors increase in magnitude the risk increases monotonically. While load location and strength limits both appear to be indicators of the risk to the spine, other exposure metrics (load location, kinematics, and three-dimensional analyses) are important from a biomechanical standpoint because they influence the ability of the trunk's internal structures to support the external load. Therefore, as these measures change, they can change the nature of the loading on the back's tissues.

These studies indicate that when biomechanically meaningful assessments are collected in the workplace associations between physical factors and risk of LBD reporting are apparent. Several common features of biomechanical risk can be identified from these studies. First, increasingly accurate LBP risk can be identified in the workplace when the specific load magnitude and location relative to the body (load moment) are quantified. Second, studies have demonstrated that increased reporting of LBP can be characterized well when the trunk's three-dimensional kinematic demands

due to work are described. Finally, these assessments have shown that LBP risk is multidimensional. There appears to be a synergy among risk factors that is often associated with increased reporting of LBP. Many studies have also suggested that some of these relationships are nonmonotonic. In summary, these efforts have suggested that the better the exposure characteristics are quantified in terms of biomechanical demand, the better one can assess the association with risk.

## 7 PROCESS OF IMPLEMENTING ERGONOMIC CHANGE

The literature demonstrated that there are interactions between biomechanical loading of the spine and psychosocial factors (Davis et al., 2002; Marras et al., 2000c). Consequently, one must not only address the physical aspects of the workplace but also consider the organizational environment. Ergonomic changes to the work environment must consider biomechanical loading as well as the psychosocial environment. The ergonomic process represents an excellent mechanism for accomplishing these dual goals. Ergonomic processes have been proven effective in introducing and accepting physical change in the workplace (GAO, 1997). Interventions can reduce workers' compensation costs if they are implemented correctly.

The ergonomics process is designed to address occupational health issues in a timely manner and establish an environment that makes the workers accepting of engineering interventions. Ergonomics processes were originally designed to control musculoskeletal disorders in high-risk meat-packing facilities [Occupational Safety and Health Administration (OSHA), 1993]. The objective of this approach is to develop a system or process to identify musculoskeletal problems before they become disabling and correct the features of the work. This is considered a process instead of a program because it is intended to become an ongoing surveillance and correction component of the business operation instead of a one-time effort.

The ergonomics process is intended to encourage communication between management and labor and working as a team to accomplish a common goal of worker health. In order to address the psychosocial environment in the workplace, a key component of the process is worker empowerment. Workers are expected to take an active role in the process and assume control and ownership of work design suggestions and changes. Thus, this process is based upon a participatory approach. Benefits of this approach include positive worker motivation, increased job satisfaction, and greater acceptance of change. The ultimate objective is to create a work environment where the success of the operation is the common goal as opposed to focusing on the interests of any given individual.

There are several common features of a successful ergonomics processes: management leadership and commitment, employee participation, job analysis resulting in injury prevention and control, training, medical management, program evaluation, and effort

documentation. The process is initiated with the creation of an ergonomics committee. Ideally, the committee should be constructed so that it has a balanced representation between management and labor. Committee members should include those involved with the layout of the work as well as those empowered to control scheduling. It is also important to include labor representatives on the committee as well as those employees who have broad experience with many of the jobs in the facility. Finally, it is often wise to include those employees who can communicate well with the majority of the work force as committee members. The ergonomics committee should be at the center of all ergonomic-related activities within the facility.

The ergonomics process can be thought of as a system where the different components of the system interact to produce the desired effect. The interactions among the system components are shown in Figure 11. As shown here, all activities interact in some way with the ergonomics committee to "drive" the process. The ergonomics process begins with management involvement. Ergonomic processes should be top down and therefore must be driven from the top. Management must establish and initiate the process and visibly demonstrate commitment to the process. Furthermore, commitment must be matched with resources made available to the committee. Resources should include not only financial resources so that physical interventions can be implemented but also access to information such as injury records and production schedules.

As shown in Figure 11, there are three fundamental functions of the ergonomics committee. First, the committee must monitor the workplace in order to identify where clusters of work-related LBDs are occurring. Surveillance techniques include monitoring of injury reports for LBP reporting as well as active surveillance of workers for symptoms of LBP. In order to make the effort proactive rather than reactive, it is important to solicit the cooperation of the workforce in this effort. Medical personnel can be recruited to help facilitate this effort by assisting the committee in the interpretation of LBP trends. The second function of the committee involves the control and prevention of work-related LBDs. The variety of techniques discussed earlier can be employed to help isolate and understand the underlying nature of the problems associated with the design of work. In this framework, the question of interest is often "how much exposure to risk factors is too much exposure?" Quantitative methods can be used to help determine which changes are necessary and to estimate their probable impact. As shown in Figure 11, it is important to involve an ergonomic expert in assisting the committee in performing these assessments. The third function of the committee involves the training and education of the workforce. Several levels of training are necessary within the process. All workers should receive awareness training to introduce them to the ergonomics process, familiarize them with LBP risk factors, and explain to them how low-back problems develop. All workers should receive training as to the types of symptoms that need to be reported to the committee in order to optimize prevention efforts. More detailed ergonomics training should also be made available to engineers and supervisors. The goal of the training should be to provide sufficient detail so that management understands the functioning of the process. If this is accomplished, they should not become an impediment to the process success.

Medical management specialists and ergonomics experts serve as resources to the committee within the ergonomics process framework. The goal is not to turn the ergonomics committee into ergonomics experts, but to encourage them to actively work with trained

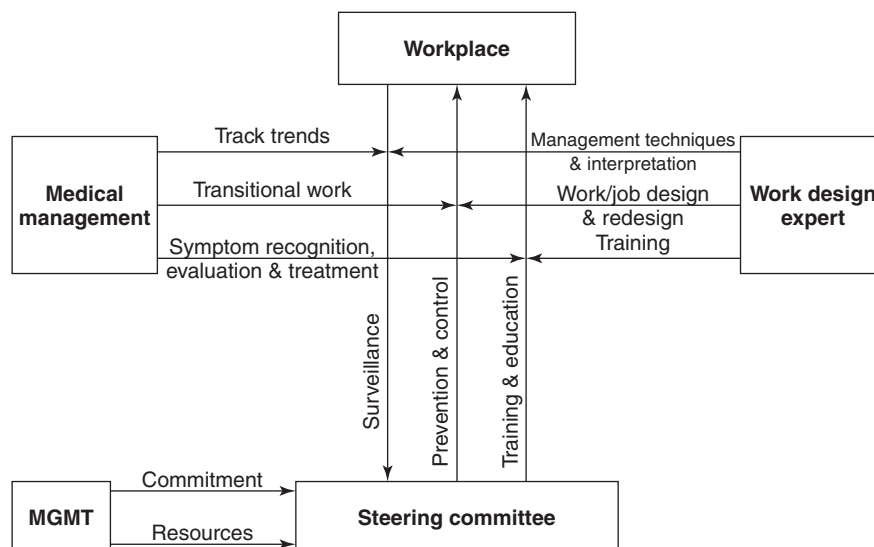

**Figure 11** Interaction of elements within an ergonomics process.

ergonomics experts to accomplish the objectives of the process.

It is essential that the process be evaluated periodically in order to justify its continuation. Metrics such as the achievement of program goals, reductions of LBD reports, hazard reduction, and employee feedback should be considered as indicators of process success. It is also important to recognize that the evaluation provides an opportunity to fine tune the process. All ergonomics processes need to be custom fit to the organization and thus fine tuning is essential. Finally, documentation is a critical part of a successful process. Records documenting the changes made to the workplace as well as their impact on LBDs can serve as justification for process expenditures. These records are also important for process history so that knowledge can be transferred to new team members.

The ergonomics process can have a significant impact on LBD risk, but only if the process is performed consistently and maintained adequately within the organization. Keys to process maintenance consist of strong direction, realistic and achievable goals, establishment of a system to address employee concerns, demonstration of early intervention success, and publicity for the intervention.

## 8  CONCLUSIONS

This chapter has demonstrated that LBDs are common at the work site and strongly linked with occupational tasks when risk factors such as manual materials handling, large moment exposure, bending and twisting, and whole-body vibration are present. The concept of the load–tolerance relationship represents a biomechanically plausible avenue to support the epidemiological findings regarding risk. Advanced biomechanical laboratory-based models have been developed that have been used to quantitatively assess and understand the risk associated with many work situations. There are also a host of workplace assessment tools available to assess risk directly at the work site; however, these tools must be used appropriately, recognizing their limitations. Workplace assessment tools have been shown to be most sensitive for minimizing risk to the low back if they consider multiple risk factors collectively, including load moment exposure and torso kinematic responses to work situations in three-dimensional space. The more precisely these job requirements can be quantified and assessed, the better the association with risk. Finally, the implementation of interventions to minimize risk to the low back must consider psychosocial issues within the workplace in order to foster worker acceptance. An ergonomics process can be useful for these purposes.

## 1 INTRODUCTION

### 1.1 Extent of Problem

The annual health and economic burden of work-related musculoskeletal disorders (WMSDs) in the United States was estimated at between $13 and $54 billion [National Institute for Occupational Safety and Health (NIOSH), 2001]. To adequately address the severity and burden of WMSDs, the NIOSH formed the National Occupational Research Agenda (NORA), which designated musculoskeletal disorders as one of its 21 priority research areas. Musculoskeletal disorders include nonfatal and/or nontraumatic injuries to the

upper extremity, neck, back, trunk, and lower extremity. The U.S. Bureau of Labor Statistics (BLS) reported a total of 335,390 cases, an incidence rate of 35.4, and median days away from work as 9 days in 2007 (Bureau of Labor Statistics, 2008, reissued in 2009). WMSD cases accounted for about one-third of 1.15 million cases of nonfatal injuries and illnesses involving days away from work in private industries. The BLS reported highest incidence rates in the following five occupations: (1) nursing aides, orderlies, and attendants; (2) emergency medical technicians and paramedics; (3) laborers and freight stock and material movers; (4) reservation and transportation ticket agents; and (5) light or delivery service truck drivers. According to the report, in 2007, days away from work declined by 21,770 cases while the incidence rate decreased by 8% from 2006. The survey utilized four characteristics—nature (e.g., sprain), part of the body (e.g., back), source (e.g., health care patient), and event of exposure (e.g., overexertion in lifting)—to characterize the cases of WMSDs.

## 1.2   Definitions

Sommerich et al. (2006) reviewed the definition of the umbrella term WMSD. According to Hagberg et al. (1995), the term *work-related musculoskeletal disorders* defines those disorders and diseases of the musculoskeletal system that have a proven or hypothetical work-related causal component. Musculoskeletal disorders are pathological entities in which the functions of the musculoskeletal system are disturbed or abnormal, whereas diseases are defined pathological entities with observable impairments in body configuration and function. Although work-related upper extremity disorders (WUEDs) are a heterogeneous group of disorders, and the current state of knowledge does not allow for a general description of the course of these disorders, it is possible nevertheless to identify a group of generic risk factors, including biomechanical factors, such as static and dynamic loading on the body and posture, cognitive demands, and organizational and psychosocial factors, for which there is evidence of work relatedness and a higher risk of developing WUEDs.

The generic risk factors, which typically interact and accumulate to form cascading cycles, are assumed to be directly responsible for pathophysiological phenomena which depend on location, intensity, temporal variation, duration, and repetitiveness of the generic risk factors (Hagberg et al., 1995). It was also proposed that both insufficient and excessive loading on the musculoskeletal system have deleterious effects and that the pathophysiological process is dependent on a person's characteristics with respect to body responses, coping mechanisms, and adaptation to risk factors. The generic risk factors, workplace design features, and pathophysiological phenomena are parts of the generic model for WUED prevention proposed by Armstrong et al. (1993) and demonstrated in later in this chapter in Figure 4.

## 1.3   Cumulative-Trauma Disorders of Upper Extremity

Since WMSDs are used as an umbrella term rather a diagnostic term, different regions of the world label

these disorders differently. For instance, WMSD is labeled as repetitive-strain injury (RSI) in Canada and Europe, both RSI and occupational overuse syndrome in Australia, and cumulative-trauma disorder (CTD) in the United States. Putz-Anderson (1993) defined CTD by combining the literal meaning of each word. *Cumulative* indicates that these disorders develop gradually over periods of time as a result of repeated stresses. The cumulative concept is based on the assumption that each repetition of an activity produces some trauma or wear and tear on the tissues and joints of the particular body part. The term *trauma* indicates bodily injury from mechanical stresses, whereas *disorders* refers to physical ailments. The definition above also stipulates a simple cause-and-effect model for CTD development. According to such a model, since the human body needs sufficient intervals of rest time between episodes of repeated strains to repair itself, if the recovery time is insufficient, combined with a high repetition of forceful and awkward postures, the worker is at higher risk of developing a CTD. In the context of the generic model for prevention proposed by Armstrong et al. (1993), the definition above is oriented primarily toward biomechanical risk factors for WUEDs and therefore is incomplete.

Ranney et al. (1995) pointed out that the evidence that chronic musculoskeletal disorders of the upper extremities are work related is growing rapidly. Several comprehensive reviews have examined multiple sources of evidence and data [Bernard, 1997; Viikari-Juntura and Silverstein, 1999; National Research Council (NRC), 2001; Buckle and Devereux, 2002]. Palmer and Smedley (2007) noted that most investigations suffer from such limitations as small sample size, confounding, incomplete blinding, and crude exposure assessment. Despite those limitations, they have found evidence of neck pain associated with work-related exposure. Another recent study by Harrington et al. (2009) found association between increase in job demand and upper extremity symptoms.

Previously, Armstrong et al. (1993) concluded that it was not possible to define the dose–response relationships and exposure limits for the WUED problems. To establish the work relatedness of these disorders, both the quantification of exposures involved in work and a determination of health outcomes, including details of the specific disorders (Luopajarvi et al., 1979; Moore et al., 1991; Stock, 1991; Hagberg, 1992), are needed. Also, more detailed medical diagnoses are required for choosing appropriate exposure measures as well as for structuring treatment, screening, and prevention programs (Ranney et al., 1995). However, due to recent development in valid and reliable construction of exposure assessment and quantification, a few studies were able to establish dose–response relationships. For example, recently, Engholm and Holmstrom (2005) found a location-specific dose–response relationship between work-related physical factors, that is, awkward posture and musculoskeletal disorders among construction workers. Another study by Sauni et al. (2009) on finish metal workers, by means of a questionnaire on exposure and symptoms, found a dose–response

relationship between the cumulative lifetime vibration dose of hand–arm vibration and finger blanching, sensorineural symptoms, symptoms of carpal tunnel syndrome, and musculoskeletal symptoms of upper limbs and neck.

## 2 CONCEPTS AND CHARACTERISTICS

### 2.1 Epidemiology

The World Health Organization (WHO, 1985) defines an *occupational disease* as a disease for which there is a direct cause–effect relationship between hazard and disease (e.g., silica-silicosis). Work-related diseases (WRDs) are defined as multifactorial when the work environment and the performance of work contribute significantly to the causation of disease (WHO, 1985). Work-related diseases can be partially caused by adverse work conditions. However, personal characteristics, environmental factors, and sociocultural factors are also recognized as risk factors for these diseases.

As reviewed by Armstrong et al. (1993) and summarized by Hagberg et al. (1995), Bernard (1997), and NRC (2001), evidence of the work relatedness of musculoskeletal disorders is established by the pattern supplied through numerous epidemiological studies conducted over the last 35 years of research in the field. The incidence and prevalence of musculoskeletal disorders in the reference populations of the studies were low but not zero, indicating that there are non-work-related causes of these disorders as well. Such variables as cultural differences and psychosocial and economic factors, which may influence one's perception and tolerance of pain and consequently affect the willingness to report musculoskeletal problems, may have a significant impact on the progressions from disorder to work disability (WHO, 1985; Leino, 1989). Descriptions of common musculoskeletal disorders and related job activities were summarized by Kroemer et al. (1994) and are given in Table 1.

### 2.2 Evidence of Work Relatedness of Upper Extremity Disorders

The WRDs of the upper extremity include, among others, carpal tunnel syndrome, tendonitis, ganglionitis, tenosynovitis, bursitis, and epicondylitis (Putz-Anderson, 1993). As reported in a recent BLS (Bureau of Labor Statistics, 2008) account, workers employed in nursing, emergency medicine, laborers and freight stock and material movers, reservation and transportation ticket agents, and light or delivery service truck drivers are at a high risk of developing WUEDs, having incidence rates between 117 and 252. Although the occurrence of WUEDs at work has been well documented (Hagberg et al., 1995), because of the high complexity of the problem, there is a lack of clear understanding of the cause–effect relationship characteristics for these disorders, which prevents accurate classification, implementation of effective control measures, and/or subsequent rehabilitation and return-to-work strategies. The problem may be confounded

by poor management–labor relationships and lack of willingness for open communication about the potential problems and how to solve them for the fear of legal litigation, including claims of unfair labor practices (Sommerich et al., 2006).

### 2.2.1 Definition of Risk Factors

Risk factors are defined as variables that are believed to be related to the probability of a person's developing a disease or disorder (Kleinbaum et al., 1982). Hagberg et al. (1995) classified the generic risk factors for development of WMSDs by considering their explanatory value, biological plausibility, and the relation to the work environment: These generic risk factors are (1) fit, reach, and see; (2) musculoskeletal load; (3) static load; (4) postures; (5) cold, vibration, and mechanical stresses; (6) task in invariability; (7) cognitive demands; and (8) organizational and psychosocial work characteristics. These WMSD risk factors are present at varying levels for different jobs and tasks. They are assumed to interact and to have an accumulative effect, forming the cascading cycles described by Armstrong et al. (1993), the extent and severity of which depends on their intensity, duration, and so on, meaning that the mere presence of a risk factor does not necessarily suggest that an exposed worker is at excessive risk of injury.

### 2.2.2 Biomechanical Factors

According to Armstrong et al. (1986), the following are categories of biomechanical risk factors for development of WUEDs: (1) forceful exertions and motions; (2) repetitive exertions and motions; (3) extreme postures of the shoulder (elbow above midtorso or reaching down and behind), forearm (inward or outward rotation with a bent wrist), wrist (palmar flexion or full extensions), and hand (pinching); (4) mechanical stress concentrations over the base of the palm, on the palmar surface of the fingers, and on the sides of the fingers; (5) duration of exertions, postures, and motions; (6) effects of hand–arm vibration; (7) exposure to a cold environment; (8) insufficient rest or break time; and (9) the use of gloves. Furthermore, wrist angular flexion–extension acceleration was also determined to be a potential risk factor for hand–wrist CTDs under conditions of dynamic industrial tasks (Marras and Schoenmarklin, 1993; Schoenmarklin et al., 1994). More recently, comprehensive reviews of epidemiological and experimental studies of work-related MSDs have concluded that there is sufficient evidence of associations between physical exposures in the workplace and MSDs (Bernard, 1997; Viikari-Juntura and Silverstein, 1999; NRC, 2001; Buckle and Devereux, 2002; Larsson et al., 2007). Conclusions from the reviews by Bernard (1997) and NRC (2001) are summarized in Tables 2 and 3, respectively. Tables 4 and 5 present a summary of work-related postural risk factors for wrist and shoulder disorders.

Inadequate design of tools with respect to weight and size can impose extreme wrist positions and high forces on a worker's musculoskeletal system (Armstrong et al., 1993). For example, holding a heavier object requires increased power grip and high tension in the finger flexor

**Table 1 Common WMSDs**

| Disorder[a] | Description | Typical Job Activities |
|---|---|---|
| Carpal tunnel syndrome (writer's cramp, neuritis, median neuritis) (N) | The result of compression of the median nerve in the carpal tunnel of the wrist. This tunnel is an opening under the carpal ligament on the palmar side of the carpal bones. Through this tunnel pass the median nerve and the finger flexor tendons. Thickening of the tendon sheaths increases the volume of tissue in the tunnel, thereby increasing pressure on the median nerve. The tunnel volume is also reduced if the wrist is flexed or extended or ulnarly or radially pivoted. | Buffing, grinding, polishing, sanding, assembly work, typing, keying, cashiering, playing musical instruments, surgery, packing, housekeeping, cooking, butchering, hand washing, scrubbing, hammering |
| Cubital tunnel syndrome (N) | Compression of the ulnar nerve below the notch of the elbow. Tingling, numbness, or pain radiating into ring or little fingers. | Resting forearm near elbow on a hard surface and/or sharp edge, also when reaching over obstruction |
| DeQuervain's syndrome (or disease) (T) | A special case of tenosynovitis which occurs in the abductor and extensor tendons of the thumb, where they share a common sheath. This condition often results from combined forceful gripping and hand twisting, as in wringing clothes. | Buffing, grinding, polishing, sanding, pushing, pressing, sawing, cutting, surgery, butchering, use of pliers, "turning" control such as on a motorcycle, inserting screws in holes, forceful hand wringing |
| Epicondylitis ("tennis elbow") | Tendons attaching to the epicondyle (the lateral protrusion at the distal end of the humerus bone) become irritated. This condition is often the result of impacts of jerky throwing motions, repeated supination and pronation of the forearm, and forceful wrist extension movements. The condition is well known among tennis players, pitchers, bowlers, and people hammering. A similar irritation of the tendon attachments on the inside of the elbow is called medical epicondylitis, also known as "golfer's elbow." | Turning screws, small parts assembly, hammering, meat cutting, playing musical instruments, playing tennis, pitching, bowling |
| Ganglion (T) | A tendon sheath swelling that is filled with synovial fluid or a cystic tumor at the tendon sheath or a joint membrane. The affected area swells up and causes a bump under the skin, often on the dorsal or radial side of the wrist. (Since it was in the past occasionally smashed by striking with a Bible or heavy book, it was also called a "Bible bump.") | Buffing, grinding, polishing, sanding, pushing, pressing, sawing, cutting, surgery, butchering, use of pliers, "turning" control such as on a motorcycle, inserting screws in holes, forceful hand wringing |
| Neck tension syndrome (M) | An irritation of the levator scapulae and the trapezius muscle of the neck, commonly occurring after repeated or sustained work. | Belt conveyor assembly, typing, keying, small parts assembly, packing, load carrying in hand or on shoulder, overhead work |
| Pronator (teres) syndrome | Result of compression of the median nerve in the distal third of the forearm, often where it passes through the two heads of the pronator teres muscle in the forearm; common with strenuous flexion of elbow and wrist. | Soldering, buffing, grinding, polishing, sanding |
| Shoulder tendonitis (rotator cuff syndrome or tendonitis, supraspinatus tendonitis, subacromial bursitis, subdeltoid bursitis, partial tear of the rotator cuff) (T) | The rotator cuff consists of four muscles and their tendons that fuse over the shoulder joint. They medially and laterally rotate the arm and help to abduct it. The rotator cuff tendons must pass through a small bony passage between the humerus and the acromion with a bursa as cushion. Irritation and swelling of the tendon or of the bursa are often caused by continuous muscle and tendon effort to keep the arm elevated. | Punch press operations, overhead assembly, overhead welding, overhead painting, overhead auto repair, belt conveyor assembly work, packing, storing, construction work, postal "letter carrying," reaching, lifting, carrying load on shoulder |

**Table 1** (*Continued*)

| Disorder[a] | Description | Typical Job Activities |
|---|---|---|
| Tendonitis (T) | An inflammation of a tendon. Often associated with repeated tension, motion, bending, being in contact with a hard surface, vibration. The tendon becomes thickened, bumpy, and irregular in its surface. Tendon fibers may be frayed or torn apart. In tendons without sheaths, such as the biceps tendon, the injured area may calcify. | Punch press operation, assembly work, wiring, packaging, core making, use of pliers |
| Tenosynovitis (tendosynovitis, tendovaginitis) (T) | Inflammation of the synovial sheaths. The sheath swells. Consequently, movement of the tendon with the sheath is impeded and painful. The tendon surfaces can become irritated, rough, and bumpy. If the inflamed sheath presses progressively onto the tendon, the condition is called stenosing tendosynovitis. ''DeQuervain's syndrome'' (see there) is a special case occurring at the thumb; the ''trigger finger'' (see there) condition occurs in flexors of the fingers. | Buffing, grinding, polishing, sanding, pushing, pressing, sawing, cutting, surgery, butchering, use of pliers, ''turning'' control such as on a motorcycle, inserting screws in holes, forceful hand wringing |
| Thoracic outlet syndrome (neurovascular compression syndrome, cervicobrachial disorder, brachial plexus neuritis, costoclavicular syndrome, hyperabduction syndrome) (V, N) | A disorder resulting from compression of the nerves and blood vessels of the brachial plexus between clavicle and first and second ribs. If this neurovascular bundle is compressed by the pectoralis minor muscle, blood flow to and from the arm is reduced. This ischemic condition makes the arm numb and limits muscular activities. | Buffing, grinding, polishing, sanding, overhead assembly, overhead welding, overhead painting, overhead auto repair, typing, keying, cashiering, wiring, playing musical instruments, surgery, truck driving, stacking, material handling, postal ''letter carrying,'' carrying heavy loads with extended arms |
| Trigger finger (or thumb) (T) | A special case of tenosynovitis (see there) where the tendon forms a nodule and becomes nearly locked, so that its forced movement is not smooth but in a snapping or jerking manner. This is a special case of stenosing tenosynovitis crepitans, a condition usually found with the digit flexors at the AI ligament. | Operating trigger finger, using hand tools that have sharp edges pressing into the tissue or whose handles are too far apart for the user's hand so that the end segments of the fingers are flexed while the middle segments are straight |
| Ulnar artery aneurysm (V, N) | Weakening of a section of the wall of ulnar artery as it passes through the Guyon tunnel in the wrist; often from pounding or pushing with the heel of the hand. The resulting ''bubble'' presses on the ulnar nerve in the Guyon tunnel. | Assembly work |
| Ulnar nerve entrapment (Guyon tunnel syndrome) (N) | Results from the entrapment of the ulnar nerve as it passes through the Guyon tunnel in the wrist. It can occur from prolonged flexion and extension of the wrist and repeated pressure on the hypothenar eminence of the palm. | Playing musical instruments, carpentering, brick laying, use of pliers, soldering, hammering |
| White finger (''dead finger,'' Raynaud's syndrome, vibration syndrome) (V) | Stems from insufficient blood supply bringing about noticeable blanching. Finger turns cold or numb and tingles, and sensation and control of finger movement may be lost. The condition results from closure of the digit's arteries caused by vasospasms triggered by vibrations. A common cause in continued forceful gripping of vibrating tools particularly in a cold environment. | Chain sawing, jackhammering, use of vibrating tool, sanding, paint scraping, using vibrating tool too small for the hand, often in a cold environment |

| Carpal tunnel syndrome | 18[a] | 12 |
| Hand–arm vibration syndrome | 13 | 12 |

[a]Nine studies provided 18 risk estimators.

tendons, which causes increased pressure in the carpal tunnel. Furthermore, a task that induces hand and arm vibration causes an involuntary increase in power grip through a reflex of the strength receptors. Vibration can also cause protein leakage from the blood vessels in the nerve trunks and result in edema and increased pressure in the nerve trunks and therefore can also result in edema

and increased pressure in the nerve (Lundberg et al., 1990).

Historically, several millions of workers in occupations such as vehicle operation are intermittently exposed every year to hand–arm vibration that significantly stresses the musculoskeletal system (Haber, 1971). Hand–arm vibration syndrome (HAVS) that is

**Table 4 Postural Risk Factors Reported in the Literature for the Wrist**

| Risk Factor | Results: Outcome and Details |
| --- | --- |
| Wrist flexion | Carpal tunnel syndrome (CTS), exposure of 20–40 h per week; increased median nerve stresses (pressure); increased finger flexor muscle activation for grasping; median nerve compression by flexor tendons. |
| Wrist extension | Median nerve compression by flexor tendons; CTS, exposure of 20–40 h per week; increased intracarpal tunnel pressure for extreme extension of 90°. |
| Wrist ulnar deviation | Exposure response effect found: If deviation greater than 2W, increased pain and pathological findings. |
| Deviated wrist positions | Workers with CTS used these postures more often. |
| Hand manipulations | More than 1500–2000 manipulations per hour led to tenosynovitis. |
| Wrist motion | 1276 flexion extension motions led to fatigue; higher wrist accelerations, and velocities in high-risk wrist WMSD jobs. |

*Source:* Adapted from Kuorinka and Forcier (1995).

characterized by intermittent numbness and blanching of the fingers with reduced sensitivity to heat, cold, and pain can affect up to 90% of workers in occupations such as chipping, grinding, and chain-sawing (Wasserman et al., 1974; Taylor and Pelmear, 1976). HAVS is caused primarily by vibration of a part or parts of the body of which the main sources are hand-held power tools such as chain saws and jackhammers (Sommerich et al., 2006).

A very recent study by da Costa and Vieira (2010) that reviewed only case–control or cohort studies utilized five criteria for association: strength of association, consistency, between studies, temporality, dose–response relationship, and coherence (following Bernard, 1997). In their study, da Costa and Vieira (2010) considered "strong evidence risk factors" for those that would satisfy at least four of the five, "reasonable evidence risk factors" for those that would satisfy at least one of the five, and "insufficient evidence risk factors" for those that would satisfy none of the criteria for causality but rather presented clear bias or confounding factors. The review study categorized these three levels of risk factors to specific body segments; see Table 6.

### 2.2.3 Work Organization Factors

According to Sommerich et al. (2006), work organization and environmental factors may also play a significant role in development of WUEDs. Work organization is defined as "the objective nature of the work process. It deals with the way in which work is structured, supervised, and processed" (Hagberg et al., 1995).

**Table 5 Postural Risk Factors Reported in the Literature for the Shoulder**

| Risk Factor | Results: Outcome and Details |
| --- | --- |
| More than 60° abduction or flexion for more than 1 h per day | Acute shoulder and neck pain |
| Less than 15° median upper arm flexion and 10° abduction for continuous work with low loads | Increased sick leave resulting from musculoskeletal problems |
| Abduction greater than 30° | Rapid fatigue at greater abduction angles |
| Abduction greater than 45° | Rapid fatigue at 90° |
| Shoulder forward flexion of 30°, abduction greater than 30° | Hyperabduction syndrome with compression of blood vessels |
| Hands no greater than 35° above shoulder level | Impairment of blood flow in the supraspinatus muscle |
| Upper arm flexion or abduction of 90° | Onset of local muscle fatigue |
| Hands at or above shoulder height | Electromyographic signs of local muscle fatigue in less than 1 min |
| Repetitive shoulder flexion | Tendonitis and other shoulder disorders |
| Repetitive shoulder abduction or flexion | Acute fatigue |
| Postures invoking static shoulder loads | Neck–shoulder symptoms negatively related to movement rate |
| Arm elevation | Tendonitis and other shoulder disorders |
| Shoulder elevation | Pain |
| Shoulder elevation and upper arm abduction | Neck–shoulder symptoms |
| Abduction and forward flexion invoking static shoulder loads | Neck–shoulder symptoms, shoulder pain and sick leave resulting from musculoskeletal problems |
| Overhead reaching and lifting | Pain |

**Table 6  Levels of Evidence of Different Risk Factors of WMSDs by Body Parts**

| Body Part | Strong Evidence | Reasonable Evidence | Insufficient Evidence |
|---|---|---|---|
| Neck | None | Psychosocial factors<br>Smoking<br>Gender<br>Posture<br>Comorbidity | Heavy physical work<br>Lifting<br>Sedentary work<br>Aging<br>High body mass index |
| Nonspecific upper limb | None | Comorbidity | Psychosocial factors<br>Aging<br>Smoking<br>Heavy physical work<br>High body mass index |
| Shoulder | None | Heavy physical work<br>Psychosocial factors | Repetitive work<br>Aging<br>High body mass index<br>Sedentary work |
| Elbow/forearm | None | Awkward posture<br>Comorbidity<br>Repetitive work<br>Aging | High body mass index<br>Heavy physical work<br>Gender<br>Monotonous work<br>Associated WUED |
| Wrist/hand | None | Prolonged computer work<br>Heavy physical work<br>High body mass index<br>Aging<br>Gender<br>Awkward posture<br>Repetitive work | Smoking<br>Comorbidity<br>Psychosocial factors |

The mechanisms by which work organizational factors can modify the risk for WUEDs include modifying the extent of exposure to other risk factors (physical and environmental) and modifying a person's stress response, thereby increasing the risk associated with a given level of exposure. Specific work organization factors that have been shown to fall into at least one of these categories include (but are not limited) to the following: (1) wage incentives, (2) machine-paced work, (3) workplace conflicts of many types, (4) absence of worker decision latitude, (5) time pressures and work overload, and (6) unaccustomed work during training periods or after returning from long-term leave. As discussed by Hagberg et al. (1995), the organizational context in which work is carried out has major influences on a worker's physical and psychological stress and health. The work organization defines the level of work output required (work standards), the work process (how the work is carried out), the work cycle (work–rest regimens), the social structure, and the nature of supervision.

### 2.2.4  Psychosocial Work Factors

Psychosocial work factors are defined as "the subjective aspects of work organization and how they are perceived by workers and managers" (Hagberg et al., 1995). Factors commonly investigated include job dissatisfaction and perceptions of workload, supervisor, and co-worker support, job control, monotony of work, job clarity, and interactions with clients. Recent reviews have concluded that high perceived job stress and non-work-related stress (worry, tension, distress) are consistently linked to WUEDs (NRC, 2001; Bongers et al., 2002). Bernard (1997) and NRC (2001) also found high job demands/workload to be linked to WUED in the majority of studies they reviewed that considered it. The NRC (2001) review concluded that the evidence was insufficient for linking WUED and low decision latitude, social support, or limited rest–break opportunities. MacDonald et al. (2001) presented evidence of high degrees of correlation between some physical and psychosocial work factors. This makes studying these factors more difficult, requiring collection of information on both types of factors and use of sophisticated data analysis techniques in order to draw correct conclusions about any associations between risk factors and WUED. However, it also means that the risk factors may be linked through work organization elements and that, by thoughtfully addressing those elements, exposures to both physical and psychosocial risk factors may be reduced.

### 2.2.5  Individual Factors

Individual characteristics of a worker, including anthropometry, health, sex, and age, may alter the way in

which work is performed and may affect a worker's capacity for or tolerance of exposure to physical or other risk factors. In particular, Lundberg (2002) and Treaster and Burr (2004) determined that women were at greater risk than men for WUED development. Treaster and Burr (2004) found this to hold even after accounting for confounders such as age and work factor exposure. They suggested a number of reasons why this might occur, including differences in exposures due to mismatches between female workers and their workstations, tools, and strength requirements of tasks, and so on (anthropometry); psychosocial or psychological factors, which may be the result of differences in job status (e.g., many women's jobs may tend to have less autonomy); the perceived need to work harder to prove one's self in a male-dominated workplace or profession; additional psychological pressure or workload due to responsibilities outside work (care of home, children, or aging parents); or biological differences, possibly related to the effects of sex hormones on soft tissues (Hart et al., 1998).

### 2.2.6 Basic Classification of Disorders

Since most manual work requires the active use of the arms and hands, the structures of the upper extremity are particularly vulnerable to soft tissue injury. WUEDs are typically associated with repetitive manual tasks with forceful exertions, such as those performed at assembly lines, or when using hand tools, computer keyboards, and other devices or operating machinery. These tasks impose repeated stresses to the upper body,

that is, muscles, tendons, ligaments, nerve tissues, and neurovascular structures. WEUD may be classified by the type of tissue that is primarily affected. Table 7 lists a number of upper extremity MSDs by the tissue that is primarily affected.

Generally, the greater the exposure to a single risk factor or combination of factors, the greater the risk of a WMSD. Furthermore, as the number of risk factors present increases, so does the risk of injury. The interaction between risk factors is more likely to have a multiplicative rather than an additive effect. Evidence for this can be found in the investigation of the effects of repetition and force exposure by Silverstein et al. (1986, 1987). However, risk factors may pose minimal risk of injury if sufficient exposure does not occur or if sufficient recovery time is provided. It is known that changes in the levels of risk factors will result in changes in the risk of WUEDs. Therefore, a reduction in WUED risk factors should also reduce the risk for WMSDs.

### 2.3 Physical Assessments of Workers

Ranney et al. (1995) performed precise physical assessments of workers in highly repetitive jobs as part of a cross-sectional study to assess the association between musculoskeletal disorders and a set of work-related risk factors. A total of 146 female workers employed in five different industries (garment and automotive trim sewing, electronic assembly, metal parts assembly, supermarket cashiering, and packaging) were examined for the presence of potential work-related musculoskeletal disorders. The prerequisites for selection of industries

**Table 7 Upper Extremity MSDs Classified by Tissue That Is Primarily Affected**

| Tendon-Related Disorders | Nerve-Related Disorders | Muscle-Related Disorders | Circulatory/Vascular Disorders | Joint-Related Disorders | Bursa-Related Disorders |
|---|---|---|---|---|---|
| Paratenonitis, peritendonitis, tendonitis, tendinosis, tenosynovitis | Carpal tunnel syndrome | Muscle strain | Hypothenar hammer syndrome | Osteoarthritis | Bursitis |
| Epicondylitis | Cubital tunnel syndrome | Myofascial pain, trigger points, myositis, fibromyalgia, fibrositis | Raynaud's syndrome | | |
| Stenosing tenosynovitis (DeQuervain's disease; trigger finger) | Guyon canal syndrome | | | | |
| | Radial tunnel syndrome | | | | |
| Dupuytren's contracture | Thoracic outlet syndrome, digital neuritis | | | | |
| Ganglion cyst | | | | | |

*Source:* Almekinders (1998) and Buckle and Devereux (2002).
Notes (based on Almekinders (1998), NRC (2001); refer also to Figure 5 later in this chapter):
Paratenonitis: involves tendon sheath; para-, meso-, and epitenon.
Peritendonitis: involves para-, meso-, and epitenon (may also involve tendon sheath, depending on reference).
Tendonitis: involves tendon, endotenon.
Tendinosis (insertional or midsubstance): involves tendon, endotenon, tendon–bone junction; refers to situation where there are degenerative changes within the tendon without evidence of inflammatory cells.
Tenosynovitis: involves tendon sheath: para-, meso-, and epitenon: refers to inflammation of the involved tissue(s).
Stenosing tenosynovitis occurs when tendon gliding is restricted due to thickening of the sheath or tendon.

and tasks within these industries were (1) the existence of repetitive work using the upper limb, (2) at least 5–10 female workers performing the same repetitive job, (3) a range of jobs from light to demanding, (4) minimal job rotation, (5) no major change in the plant for at least one year, and (6) the support from both union or employee group and management.

The study showed that 54% of the workers had evidence of musculoskeletal disorders in the upper extremities that were judged as potentially work related. Many workers had multiple problems, and many were affected bilaterally (33% of workers). Muscle pain and tenderness were the largest problems in both the neck–shoulder area (31%) and the forearm–hand musculature (23%). Most forearm muscle problems were found on the extensor side. Carpal tunnel syndrome

(CTS) was the most common form of disorder, with 16 workers affected (7 people affected bilaterally). DeQuervain's tenosynovitis and wrist flexor tendonitis were the most commonly found tendon disorders in the distal forearm (12 workers affected for each diagnosis). In view of the study results, it was concluded that muscle tissue is highly vulnerable to overuse; that the stressors that affect muscle tissue, such as static loading, should be studied in the forearm as well as in the shoulder; and that exposure should be evaluated bilaterally. Finally, the predominance of forearm muscle and epicondyle disorders on the extensor side was linked to the dual role of these muscles for supporting the hands against gravity plus postural stability during grasping.

The criteria for establishing the work site diagnosis for various WMSDs are shown in Tables 8 and 9.

**Table 8  Minimal Clinical Criteria for Establishing Work Site Diagnoses for Work-Related Muscle or Tendon Disorders**

| Disorder | Symptoms | Examination |
|---|---|---|
| Neck myalgia | Pain in one or both sides of the neck increased by neck movement | Tender over paravertebral neck muscles |
| Trapezius myalgia | Pain on top of shoulder increased by shoulder elevation | Tender top of shoulder or medial border of scapula |
| Scapulothoracic pain syndrome[a] | Pain in scapular region increased by scapular movement | Tender over rib angles, 2, 3, 4, 5, and/or 6 |
| Rotator cuff tendonitis[b] | Pain in deltoid area or front of shoulder increased by glenohumeral movement | Rotator cuff tenderness[c] |
| Triceps tendonitis | Elbow pain increased by elbow movement | Tender triceps tendon |
| Arm myalgia | Pain in muscle(s) of the forearm | Tenderness in a specific muscle of the arm |
| Epicondylitis/tendonitis[d] | Pain localized to lateral or medial aspect of elbow | Tenderness of lateral or medial epicondyle localized to this area or to soft tissues attached for a distance of 1.5 cm |
| Forearm myalgia[e] | Pain in the proximal half of the forearm (extensor or flexor aspect) | Tenderness in a specific muscle in the proximal half of the forearm (extensor or flexor aspect) more than 1.5 cm distal to the condyle |
| Wrist tendonitis[f] | Pain on the extensor or flexor surface of the wrist | Tenderness is localized to specific tendons and is not found over bony prominences |
| Extensor finger tendonitis[f,g] | Pain on the extensor surface of the hand | Tenderness is localized to specific tendons and is not found over bony prominences |
| Flexor finger tendonitis[f,g] | Pain on the flexor aspect of the hand or distal forearm | Pain on resisted finger flexion localized to area of tendon |
| Tenosynovitis (finger/thumb) | Clicking or catching of affected digit on movement; may be pain or a lump in the palm | Demonstration of these complaints, tenderness anterior to metacarpal of affected digit |
| Tenosynovitis, DeQuervain's | Pain on the radial aspect of wrist | Tenderness over first tendon compartment and positive Finkelstein's test |
| Intrinsic hand myalgia | Pain in muscles of the hand | Tenderness in a specific muscle in the hand |

Source: Adapted from Ranney et al. (1995).
[a]Crepitation on circumduction of the shoulder.
[b]Positive impingement test.
[c]Frozen shoulder excluded.
[d]Positive Mills's test or reverse Mills's test (lateral or medial epicondylitis).
[e]Pain localized to the muscle belly of the muscle being stressed during resisted activity.
[f]Pain localized to tendon being stressed during resisted activity.
[g]Only diagnosed moderate or severe. Classification of severity of muscle/tendon problems: mild, above criteria met; moderate, pain persists more than 2 h after cessation or work but is gone after a night's sleep, or tenderness plus pain on resisted activity if localized in an anatomically correct manner, or see notes a, b, and d to f; severe, pain not completely relieved by a night's sleep.

**Table 9  Minimal Clinical Criteria for Establishing Work Site Diagnoses for Work-Related Neuritis**

| Disorder | Symptoms | Examination |
|---|---|---|
| Carpal tunnel syndrome | Numbness and/or tingling in thumb, index, and/or midfinger with particular wrist postures and/or at night | Positive Phalen's test or Tinel's sign present over the median nerve at the wrist |
| Scalenus anticus syndrome | Numbness and/or tingling on the preaxial border of the upper lip | Tender scalene muscles with positive Adson's or Wright's test |
| Cervical neuritis | Pain, numbness, or tingling following a dermatomal pattern in the upper limb | Clinical evidence of intrinsic neck pathology |
| Lateral ante-brachial neuritis | Lateral forearm pain, numbness, and tingling | Tenderness of coracobrachialis origin and reproduction of symptoms on palpation here or by resisted coracobrachialis activity |
| Pronator syndrome | Pain, numbness, and tingling in the median nerve distribution distal to the elbow | Tenderness of pronator teres or superficial finger flexor muscle, with tingling in the median nerve distribution on resisted activation of same |
| Cubital tunnel syndrome | Numbness and tingling distal to elbow in ulnar nerve distribution | Tender over ulnar nerve with positive Tinel's sign and/or elbow flexion test |
| Ulnar tunnel syndrome | Numbness and tingling in ulnar nerve distribution in the hand distal to the wrist | Positive Tinel's sign over the ulnar nerve at the wrist |
| Wartenberg's syndrome | Numbness and/or tingling in distribution of the superficial radial nerve | Positive Tinel's sign on tapping over the radial sensory nerve |
| Digital neuritis | Numbness or tingling in the fingers | Positive Tinel's sign on tapping over digital nerves |

Studies that include physical assessment to identify cases of a disorder are often viewed as more rigorous than those that rely exclusively on subjective recall in response to questions concerning musculoskeletal discomfort or disorder. However, there are a variety of ways in which physical examinations can be conducted and interpreted. When studying a disorder, adhering to a specific definition of the disorder is a key factor in classifying study participants as cases or noncases and thereafter determining the degree of association between the disorder and the risk factor(s) being studied. Recognizing the importance of this, criteria are put forth in order that researchers might begin to use common methods of classifying study of patients/participants. Consensus criteria for conducting physical assessments for classification of CTS in epidemiological studies are provided by Rempel et al. (1998). Sluiter et al. (2001) provided criteria for identifying 11 specific WUEDs, including CTS, and a four-step approach for determining work relatedness of a disorder once it is identified. Although these two groups took an expert consensus approach to criteria development, Helliwell et al. (2003) took a statistical approach, relying on multivariate modeling to identify the most discriminating symptoms and signs for classifying six different WUEDs. Authors of the latter two documents also address "nonspecific" upper extremity disorders as well.

Recently, David (2005) reviewed the various ergonomic methods used for assessing the risk factors of WMSDs. These methods are broadly categorized into three: (1) self-reports, (2) observational methods, and (3) direct measurements. Table 10 summarizes the methods, specific technique, main features, functions, and studies employed these techniques.

## 3  ANATOMY OF UPPER EXTREMITY

This section briefly discusses the anatomy of the hand, elbow, forearm, and shoulder following the description provided by Sommerich et al. (2006). The anatomy of the upper extremity provides for great functionality but also puts certain soft tissue components at risk of damage from repeated or sustained compressive, shear, and/or tensile loading. The shoulder complex joins the upper extremity to the axial skeleton. It provides the greatest range of motion of all the body's joints, yet this comes with several associated costs, including reduced joint stability and potential for entrapment of various soft tissues when the arm is elevated or loaded. All hand-held loads pass through the shoulder joint, but their effects are magnified increasingly the farther in the transverse plane the hands are located away from the shoulder. The elbow is a simpler joint than the shoulder yet can also be a sight of nerve entrapment. The hand is small in dimension yet is capable of producing large amounts of force. In addition, the hand is capable of configuring itself in a variety of orientations and can generate force with either the whole hand in a power grip or combinations of fingers in opposition to the thumb, as in a pinch grip. It is this very flexibility in capability that makes the upper extremity susceptible to CTDs. Refer

to Figures 1–3 for some views of the anatomy of the upper extremity.

### 3.1  Anatomy of Hand

The anatomy of the hand is illustrated in Figure 1. To achieve a variety of functions, the hand is constructed so that it contains numerous small muscles which facilitate fine, precise positioning of the hand and fingers but few power-producing muscles. One of the only power-producing muscles in the hand is a group of three muscles that form the thenar group, which flex, abduct, and position the thumb for opposition. Strong grasping is produced by extrinsic finger flexor muscles that are located in the forearm. Force is transmitted to the fingers through a network of long tendons (tendons attach muscles to bone). These tendons pass from the muscles in the forearm through the wrist (and through the carpal canal), through the hand, and to the fingers. These tendons are secured at various points along this path with ligaments that keep the tendons in close proximity

to the bones. The transverse carpal ligament forms the palmar boundary of the carpal tunnel, and the carpal bones form the remainder of the boundary. The tendons of the upper extremity are also encased in a sheath, which assists in the sliding of the tendons that occurs in concert with muscle contraction and prevents the tendons from sliding directly over the carpal bones or the transverse carpal ligament. A common sheath envelops the nine tendons passing through the carpal tunnel. For the fingers to generate force, a great deal of tension must be passed through these tendons. Since there are various possible combinations of tendons experiencing tension depending on the configuration of the fingers, type of grip, and grip force required, many of these tendons experience friction. This frictional component can be exacerbated by several factors, including position of the wrist and fingers, motion of the wrist and fingers, and insufficient rest periods. The extrinsic finger flexor muscles are paired with a set of extrinsic finger extensors on the dorsal side of the forearm and hand.
**Figure 1** Anatomy of the hand.

**Figure 2** Superficial muscles of the anterior forearm. The two sets of extrinsic muscles that flex the fingers are part of the intermediate and deep layers of anterior forearm muscles. (Modified from Gray's Anatomy, 1918.)

Other structures in the hand are also important to the development of cumulative trauma in the distal portion of the upper extremity. As shown in Figure 1, two major blood vessels pass through the hand. Both the radial artery and the ulnar artery provide the tissues and structures of the hand with a blood supply. One of the key structures of the hand that is often involved with cumulative-trauma experiences is the nerve structure. The median nerve enters the lower arm and passes through the carpal canal. Once it passes through the carpal canal, the median nerve becomes superficial at the base of the wrist and then branches off to serve the thumb, index finger, middle finger, and radial side of the ring finger. This nerve also serves the palmar surface of the hand connected to these fingers as well as the dorsal portion up to the first two knuckles on the fingers mentioned above as well as the thumb up to the first knuckle.

### 3.2 Anatomy of Forearm and Elbow

Located on the humerus, the medial epicondyle is the attachment site for the primary wrist flexor muscles and the extrinsic finger flexor muscles; the lateral epicondyle is the attachment site for the primary wrist extensor muscles and extrinsic finger extensor muscles. Repeated activation of either of these groups of muscles has been associated with development of epicondylitis at the relevant epicondyle. At the elbow, the ulnar nerve passes between the olecranon process of the ulna and the medial epicondyle. The space is referred to as the cubital tunnel. Cubital tunnel syndrome may develop as a result of compressive loading of the ulnar nerve as it passes through that tunnel when the elbow is flexed, either

repeatedly or over a sustained period. Direct pressure can also be applied to the nerve when part of the body's weight is supported by the elbows, depending on the shallowness of the space. The extrinsic finger extensor muscles, located on the posterior side of the forearm, are a common site of discomfort, as are their tendons and the tendons of the thumb's extrinsic extensor and abductor muscles. An illustration of the anterior view of the forearm appears in Figure 2.

### 3.3 Anatomy of Shoulder

The glenohumeral joint, where the head of the humerus partially contacts the glenoid fossa of the scapula, is what most people think of when the term shoulder is used. However, there are four articulations that make up the shoulder complex; the other three are the acromioclavicular, sternoclavicular, and scapulothoracic joints. The four joints work in a coordinated manner to provide the wide range of motion possible in a healthy shoulder. The shoulder complex is also composed of approximately 16 muscles and numerous ligaments. The extensive range of motion at the glenohumeral joint is afforded, in part, because of the minimal contact made between the humerus and scapula. The connection is secured by a group of muscles referred to as the rotator cuff (teres minor, infraspinatus, supraspinatus, and subscapularis muscles). They create a variety of torques about the joint and also help protect against subluxation (incomplete dislocation). The supraspinatus tendon is thought to be particularly susceptible to injury (tears and tendonitis) for three reasons: (1) It may have an avascular zone near its insertion, (2) it is placed under significant tension when the arm is elevated, and (3) it passes through a confined space above the humeral

**Figure 3** Frontal plane view of the shoulder. (Modified from LifeART, 2000.)

head and below the acromion. Scapular anatomy also makes the supraspinatus tendon prone to compression between the humeral head and coracoacromial arch. The coracoacromial arch is formed by the acromion of the scapula and the coracoacromial ligament, which joins the corticoid process and acromion. The arch is a structure above the supraspinatus that can apply a compression force to the tendon if the humeral head migrates superiorly (Soslowsky et al., 1994). The subdeltoid and subacromial bursas are subject to compressive forces when the humerus is elevated, as is the tendon of the long head of the biceps. That tendon is also subject to frictional forces as it moves relative to the humerus within the bicipital groove, when the humerus is elevated.

Other structures within the shoulder complex are also important to the development of cumulative trauma in the proximal portion of the upper extremity. These include the brachial plexus (the anterior primary rami of the last four cervical spinal nerves and the first thoracic nerve, which go on to form the radial, median, and ulnar nerves in the upper extremity), the subclavian artery, and the subclavian vein. These structures all pass over the

first cervical rib, in close proximity to it. The artery and plexus pass in between the anterior and medial scalene muscles (which attach to the first cervical rib), and the vein lies anterior to the anterior scalene muscle, which separates the vein from the artery. The plexus, artery, and nerve all pass underneath the pectoralis minor muscle. These structures can be compressed by the muscles or bones in proximity to them when the humerus is elevated or when the shoulders are loaded directly (such as when wearing a backpack) or indirectly (as when holding a load in the hands). Additionally, the muscles of the shoulder, particularly trapezius, infraspinatus, supraspinatus, and levator scapula, are also common sites of pain and tenderness (Norregaard et al., 1998). The anterior view of the shoulder, from magnetic resonance imaging (MRI), is illustrated in Figure 3.

## 4  CAUSATION MODELS FOR DEVELOPMENT OF DISORDERS

### 4.1  Conceptual Model

Armstrong et al. (1993) developed a conceptual model for the pathogenesis of work-related musculoskeletal disorders which is not specific to any particular disorder. The model is based on the set of four cascading and interacting state variables of exposure, dose, capacity, and response, which are measures of the system state at any given time. The response at one level can act as the dose at the next level (see Figure 4). Furthermore, it is assumed that a response to one or more doses can diminish or increase the capacity for responding to successive doses. This conceptual model for development of WUEDs reflects the multifactorial nature of these disorders and the complex nature of the interactions among exposure, dose, capacity, and response variables. The model also reflects the complexity of interactions among the physiological, mechanical, individual, and psychosocial risk factors.

In the proposed model, exposure refers to the external factors (i.e., work, requirements) that produce the internal dose (i.e., tissue loads and metabolic demands and factors). Workplace organization and hand tool design characteristics are examples of such external factors, which can determine work postures and define loads on the affected tissues or the velocity of muscular contractions. Dose is defined by a set of mechanical, physiological, or psychological factors that in some way disturb an internal state of the affected worker. Mechanical disturbance factors may include tissue forces and deformations produced as a result of exertion or movement of the body. Physiological disturbances are such factors as consumption of metabolic substrates, or tissue damage, whereas psychological disturbance factors are those related to, for example, anxiety about work or inadequate social support.

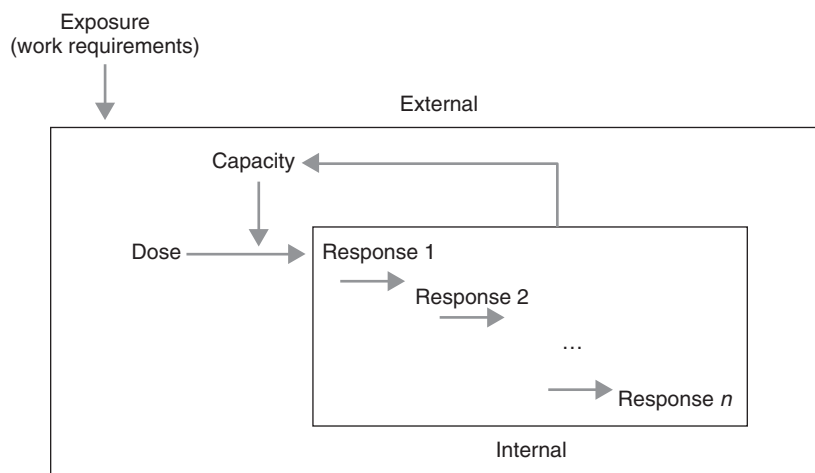
Changes in the states of variables of the worker are defined as responses. A response is an effect of the dose caused by exposure. The model also allows for a given response to constitute a new dose, which then produces


**Figure 4** Conceptual model for development of WMSDs proposed by Armstrong et al. (1993).

a secondary response (called the tertiary response). For example, hand exertion can cause elastic deformation of tendons and changes in tissue composition and/or shape, which in turn may result in hand discomfort (Armstrong et al., 1993). The dose–response time relationship implies that the effect of a dose can be immediate or the response may be delayed for a long period of time.

The model requires that system changes (responses) can also result in either increased dose tolerance (adaptation) or reduced dose tolerance lowering the system capacity. Capacity is defined as the worker's ability (physical or psychological) to resist system destabilization resulting from various doses. Whereas capacity can be reduced or enhanced by previous doses and responses, it is assumed that most people are able to adapt to certain types and levels of physical activity. Table 11 shows characterization of WMSDs with respect to exposure–dose relationship, the worker's capacity, and the response model proposed by Armstrong et al. (1993).

The main purpose of the dose–response model is to account for the factors and processes that result in WMSDs to specify acceptable limits with respect to work design parameters for a given person. The exposure, dose, response, and capacity variables need to be measured and quantified. Exposure can be measured using the job title or job classification, questionnaires on possible risk factors, job checklists, or direct measurements. Dose can be measured by estimating muscle forces and joint positions. Worker capacity can be measured using anthropometry, muscle strength, and psychological characteristics. The model proposed should be useful in the design of studies on the etiology and pathomechanisms of WMSDs. The model should also complement epidemiological studies that focus on associations between the physical workload, psychological demands, and environmental risk factors of work at one end and the manifestations of symptoms, diseases, or disabilities at the other.

## 4.2 Pathomechanical and Pathophysiological Models

Numerous epidemiological studies are consistent in their finding of statistically significant associations between workplace exposures to various physical risk factors and the incidence and/or prevalence of upper extremity MSDs in workers. Experimental studies on humans (in vivo) and investigations that utilize cadavers (in vitro) provide more direct evidence to support hypotheses regarding the internal responses to exposure doses of which Armstrong et al. (1993) wrote. However, the types of experimental studies that can establish direct causal links are those based on animal models, where the exposure dose and potential confounding factors can be strictly controlled and the effects measured over time to provide a view of the natural history of a disorder's progression. A number of reviews have been published recently which piece together information from these various types of studies in order to examine, from all sides, the patterns of evidence in support of workplace physical exposures as causes of musculoskeletal disorders in workers. These include NRC (2001) and Barr and Barbe (2002), which reviewed studies concerning the mechanobiology and pathophysiology of tendons, muscles, peripheral nerves, and other tissues that are involved in MSDs; Buckle and Devereux (2002), who conducted a similar review for the European Commission; Visser and van Dieen (2006), who focused on upper extremity muscle disorders; and Viikari-Juntura and Silverstein (1999), who focused on CTS. A sampling of key details and excerpts from their conclusions are provided herein. Readers are encouraged to read the full reviews and original research studies for a deeper appreciation of the strength of the evidence provided by these studies.

### 4.2.1 Tendons

Tendons are a complex composite material consisting of collagen fibrils embedded in a matrix of proteoglycans.

**Table 11　Characterization of Work-Related Musculoskeletal Disorders in General and Muscle, Tendon, and Nerve Disorders in Particular According to Sets of Cascading Exposure and Response Variables as Conceptualized in Model**

| Exposure Dose | Worker's Capacity | Response |
|---|---|---|
| Musculoskeletal system | | |
| Work load | Body size and shape | Joint position |
| Work location | Physiological state | Muscle force |
| Work frequency | Psychological state | Muscle length |
| | | Muscle velocity |
| | | Frequency |
| Muscle disorders | | |
| Muscle force | Muscle mass | Membrane permeability |
| Muscle velocity | Muscle anatomy | Ion flow |
| Frequency | Fiber type and composition | Membrane action potentials |
| Duration | Enzyme concentration | Energy turnover (metabolism), muscle |
| | Energy stores | enzymes, and energy stores |
| | Capillary density | Intramuscular pressure |
| | | Ion imbalances |
| | | Reduced substrates |
| | | Increased metabolites and water |
| | | Increase in blood pressure, heart rate, |
| | | cardiac output, muscle blood flow |
| | | Muscle fatigue |
| | | Pain |
| | | Free radicals |
| | | Membrane damage |

| | | Swelling |
| | | Pain |
| Nerve disorders | | |
| Muscle force | Anthropometry | Stress |
| Muscle length | Nerve anatomy | Strain |
| Muscle velocity | Electrolyte status | Ruptures in perineural tissues |
| Frequency | Basal compartment pressure | Protein leakage |
| Joint position | | Ruptures in perineural tissue |
| Compartment | | Protein leakage in nerve trunks |
| pressure | | Edema |
| | | Increased pressure |
| | | Impaired blood flow |
| | | Numbness, tingling, conduction block |
| | | Nerve action potentials |

*Source:* Adapted from Armstrong et al. (1993).

A schematic representation of tendon structure is provided in Figure 5.

***Biomechanics***　Tendons transmit tensile loads between the muscles and the bones to which they are attached. However, they are also subjected to compressive and frictional/shear loads from adjacent structures (bone, other tendons, tendon sheaths, muscle, etc.).

Estimates of these loads have been made by modeling tendons as mechanical pulley systems (Armstrong and Chaffin, 1979). When loads on tendons are excessive (in magnitude, duration, repetition, or in some combination of these), damage is thought to occur. Moore (2002) presented a biomechanical model which incorporated the pulley tendon model to express the relative importance of load duration and repetition in the development of tendon entrapment at the dorsal wrist compartments. The most common of these is de Quervain's disease (stenosing tenosynovitis), which involves the tendons of the abductor pollicis longus and
**Figure 5** Tendon structure. The paratenon is essentially doubled for those tendons that are surrounded by a synovial sheath (not shown in the figure). The mesotenon (not shown in the figure) are synovial layers that pass from the tendon to the wall of the sheath.

extensor pollicis brevis (two extrinsic thumb-moving muscles).

***Pathophysiology and Pathomechanics*** The NRC (2001) review of the mechanobiology of tendons concluded that "basic science studies support the conclusion that repetitive motion or overuse loading can cause chronic injury to tendon tissues." The review noted that fibrocartilaginous tissue is found within tendons, where they wrap around bone (e.g., the long head of biceps tendon within the bicipital groove of the humerus). The review also cited animal studies in which excessive repetitive loading was shown to result in degenerative changes to tendons and edema, increased numbers of capillaries, fibrosis, and other changes to the paratenon (the loose connective tissue that surrounds tendons that are not surrounded by a sheath). These changes are similar to those associated with peritendonitis and tendinosis in humans. Recently, Barbe et al. (2003) found evidence of tendon fraying at the muscle–tendon junction within the reaching limb of rats that performed a voluntary, low-force, repetitive reaching task for six to eight weeks. They also found progressive increases, over the course of the study, in the number of infiltrating macrophages in tendons and other tissues in both forward limbs but more so in the reaching limb. [Macrophages are large cells that possess the property of ingesting bacteria, foreign particles, and other cells.

Infiltrating macrophages are typically found at sites of inflammation. Inflammation is a fundamental pathological process that occurs in response to an injury or abnormal stimulation caused by a physical, chemical, or biological agent (McDonough, 1994).] Effects were also seen in tendons that were not directly related to the reaching task, indicating not just a local effect but also a systemic effect of the repetitive hand/paw-use intensive task.

### 4.3 Muscle

Muscle is a composite structure made up of muscle cells, organized networks of nerves and blood vessels, and extracellular connective matrix. Cells are fused together to form each muscle fiber, the basic structural element of skeletal muscle. Muscle is unique among the tissues in the body for its ability to contract in response to a stimulus from a motoneuron. A motor unit is made up of a single alpha motoneuron and the muscle fibers it innervates. There are essentially three types of fibers or motor units. All the fibers within a motor unit are of the same type. Type I fibers are small and are recruited first and at low levels of contraction. They have a high capillary density and are fatigue resistant. Type II fibers are larger and are recruited later, when more force is required. They have low capillary density and are the most fatiguable of the three types. Type IIA have a mix of properties of the other two types. Muscles usually contain all three types in varying proportions, based on the role of the muscle as well as the construction of the person.

***Biomechanics*** Muscle fiber damage can occur when external loads exceed the tolerance of the active contractile components and the passive connective tissue. Nonfatiguing muscle exertions require energy and oxygen, supplied by the blood. The flow of blood can be reduced when a muscle contracts if the intramuscular pressure increases beyond about 30 mm Hg (capillary closing pressure). Järvholm et al. (1988, 1991) demonstrated reductions in blood flow in rotator cuff muscles as a function of arm position (abduction or flexion) and weight held in the hand (0–2 kg). Even mild elevations, $30°$ of abduction combined with $45°$ of flexion, increased intramuscular pressure to 70 mm Hg. Contraction of the supraspinatus to only 10% of maximum capability increased intramuscular pressure to 50 mm Hg. Elevated intramuscular pressure may lead to localized muscle fatigue or more serious outcomes. Studies have shown that intramuscular pressure sustained at 30 mm Hg for 8 h resulted in muscle fiber atrophy, splitting, necrosis, and other damage (NRC, 2001).

***Pathophysiology and Pathomechanics*** The NRC (2001) review of the mechanobiology of skeletal muscle concluded that "the scientific studies reviewed support the conclusion that repetitive mechanical strain exceeding tolerance limits ... results in chronic skeletal muscle injury." In addition to finding changes in tendon, Barbe et al. (2003) also found infiltrating macrophages in the muscles of the reaching and nonreaching limb of test rats which performed the repetitive, low-force reaching task. Muscles in the paw and the distal forearm were affected, as were muscles that were involved in the task only indirectly (forearm extensors, upper arm and shoulder muscles) or not at all (tibial muscles). Heat-shock protein (HSP) cells increased, first in the intrinsic hand muscles and then in the distal forelimb flexor muscles. Heat-shock proteins have a protective role in the cell. Cells increase their production of HSPs when they experience acute or chronic stress. Precursors that stimulate HSP production include inflammation, ischemia, and nerve crush as well as other stimulating factors.

Visser and van Dieen (2006) reviewed several hypotheses concerning the pathogenesis of work-related

upper extremity muscle disorders and concluded that no complete proof existed in the literature for any of them but that some of them were likely to interact or follow one another in a downward spiral of damage. It appears that the selective and sustained motor unit recruitment (of small type I fibers) in combination with homeostatic disturbances possibly due to limitations in blood supply and metabolite removal offers a plausible basis for the pathogenesis of muscle disorder in low-intensity tasks. The bulk of the findings from the biopsy studies reviewed, which indicate mitochondrial dysfunction of type I fibers in myalgic muscles, could also be accounted for by such a mechanism. As a response to the release of metabolites in the muscle, the circulation increases. Sympathetic activation (stress) might lead to a reduction of circulation and an increase of muscle activation. Sustained exposure can result in an accumulation of metabolites, stimulating nociceptors. This process can be enhanced in subjects with relatively large type I fibers and low capillarization, which paradoxically may have developed as an adaptation to the exposure. Nociceptor activation can disturb the proprioception and thereby the motor control most likely leading to further increased disturbance of muscle homeostasis. In addition, in the long run a reduction of the pain threshold and an increase of pain sensitivity can develop. It is worth noting that initial nociceptor stimulation may be a response to metabolite accumulation and not to tissue damage.

### 4.3.1 Peripheral Nerves

Peripheral nerves are composed of nerve fibers, connective tissue, and blood vessels. A nerve fiber is a long process that extends from a nerve cell body. The term *nerve* refers to a bundle of axons, some of which send information from the spinal cord to the periphery (e.g., muscles, vessels) and some of which send information from peripheral tissues (e.g., skin, muscle, tendon) to the spinal cord. Figure 6 illustrates a single nerve cell (motor neuron) and a nerve.

***Biomechanics*** Peripheral nerves are well vascularized in order to supply energy needs for impulse transmission and axonal transport (transportation of nutrition and waste products within a nerve cell). If pressure is elevated within the nerve (due to edema or external compression), blood flow is reduced, and as a result, impulse transmission and axonal transport can be slowed or disrupted. Structural damage may also occur.

***Pathophysiology and Pathomechanics*** Numerous studies of nerve function have identified threshold levels of pressure ranging from 20 to 40 mm Hg, above which nerve function, including circulation, axonal transport, and impulse conduction, is compromised (Rydevik et al., 1981; Szabo and Gelberman, 1987). Damage to nerves comes in the form of loss of myelin (Mackinnon et al., 1984), large myelinated fibers (Hargens et al., 1979), and damage to small unmyelinated fibers (Hargens et al., 1979). The physiological and histological effects of pressure on a nerve depend on the amount of pressure, how it is applied (dispersed or focal), and duration of application. Vibration can also cause damage to peripheral nerves, including breakdown of myelin, interstitial and perineural fibrosis, and axonal loss, based on evidence from biopsies from humans exposed to vibrating hand tools and empirical animal studies (NRC, 2001).

### 4.3.2 Carpal Tunnel Syndrome

Carpal tunnel syndrome is the most commonly encountered peripheral neuropathy (Falkiner and Myers, 2002; Werner and Andary, 2002). The term describes a constellation of symptoms that result from localized compression of the median nerve within the carpal tunnel. The carpal tunnel is a fibro-osseous canal created by the carpal bones (floor and walls) and the flexor retinaculum (ceiling). The contents include the median nerve, the eight extrinsic flexor tendons of digits 2–5 [flexor digitorum superficialis and profundus (FDS and FDP), respectively], and tendons of the flexor pollicis longus (FPL) and flexor carpi radialis (FCR) (the latter is somewhat separated from the other contents, in its own subtunnel). Part of the volume of the carpal tunnel is also taken up by the synovial sheaths that surround the tendons.

The contents of the tunnel are not static. The nerve moves transversely within the tunnel, and relative to the

**Figure 6** (*a*) Neuron and (*b*) nerve.

tendons, when the extrinsic finger flexors are activated isometrically (Nakamichi and Tachibana, 1992), when the fingers are flexed or extended (Ham et al., 1996), and when the wrist is flexed or extended (Zeiss et al., 1989), and change in the nerve's location seems to be somewhat variable from one person to the next. The extrinsic finger flexor tendons slide proximally with finger flexion and distally with finger extension. Further, in some people lumbrical muscles may enter the tunnel during pinching (Ditmars, 1993) and appear consistently to enter the tunnel with full finger flexion (Siegel et al., 1995; Ham et al., 1996). Distal fibers of the FDS and FDP may enter during wrist extension (Keir and Bach, 2000). The cross-sectional area of the tunnel also changes, being smaller when the fingers are fully extended than when flexed (Ham et al., 1996). The area of the tunnel is reduced in wrist flexion and extension compared with a neutral posture (Keir, 2001).

***Biomechanics*** Soft tissues appear to be subjected to mechanical stress within the carpal tunnel. The median nerve takes on an oval or somewhat flattened shape within the carpal tunnel (Robbins, 1963; Zeiss et al., 1989). In a study of cadaver hands (donor health history unknown), Armstrong et al. (1984) observed increased subsynovial and adjacent connective tissue densities, increased synovial hyperplasia, and arteriole and venule muscular hypertrophy, with changes being most pronounced near the distal wrist crease. The authors suggested that the types of changes similar to those seen in CTS biopsy specimens and the extent to which their severity corresponded to their proximity to the distal wrist crease indicated that repeated flexion and extension at the wrist imposes mechanical stress on the tissues that cross that joint and that their alterations were in direct response to that stress. They also suggested that highly repetitive use of the wrist might bring about alterations that would be severe enough to elicit CTS symptoms. In patients undergoing CTS release surgery, Schuind et al. (1990) found fibrous hyperplasia of the flexor tendon synovium and increased amounts of collagen fibers (irregular and disorganized). More advanced lesions contained necrotic areas as well. The authors concluded that these histological lesions were "typical of a connective tissue undergoing degeneration under repeated mechanical stresses."

***Pathophysiology and Pathomechanics*** The median nerve can be damaged by direct force (damaging myelin and other structural components) and by elevated hydrostatic pressure (ischemic response). Schuind et al. (1990) hypothesized that, following an initial mechanical stress upon the flexor tendon synovium, a vicious cycle develops in which changes in synovium increase frictional loads on the tendons as they move back and forth through the tunnel, which causes further irritation to the synovium. Effects on the median nerve are increased pressure due to a reduction of free volume within the carpal tunnel and possibly restrictions on the nerve's freedom to move within the tunnel during wrist movement (contact stress). This is consistent with the cascade model of work-related upper limb musculoskeletal disorders proposed by Armstrong et al. (1993). Another cascade model theorizes that elevated pressure within the carpal tunnel leads to ischemia in the tendons, sheaths, and median nerve. This is followed by tissue swelling, which further increases the pressure in the tunnel and can result in physiological and histological changes in the median nerve (Lluch, 1992).

Studies of nerve function have identified threshold levels of pressure ranging from 20 to 40 mm Hg, above which nerve function, including circulation, axonal transport, and impulse conduction, is compromised (Rydevik et al., 1981; Szabo and Gelberman, 1987). Short-term laboratory-based studies have also shown that carpal tunnel pressure (CTP) in healthy people exceeds these levels with nonneutral wrist postures (Keir et al., 1998b) or in using the hand in ordinary ways, such as pressing with the fingertip or pinching (Keir et al., 1998a) or typing (Sommerich et al., 1996). Even with hands inactive and wrists in a neutral posture, CTP is elevated in people with CTS (Rojviroj et al., 1990). Cyclic movement of the wrist was shown to induce sustained, elevated CTP in patients with early or intermediate CTS (Szabo and Chidgey, 1989).

Viikari-Juntura and Silverstein (1999) examined the pattern of evidence of the role of physical factors in the development of CTS by reviewing studies from various areas: epidemiological, experimental, cadaver, and animal. One of the consistent and unifying threads they found was the connection (manifestation) of these external, physical factors (posture, force, repetition, and external pressure) as CTP or as having an effect on CTP. They concluded that there is sufficient evidence that duration, frequency, or intensity of exposure to forceful repetitive work and extreme wrist postures is likely to be related to the occurrence of CTS in working populations. Recent work by Clark et al. (2003, 2004) provides additional insight into the effects of performing highly repetitive tasks in rats performing voluntary hand/paw use-intensive tasks. Effects of a low-force, repetitive reaching task included increased numbers of infiltrating macrophages (a sign of inflammation) in the median nerve, with a greater increase in the reach than in the nonreach limb, and myelin degradation and fibrosis, particularly in the epineurium at the wrist and just distal to the carpal ligament (associated with increased compression) (Clark et al., 2003). Effects of a high-force, repetitive grasping task included infiltrating macrophages in all connective tissue associated with the nerve and increased collagen type I (fibrosis) in perineurium, epineurium, and surrounding tissues. For both of these effects, there was no difference between the reach and nonreach limbs (Clark et al., 2004). These bilateral effects are important, because bilateral presentation of CTS in workers is taken by some to be an indication that work is not the cause of the condition.

## 4.4 Causal Models Summary

Evidence of the role of physical factors in the development of upper extremity MSDs from epidemiological, experimental, cadaver, and animal studies seems to support the conceptual model of Armstrong et al. (1993).

Additional animal models, to replicate and extend the work of Clark and colleagues, will serve to clarify and begin to quantify the relationships between external dose and internal response. Eventually, such work will lead to quantitative, preventive models that can be used to reduce risk of WUED in human workers.

## 5 QUANTITATIVE MODELS FOR CONTROL OF DISORDERS

### 5.1 Challenges

Today, only a few quantitative models that are based on the physiological, biomechanical, or psychophysical data and that relate the specific job risk factors for musculoskeletal disorders to increased risk of developing such disorders have been developed. As discussed by Moore and Garg (1995), this is mainly because (1) the dose–response (cause–effect) relationships are not well understood; (2) measurement of some task variables, such as force and even posture, is difficult in an industrial setting; and (3) the number of task variables is very large. However, it is generally recognized that biomechanical risk factors such as force, repetition, posture, recovery time, duration of exposure, static muscular work, use of the band as a tool, and type of grasp are important for explaining the causation mechanism of WUEDs (Armstrong and Lifshiz, 1987; Keyserling et al., 1993). Given the foregoing knowledge, even though limited in scope and subject to epidemiological validation, a few methodologies that allow discrimination between safe and hazardous jobs in terms of workers being at increased risk of developing the WUEDs have been developed and reported in the subject literature. Some of the quantitative data and models for evaluation and prevention of WUEDs available today are described below.

### 5.2 Maximum Acceptable Forces for Repetitive Wrist Motions for Females

Snook et al. (1995) utilized the psychophysical methodology to determine the maximum acceptable forces for various types and frequencies of repetitive wrist motion, including (1) flexion motion with a power grip (handle diameter 40 mm, handle length 135 mm); (2) flexion motion with a pinch grip (handle thickness 5 mm, handle length 55 mm); and (3) extension motion with a power grip (handle diameter 40 mm, handle length 135 mm). Subjects were instructed to work as if they were on an incentive basis, getting paid for the amount of work that they performed. They were asked to work as hard as they could (i.e., against as much resistance as they could) without developing unusual discomfort in the hands, wrists, or forearms.

Fifteen women worked 7 h each day, 2 days per week, for 40 days in the first experiment. Repetition rates of 2, 5, 10, 15, and 20 motions per minute were used with each flexion and extension task. Maximum acceptable torque was determined for the various motions, grips, and repetition rates without dramatic changes in wrist strength, tactile sensitivity, or number of symptoms. Fourteen women worked in the second experiment, performing a wrist flexion motion

(power grip) 15 times per minute, 7 h per day, 5 days per week, for 23 days. In addition to the four dependent variables—maximum acceptable torque, maximum isometric wrist strength, tactile sensitivity, and symptoms—performance errors and duration of force were measured. The most common health symptom reported was muscle soreness (55.3%), located mostly in the hand and wrist (51.8%). Numbness in the palmar side of the fingers and thumb (69.1%) and stiffness on the dorsal (back) side of the fingers and thumb (30.6%) were also reported. The number of symptoms increased consistently as the day progressed. The number of symptoms reported was two to three times higher after the seventh hour of work than after the first hour of work (similar to the two to four times higher rate in the two-days-per-week exposure). Symptoms reports were 4.1 times higher at the end of the day than at the beginning of the day before testing began.

The maximum acceptable torque determined during the five-days-per-week exposure was 36% lower than the task performed only two days per week. Based on the assumption that maximum acceptable torque decreases 36.3% for the other repetition rates used during the two-days-per-week exposure, and using the adjusted means and coefficients of variation from the two-days-per-week exposure, the maximum acceptable torques were estimated for different repetitions of wrist flexion (power grip) and different percentages of the population. Torques were then converted into forces by dividing each torque by the average length of the handle lever (0.081 m). The estimated maximum acceptable forces for female wrist flexion (power grip) are shown in Table 12. Tables 13 and 14 show the estimated maximum acceptable forces for female wrist flexion (pinch grip) and wrist extension (power grip), respectively. The torques were converted into forces by dividing by 0.081 m for the power grip and 0.123 m for the pinch grip.

### 5.3 Hand Activity Level

In 2002 the American Congress of Governmental Industrial Hygienists (ACGIH) adopted the hand activity level (HAL) within the section on ergonomics in its annual publication of threshold limit values (TLVs). This annual publication contains recommendations and guidelines "to assist in the control of potential workplace health hazards" (ACGIH, 2002). The TLV considers the dual exposures of average hand activity level and peak hand force for monotask jobs performed for four

**Table 12 Maximum Acceptable Forces for Female Wrist Flexion (Power Grip) (N)**

| Percentage of Population | Repetition Rate | | | | |
|---|---|---|---|---|---|

or more hours per day. Peak force is normalized to the strength capability of the workforce for the activity being assessed. Combinations of force and activity either fall within an acceptable range (below the action limit line), which means that nearly all workers could be exposed repeatedly without adverse health effects, a midrange that is delineated by the action limit line below and the threshold limit line above in which some workers might be at risk, and a region that exceeds the TLV in which jobs with similar characteristics have been shown to be associated with elevated risk of upper extremity MSDs (UEMSDs). The TLV does not specifically account for contact stress, nonneutral postures, cold, gloves, or vibration, and the ACGIH urges use of professional judgment when modifying factors such as these are also present in the task. More specific information about the HAL can be found at http://www.aegih.org/ and other locations on the Web.

### 5.4  Strain Index

#### 5.4.1  Model Structure

Moore and Garg (1995) developed a self-styled semi-quantitative job analysis methodology for identifying industrial jobs associated with distal upper extremity disorders (elbow, forearm, wrist, and hand). An existing body of knowledge and theory of the physiology, biomechanics, and epidemiology of distal upper extremity disorders was used for that purpose. The following major principles were derived from the physiological model of localized muscle fatigue:

1.  The primary task variables are intensity of exertion, duration of exertion, and duration of recovery.

2.  Intensity of exertion refers to the force required to perform a task one time and is characterized as a percentage of maximal strength.

3.  Duration of exertion describes how long an exertion is applied. The sum of duration of exertion and duration of recovery is the cycle time of one exertional cycle.

4.  Wrist posture, type of grasp, and speed of work are considered by means of their effects of maximal strength.

5.  The relationship between strain on the body (endurance time) and intensity of exertion is nonlinear.

The following major principles derived from the biomechanical model of the viscoelastic properties of components of a muscle–tendon unit were utilized for the model:

1.  The primary task variables for the viscoelastic properties are intensity and duration of exertion, duration of recovery, number of exertions, wrist posture, and speed of work.

2.  The primary task variables for intrinsic compression are intensity of exertion and nonneutral wrist posture.

3.  The relationship between strain on the body and intensity of effort is nonlinear.

Finally, the major principles derived from the epidemiological literature and used for the purpose of model development were as follows:

1.  The primary task variables associated with an increased prevalence or incidence of distal upper extremity disorders are intensity of exertion (force), repetition rate, and percentage of recovery time per cycle.

2.  Intensity of exertion is the most important task variable related to disorders of the muscle–tendon unit.

3.  Wrist posture may not be an independent risk factor because it may contribute to an increased incidence of distal upper extremity disorders when combined with intensity of exertion.

4.  The roles of other task variables have not been clearly established epidemiologically.

Moore and Garg (1995) compared exposure factors for jobs associated with WUEDs to jobs without prevalence of such disorders. They found that the intensity of exertion, estimated as a percentage of maximal strength and adjusted for wrist posture and speed of work, was the major discriminating factor. The relationship between the incidence rate for distal upper extremity disorder and job risk factors was defined as

$$IR = (30 \times F^2)/RT^{0.6} \qquad (1)$$

where IR is the incidence rate (per 100 workers per year), $F$ the intensity of exertion (% of maximum strength), and RT the recovery time (% of cycle time).

### 5.4.2 Elements of Strain Index

The strain index (Sl) proposed by Moore and Garg (1995) is the product of six multipliers that correspond to six task variables: (1) intensity of exertion, (2) duration of exertion, (3) exertions per minute, (4) hand−wrist posture, (5) speed of work, and (6) duration of task per day. An ordinal rating is assigned for each of the variables according to the exposure data. The ratings that are applied to model variables are presented in Table 15. The multipliers for each task variable related to these ratings are shown in Table 16. The strain index score is defined as follows:

$$
\begin{aligned}
\text{SI} = \ & (\text{intensity of exertion multiplier}) \\
& \times (\text{duration of exertion multiplier}) \\
& \times (\text{exertions per minute multiplier}) \\
& \times (\text{posture multiplier}) \\
& \times (\text{speed of work multiplier}) \\
& \times (\text{duration per day multiplier}) \quad (2)
\end{aligned}
$$

*Intensity of exertion*, the most critical variable of the SI, is defined as the percentage of maximum strength required to perform a task once. The intensity of exertion is estimated by an observer using verbal descriptors (see Table 15) and assigned corresponding rating values (1, 2, 3, 4, or 5). The multiplier values (Table 16) are defined based on the rating score raised to a power of 1.6 to reflect the nonlinear nature of the relationship between intensity of exertion and manifestations of strain according to the psychophysical theory. The multipliers for other task variables are modifiers to the intensity of the exertion multiplier.

*Duration of exertion* is defined as the percentage of time that an exertion is applied per cycle. The terms *cycle* and *cycle time* refer to the exertional cycle and average exertional cycle time, respectively. The duration of recovery per cycle is equal to the exertional cycle time minus the duration of exertion per cycle. The duration of exertion is the average duration of exertion per exertional cycle (calculated by dividing all durations of a series of exertions by the number of exertions observed). The percentage duration of exertion is calculated by dividing the average duration of exertion per cycle by the average exertional cycle time, then multiplying the result by 100:

%duration of exertion

$$
= (\text{average duration of exertion per cycle/average}
$$

$$
\text{exertional cycle time}) \times 100 \quad (3)
$$

The percentage duration of exertion calculated is compared to the ranges in Table 15 and assigned the appropriate rating. The corresponding multipliers are identified using Table 16.

*Effort per minute* is the number of exertions per minute (e.g., repetitiveness) and is synonymous with frequency. Efforts per minute are measured by counting the number of exertions that occur during a representative observation period (as described for determining the average exertional cycle time). The results measured are compared to the ranges shown in Table 15 and given the corresponding ratings. The multipliers are defined in Table 16.

*Posture* refers to the anatomical position of the wrist or hand relative to the neutral position and

**Table 15  Rating Criteria for Strain Index**

| Rating | Intensity of Exertion | Duration of Exertion (% of Cycle) | Efforts per Minute | Hand−Wrist Posture | Speed of Work | Duration per Day (h) |
|---|---|---|---|---|---|---|
| 1 | Light | <10 | <4 | Very good | Very slow | ≤1 |
| 2 | Somewhat hard | 10−29 | 4−8 | Good | Slow | 1−2 |
| 3 | Hard | 30−49 | 9−14 | Fair | Fair | 2−4 |
| 4 | Very hard | 50−79 | 15−19 | Bad | Fast | 4−8 |
| 5 | Near maximal | ≥80 | ≥20 | Very Bad | Very fast | ≥8 |

*Source:* Adapted from Moore and Garg (1995).

**Table 16  Multipliers for Strain Index**

| Rating | Intensity of Exertion | Duration of Exertion (% of Cycle) | Efforts per Minute | Hand−Wrist Posture | Speed of Work | Duration per Day (h) |
|---|---|---|---|---|---|---|
| 1 | 1 | 0.5 | 0.5 | 1.0 | 1.0 | 0.25 |
| 2 | 3 | 1.0 | 1.0 | 1.0 | 1.0 | 0.50 |
| 3 | 6 | 1.5 | 1.5 | 1.5 | 1.0 | 0.75 |
| 4 | 9 | 2.0 | 2.0 | 2.0 | 1.5 | 1.00 |
| 5 | 13 | 3.0[a] | 3.0 | 3.0 | 2.0 | 1.50 |

*Source:* Adapted from Moore and Garg (1995).
[a] If duration of exertion is 100%, the efforts/minute multiplier should be set to 3.0.

can be rated qualitatively using verbal anchors. As shown in Table 16, posture has four relevant ratings. Postures that are "very good" or "good" are essentially neutral and have multipliers of 1.0. As hand or wrist postures progressively deviate beyond the neutral range to extremes, they are graded as "fair," bad," and "very bad."

*Speed of work* refers to the perceived pace of the task or job and can be estimated subjectively. Once a verbal anchor is selected, a rating is assigned according to Table 15. Duration of task per day is defined as the total time that a task is performed per day. As such, this variable reflects the beneficial effects of task diversity such as job rotations and the adverse effects of prolonged activity such as overtime. Duration of task per day is measured in hours and assigned a rating according to Table 15.

Application of the SI involves five steps: (1) collecting data, (2) assigning rating values, (3) determining multipliers, (4) calculating the SI score, and (5) interpreting the results. The values of intensity of exertion, wrist posture, and speed of work can be estimated using the verbal descriptors in Table 15. The values of percentage duration of exertion per cycle, efforts per minute, and duration per day are based on measurements and counts. These values are then compared to the appropriate column in Table 16 and assigned a rating. The SI multipliers are determined from Table 16. Table 17 shows the numerical example for calculating the strain index.

### 5.4.3 Application

In a preliminary test of the ability of the SI to distinguish between jobs that were high or low risk for distal UEMSDs, the SI was found to have a sensitivity of 0.92 (able to identify correctly 11 of 12 known positive jobs) and a specificity of 1.0 (able to identify correctly 13 of 13 known negative jobs) when 25 jobs in a pork processing facility were assessed. Three different studies conducted by Moore and colleagues have shown that the SI is capable of distinguishing between safe and hazardous jobs for upper extremity disorders with an odds ratio (OR) of 114 (95% confidence interval: 24–545), sensitivity of 0.90, specificity of 0.93, positive predictive value of 0.93 and negative predictive value of 0.91 (Moore and Garg, 1995; Knox and Moore, 2001; Moore et al., 2001, 2006). Findings from these studies suggested using an SI score of 5 as a threshold to distinguish between safe and hazardous jobs. Rucker and Moore (2002) performed another assessment of the SI

on 28 jobs from two different manufacturing companies. The sensitivity, specificity, positive predictive value, and negative predictive value were 1.00, 0.91, 0.75, and 1.00, respectively, providing additional evidence of the validity of the tool for assessment of single tasks. Other recent studies utilized the SI method to examine its reliability and validity (Spielholz et al., 2008; Stephens et al., 2006), its possible application on cumulative-trauma reduction (Smith, 2007) and in multiple task jobs assessment (Bao et al., 2009)

### 5.4.4 Limitations

The proposed SI methodology aims to discriminate between jobs that expose workers to risk factors (task variables) that cause WUEDs and jobs that do not. However, according to Moore and Garg (1995), the SI is not designed to identify jobs associated with an increased risk of any specific disorder. It is anticipated that jobs identified by the SI to be in the high-risk category will exhibit higher levels of WUEDs among workers who currently perform or historically performed those jobs believed to be hazardous. Finally, the authors caution that large-scale studies are needed to validate and update the methodology proposed.

The SI has the following primary limitations in terms of its application:

1. It is designed primarily to predict distal upper extremity disorders involving muscle–tendon units and CTS rather than all UEMSDs [e.g., hand–arm vibration syndrome (HAYS), ganglion cysts. osteoarthritis].

2. The SI has not been developed to predict disorders beyond the distal upper extremity, such as disorders of the shoulder, shoulder girdle, neck, or back.

3. No method has been developed for using the SI to assess multiple tasks.

## 6 ERGONOMICS EFFORTS TO CONTROL DISORDERS

### 6.1 Strategies for Prevention of Musculoskeletal Injuries

Facing the growing challenges of musculoskeletal injuries in the contemporary workplace, *Proposed National Strategies for the Prevention of Leading Work-Related Diseases and Injuries* (NIOSH, 1986) identified environmental hazards and human biological hazards among the four main factors that contribute to

**Table 17 Example to Demonstrate Procedure for Calculating the Score**

|  | Intensity of Exertion | Duration of Exertion | Efforts per Minute | Posture | Speed of work | Duration perDay (h) |
|---|---|---|---|---|---|---|
| Exposure dose | Somewhat hard | 60% | 12 | Fair | Fair | 4–8 |
| Rating | 2 | 4 | 3 | 3 | 3 | 4 |
| Multiplier | 3.0 | 2.0 | 1.5 | 1.5 | 1.0 | 1.0 |
|  | SI Score = 3.0 × 2.0 × 1.5 × l.5 × l.0 × 1.0 = 13.5 | | | | | |

*Source:* Adapted from Moore and Garg (1995).

human diseases. *Environmental hazards* to the muscu-loskeletal system associated with work were described as workplace traumatogens (i.e., a source of biomechan-ical stress from job demands that exceed the worker's strength or endurance, such as heavy lifting or repeti-tive and forceful manual exertions). Traumatogens can be measured by determining the frequency, magnitude, and direction of forces imposed on the body in rela-tion to posture and the point of application. *Hunan biological factors* include the anthropometric or innate attributes that influence a worker's capacity for perform-ing a job safely. Examples include the worker's physical size, strength, range of motion, and work endurance. These factors account partially for variability in per-formance capability in the population and the poten-tial for a mismatch between the worker and job that can be addressed by applying ergonomic principles of work design. To reduce the extent of work-related mus-culoskeletal injuries, progress in four methodological areas was expected (NIOSH, 1986): (1) identifying the biomechanical hazards accurately, (2) developing effec-tive health promotion and hazard control interventions, (3) changing management concepts and operational poli-cies with respect to expected work performance, and (4) devising strategies for disseminating knowledge on con-trol technology and promoting their application through incentives.

With the issuance of *National Occupational Research Agenda*, the NIOSH (1996) built upon these pre-vious strategies by including musculoskeletal disor-ders and several related areas (e.g., organization of work, indoor environment, special populations at risk, exposure assessment methods, intervention effective-ness research, risk assessment methods, and surveillance research methods) in its list of 21 declared priority areas, defined as areas with the highest likelihood of reducing workplace injuries/illnesses. Consistent with NIOSH's vision are the recommendations from the NRC (2001), which included encouraging the institution or extension of ergonomic and other preventive, science-based strategies and identifying areas that need fur-ther research (improved tools for exposure assessment, improved measures of outcome and case definition for use in epidemiological and intervention studies, further quantification of exposure–outcome relationships).

## 6.2 Applying Ergonomic Principles and Processes

Ergonomic job design (and redesign) efforts focus on fitting characteristics of the job to capabilities of workers. In simple terms, this can be accomplished, for example, by reducing excessive strength requirements and exposure to vibration, improving the design of hand tools and work layouts, designing out unnatural postures at work, or addressing the problem of work–rest requirements for jobs with high production rates. From the occupational safety and health perspective, the current state of ergonomics knowledge should allow for management of WUEDs in order to minimize human suffering, potential for disability, and the related worker compensation costs. Application of ergonomics can help to (1) identify working conditions under which the

WUEDs might occur, (2) develop engineering design measures aimed at elimination or reduction of the known job risk factors, and (3) identify the affected worker population and target it for early medical and work intervention efforts.

Workplace and work design–related risk factors, which often overlap, typically involve a combina-tion of poor work methods, inadequate workstations and hand tools, and high production demands. A risk factor is defined as an attribute or exposure that increases the probability of the disease or disorder (Putz-Anderson, 1993). As discussed before, the biome-chanical risk factors for WUEDs include repetitive and sustained exertions, awkward postures, and application of high mechanical forces. Vibration and cold environ-ments may also accelerate the development of WUEDs. Tools that can be used to identify the potential for development of WUEDs include plant walk-throughs and/or more detailed work–methods analyses. Check-lists, analytical tools [such as the SI (Moore and Garg, 1995) or HAL (ACGIH, 2002)], and/or expertise of the analyst are utilized to identify undesirable work site conditions or worker activities that can contribute to injury.

Since job redesign decisions may require some design trade-offs (Putz-Anderson, 1993), the ergonomic intervention process should follow these steps: (1) per-form a thorough job analysis to determine the nature of specific problems, making sure to identify the root causes for the problem; (2) evaluate and select the most appropriate intervention(s), based on the root cause and other factors relevant to the particular circumstance; (3) develop and apply conservative treatment (imple-ment the intervention) on a limited scale if possible; (4) monitor progress to ensure that the intervention has the intended effect and no adverse consequences; and (5) adjust or refine the intervention as needed.

## 6.3 Administrative and Engineering Controls

The control of WUEDs requires consideration of the following aspects of this complex problem: (1) WUED diagnosis, (2) treatment, (3) rehabilitation and return to work, (4) WUED surveillance, (5) surveillance and control of risk factors at the micro- and macrolevels, (6) training and education, and (7) management and leadership with regard to WUED-related organizational and social aspects (Hagberg et al., 1995). The spe-cific recommendations for prevention of WUEDs can be classified as being either primarily administrative (i.e., focusing on personnel solutions) or engineering (i.e., focusing on redesigning tools, workstations, and jobs) (Putz-Anderson, 1993). In general, administrative con-trols are those actions taken by the management that are intended to limit the potentially harmful effects of a physically stressful job on individual workers. Admin-istrative controls, which are focused on the workers, are modifications of existing personnel functions such as worker training, job rotation, and matching employees to job assignments. A summary of selected ergonomics measures that aim to control the incidence of WUEDs is given in Table 18.

**Table 18 Ergonomic Measures to Control Common WMSDs**

| Disorder | Avoid in General | Avoid in Particular | Recommendation | Design Considerations |
|---|---|---|---|---|
| Carpal tunnel syndrome | Rapid, often repeated finger movements, wrist deviation | Dorsal and palmer flexion, pinch grip, vibrations between 10 and 60 Hz | | Workplace design |
| Cubital tunnel syndrome | Resting forearm on sharp edge or hard surface | | | Workplace design |
| DeQuervain's syndrome | Combined forceful gripping and hard twisting | | | Workplace design |
| Epicondylitis | ''Bad tennis backhand'' | Dorsiflexion, pronation | | Workplace design |
| Pronator syndrome | Forearm pronation | Rapid and forceful pronation, strong elbow and wrist flexion | Use large muscles but infrequently and for short time | Design of work object |
| Shoulder tendonitis, rotator cuff syndrome | Arm elevation | Arm abduction, elbow elevation | Let wrists be in linewith forearm | Design of job task |
| Tendonitis | Often repeated movements, particularly with force exertion; hard surface in contact with skin, vibrations | Frequent motions of digits, wrists, forearm shoulder | Let shoulder and upper arm be relaxed | Design of hand tools (''bend tool, not the wrist'') |
| Tenosynovitis, DeQuervain's syndrome, ganglion | Finger flexion, wrist deviation | Ulnar deviation, dorsal and palmar flexion, radial deviation with firm grip | Let forearms be horizontal or more declined | Design for round corners, use pad |
| Thoracic outlet syndrome | Arm elevation, carrying loads | Shoulder flexion, arm hyperextension | | Design of work object placement |
| Trigger finger or thumb | Digit flexion | Flexion of distal phalanx alone | | Workplace design |
| Ulnar artery aneurysm | Pounding and pushing with heel of the hand | | | Workplace design |
| Ulnar nerve entrapment | Wrist flexion and extension | Wrist flexion and extension, pressure of hypothenar eminence | | Workplace design |
| White finger, vibration syndrome | Vibrations, tight grip, cold exposure | Vibrations between 40 and 125 Hz | | Workplace design |
| Neck tension syndrome | Static head posture | Prolonged static head–neck posture | Alternative head–neck postures | Workplace design |

*Source:* Adapted from Kroemer et al. (1994).

With respect to biomechanical risk factors, prevention and control efforts for WUEDs should be directed toward fulfilling several recommendations based on ergonomics principles for workplace design, work methods, and work organization. As discussed by Putz-Anderson (1993), these may include, for example, the following recommendations: (1) permit several different working postures; (2) place controls, tools, and materials between waist and shoulder heights for ease of reach and operation; (3) use jigs and fixtures for holding purposes; (4) resequence jobs to reduce the repetition; (5) automate highly repetitive operations; (6) allow self-pacing

of work whenever feasible; and (7) allow frequent (voluntary and mandatory) rest breaks.

Furthermore, with respect to hand tools used at work, the following general work design guidelines are provided:

1.  Make sure that the center of gravity of the tool is located close to the body and the tool is balanced.
2.  Use power tools to reduce the force and repetition required.
3.  Consider redesigning the straight tool handle; bend it as necessary to preserve the neutral posture of the wrist.
4.  Use tools with pistol grip or straight grips, respectively, where the axis in use is horizontal or vertical (or when the direction of force is perpendicular to the workplace).
5.  Avoid tools that require working with a flexed wrist and extended arm at the same time or tools that call for the flexion of distal phalanges (last joints) of the fingers.
6.  Minimize the tool weight; suspend all tools heavier than 20 N (or 2 kg) of force by a counterbalancing harness.
7.  Align the tool's center of gravity with the center of the grasping hand.
8.  Use special-purpose tools that facilitate fitting the task to the worker (avoid standard off-the-shelf tools for specific repetitive operations).
9.  Design tools so that workers can use them with either hand.
10. Use a power grip where power is needed and a precision grip for precise tasks.
11. The handles and grips should be cylindrical or oval with a diameter between 3.0 and 4.5 cm (for precise operations the recommended diameter is from 0.5 to 1.2 cm).
12. The minimum handle length should be 10.0 cm, whereas a 11.5–2.0-cm handle is preferable.
13. A handle span of 7.5–8.0 cm can be used by male and female workers for plier-type handles.
14. Triggers on power tools should be at least 5.1 cm wide, allowing their activation by two or three fingers.
15. Avoid form-fitting handles that cannot be adjusted easily.
16. Provide handles that are nonporous, nonslip, and nonconductive (thermally and electrically).

## 6.4  Ergonomics Programs for Prevention

An important component of WUED management efforts is development of well-structured and comprehensive ergonomics programs. According to Alexander and Orr (1992), the basic components of such a program should include the following: (1) health and risk factor surveillance, (2) job analysis and improvement, (3) medical management, (4) training, and (5) program evaluation. An excellent program should include participation of all levels of management; medical, safety, and health personnel; labor unions; engineering; facility planners; and workers and contain the following elements:

1.  Routine (monthly or quarterly) reviews of the OSHA log (injury records) for patterns of injury and illness (dedicated computer programs can be used to identify problem areas)
2.  Workplace audits for ergonomic problems that are a routine part of the organization's culture (more than one audit annually for each operating area) and timely interventions as a response to the problems identified
3.  A knowledge by management and workers regarding the list of most critical problems (i.e., jobs with the job title clearly identified)
4.  Application of both engineering solutions and administrative controls, with engineering solutions treated as long-term solutions
5.  Awareness of ergonomic considerations by design engineering that utilizes them in new or reengineered designs (people are an important design consideration)
6.  Frequent refresher training in ergonomics, including short courses and seminars for site-appointed "ergonomists"

## 6.5  Employer Benefit from Ergonomic Programs

In 1997, the U.S. Government Accountability Office (GAO) issued a report in response to a charge to (1) identify core elements of effective ergonomics programs and describe how these are operationalized within companies, (2) examine whether or not such programs have proven beneficial to companies and employees where they have been implemented, and (3) address the implications for employers who have not adopted such programs (GAO, 1997). The core elements they identified were consistent with those listed above. The parts of the report that are particularly interesting are the five case studies that are included, which provide details of the ergonomic program experiences of five different companies, in different sectors of industry, and how each tailored the generic components of a successful program to fit their circumstances, company culture, and so on. Examples of specific benefits realized by the companies are also provided and include reductions in numbers of lost workdays, workers' compensation costs (total and per case), and MSD incidence rates. Methods for supporting the case for ergonomics based on economics are provided by a number of authors (Andersson, 1992a,b; Simpson and Mason, 1995; Oxenburgh, 1997).

On a smaller scale, specific interventions may require cost–benefit analyses to justify them if a substantial initial investment is required. Seeley and Marklin (2003) employed the cost–benefit analysis method described by

Rouse and Boff (1997) to calculate the expected benefit to an electric utility company as a result of replacing the manual cutters and presses their linemen used with battery-powered models. Based on the quantification of expected benefits (reductions in medical and workers' compensation costs due to UEMSDs, costs to replace injured workers, training costs for replacement workers, and additional medical expenses for employees who postpone reporting injuries until they become severe), they determined a payback period of only four months for the $300,000 cost of the new tools. Details of their methodology are provided in Seeley and Marklin (2003).

## 6.6 Surveillance

### 6.6.1 Surveillance System

To evaluate the extent of WUEDs in a working population, a surveillance system should be used. Surveillance refers to the ongoing systematic collection, analysis, and interpretation of health and exposure data. Relevant to this chapter, this refers to the process of describing and monitoring work-related MSD occurrence. Surveillance is used to determine which jobs need further evaluation and where ergonomic interventions may be warranted. Surveillance data are used to determine the need for occupational safety and health action and to plan, implement, and evaluate ergonomic interventions and programs (Klaucke et al., 1988). Health and hazard (job risk factor) surveillance provides employers and employees with a means of evaluating WUEDs and workplace ergonomic risk factors systematically by monitoring trends over time. This information can also be of benefit for planning, implementing, and evaluating ergonomic interventions.

Although the climate for standards making has cooled in the United States, the final draft of the standard for management of WMSDs from the American National Standards Institute (ANSI) Z365 Committee (2002) is still a valuable source of information on the elements of a management program, including the surveillance component. The draft standard describes surveillance as including (1) review and analysis of existing records on worker injury and illness (OSHA 300 logs, company medical records, etc.), (2) worker reports concerning MSD symptoms or potential risk factors in the workplace, and (3) job surveys (cursory or screening-level reviews of jobs conducted to identify potential risk factors and the degree of risk they might pose to workers). The goal of surveillance, and of ergonomics programs in general, is to reduce or eliminate MSD risk factor exposure through approaches that are both reactive (after MSDs or their symptoms develop in workers) and proactive (identify hazards before workers who are exposed to the hazard develop a problem).

### 6.6.2 Worker Health Data

Analysis of existing records will be used to estimate the potential magnitude of the problem in the workplace. The number of employees in each job, department, or similar population needs to be determined first. Then the incidence rates can be calculated on the basis of hours worked:

Incidence (new case) rate (IR)

$$= \text{(no. of new cases during time} \times 200,000)/\text{work hours} \qquad (4)$$

where time refers to the time period of interest, typically one year, and work hours refers to the total number of hours worked by all employees in the group for which the rate is being calculated. The incidence rate is equivalent to the number of new cases per 100 full-time workers (assuming that each works 40 h per week and 50 weeks per year). Workplace-wide incidence rates (IRs) can be calculated for all WUEDs classified by body location for each department, process, or type of job. If specific work hours are not readily available, the number of full-time equivalent employees in each area multiplied by 2000 h can be used to estimate the denominator. Another important calculation is that of severity, used to describe the number of lost workdays. One way to calculate severity is to substitute the number of lost workdays for the number of new cases in equation (4). Another would be to examine the number of lost workdays per case. Prevalence refers to the number of existing cases relative to the number of employees in the group. These numbers can be compared within a company among different departments to see where problems exist. They can also be compared with data from the BLS to provide a sense of where a company's statistics are relative to those of its industry or business sector. That information can be found on the BLS website (http://www.bls.gov/iif/oshcdnew.htm). [Note that BLS incidence rate data are provided per 10,000 workers, not per 100, as in equation (4).]

In addition to making use of existing records, information about current symptoms can be sought through use of employee surveys. These usually provide employees with diagrams and other means by which to indicate where they are experiencing symptoms as well as the intensity and frequency of occurrence. In their chapter on surveillance, Hagberg et al. (1995) provide some examples of symptom surveys. Once a symptom survey has been conducted, the employer must be prepared to follow up with job analysis if problems are identified through the symptom survey.

### 6.6.3 Job Surveys

Job surveys are performed to identify specific jobs and processes that may put employees at risk of developing WMSDs. Conduct surveys of all jobs, a representative sample, or jobs that have been identified as potential problems through some other method (such as jobs with excessive turnover or absenteeism or when a substantial change is made to a job). Job surveys may include walkthroughs; conversations with employees, supervisors, and/or company health personnel; use of checklists; and other basic methods.

### 6.6.4 Data Collection Instruments

The surveillance system aims to link the occurrence of WMSDs to work-related risk factors. Ideally, the surveillance should make it possible to identify workplace risk factors before symptoms develop. Surveillance data collection instruments can be passive or active in nature (Hagberg et al., 1995). A summary of active and passive surveillance methods is given in Table 19. The passive surveillance process relies on information collected from existing databases and records (e.g., company dispensary logs, insurance records, workers' compensation records, accident reports, and absentee records) to identify the WRMD cases and patterns and potential problem jobs. Passive surveillance records are often useful in helping to determine the frequency with which active surveillance tools should be used and the interventions required or in assessing the effectiveness of ergonomics programs. In addition, a brief job analysis or physical demand analysis to assess the suitability of a job for the return to work of an injured worker can also be used for passive risk factor surveillance.

Active surveillance uses specifically designed tools and information, such as checklists and job analysis. As shown in Table 20, there can be both health active surveillance and risk factor active surveillance. Since

**Table 20  Summary of Tools Used in Surveillance**

| Approach | Tools |
|---|---|
| Health | |
|   Passive | Existing records |
|   Active, level 1 | Symptoms surveys or questionnaires (self or group administered) |
|   Active, level 2 | Health-related interviews and/or brief physical exams |
| Risk factors | |
|   Active, level 1 | Quick checklists of risk factors |
|   Active, level 2 | In-depth job analysis |

*Source:* Adapted from Kuorinka and Forcier (1995).

most musculoskeletal disorders produce some symptoms of pain or discomfort, health questionnaires are useful in identifying new or incipient problems as well as for assessing the effectiveness of medical interventions and ergonomic controls. In addition to symptom questionnaires, medical interviews and examination can also be used in active health surveillance (Table 21).

### 6.6.5 Analysis and Interpretation of Data

The surveillance data can be analyzed and interpreted to study possible associations between the WMSD surveillance data and the risk factor surveillance data (Hagberg et al., 1995). The two principal goals of the analysis are (1) to help identify patterns in the data that reflect differences between jobs or departments and (2) to target and evaluate intervention strategies. This analysis can be done on the number of existing WMSD cases (cross-sectional analysis) or during a specific period of time on the number of new WMSD cases in a retrospective and prospective fashion (retrospective and prospective analysis).

**Table 19  Passive and Active Surveillance Methods**

| Passive Surveillance[a] | Active Surveillance |
|---|---|
| Information source and method already exist and are usually designed for other administrative purposes | Information source and method specifically designed for surveillance |
| Relatively inexpensive | Modest to quite expensive |
| Usually requires additional coding of information for the purpose [e.g., surrogate(s) of exposure, such as job titles] | Since tools are "tailor made," includes at least job title information and other data considered important by surveillance analyst; will include data for linking of information between risk factor and WMSD data |
| *Examples:* health and safety logs, medical department logs, workers' compensation data, early retirement, medical insurance, absenteeism and transfer records, accident reports, product quality, productivity | *Examples:* for WMSD surveillance: confidential questionnaires without personal identifiers, questionnaire interviews, physical examinations; for risk factor surveillance: workplace walk-throughs, job checklists, postural discomfort surveys |

*Source:* Adapted from Kuorinka and Forcier (1995).
[a]Used mostly for health surveillance since, in practice, no existing records have been used to obtain information on risk factors associated with WMSDs.

**Table 21  Examples of Tools for WMSD Surveillance**

| Focus of Surveillance | Methods of Surveillance | |
|---|---|---|
| | Passive | Active |
| Health (WMSDs) | Company dispensary logs Insurance records Workers compensation records Accident reports Transfer requests Absentee records Grievances | Checklists Questionnaires Interviews Physical exams |
| Workplace risk factors (associated with WMSDs) | Not really used for WMSD risk factor yet[a] | Checklists Questionnaires Job analysis |

*Source:* Adapted from Kuorinka and Forcier (1995).
[a]The use of surrogate measures for exposure (e.g., job title of firm's department) could be viewed as "passive surveillance."

**Table 22  Examples of Odds Ratio Calculations for a Firm of 140 Employees**

| Risk Factor (e.g., Overhead Work for More Than 4 h) Is: | WMSDs Are:[a] | | |
|---|---|---|---|
| | Present | Not Present | Total |

| Total | 30 (A + C) | 110 (B + D) | 140 (N) |

*Source:* Adapted from Kuorinka and Forcier (1995).
[a]Number in each cell indicates the count of employees with or without WMSD and the risk factor. Odds ratio (OR) = (A x D) / (B x C) = (15 x 85) / (25 x 15) = 3.4.

One of the simplest ways to assess the association between risk factors and WMSDs is to calculate the ORs (see Table 22). For this example, the prevalence data obtained in health surveillance are linked with the data obtained in risk factor surveillance. In the example shown in Table 22 (for more details, see Hagberg et al., 1995), one risk factor is selected at a time (e.g., overhead work for more than 4 h). Using the data obtained in surveillance, the following numbers of employees are counted:

- Employees with WMSDs exposed to more than 4 h of overhead work (15 workers)
- Employees with WMSDs not exposed to more than 4 h of overhead work (15 workers)
- Employees without WMSDs exposed to more than 4 h of overhead work (25 workers)
- Employees without WMSDs not exposed to more than 4 h of overhead work (85 workers)

The overall prevalence for the company is 30/140, or 21.4%. The prevalence for those exposed to the risk factor is 37.5% (15/40) compared with 15.0% (15/100) for those not exposed. The risk of having a WMSD depending on exposure to the risk factor, the OR, can be calculated using the number of existing cases of WMSD (prevalence). In the example above, those exposed to the risk factor have 3.4 times the odds of having the WMSD than those not exposed to the risk factor. An OR greater than l indicates an elevated risk. Such ratios can be monitored over time to assess the effectiveness of the ergonomics program in reducing the risk of WMSD, and a variety of statistical tests can be used to assess the patterns seen in the data.

## 6.7  Procedures for Job Analysis

Detailed job analysis typically consists of analyzing the job at the element or microlevel. Job surveys, on the other hand, can be used for establishing work relatedness, for prioritizing jobs for further analysis, or for proactive risk factor surveillance. Job analysis involves breaking down the job into component actions, measuring and quantifying risk factors, and identifying the problems and conditions contributing to each risk factor. Tools that might be employed to perform

a job analysis include videotape, tape measure, scale to weigh tools and parts, stopwatch to measure exposure duration, and possibly more sophisticated tools (electrogoniometers to measure wrist joint posture and motion; electromyographic equipment to assess muscle activity; vibration analysis equipment for assessing a powered hand tool's vibration characteristics). Exposures are characterized by magnitude, duration, and rate of repetition. Work organization factors, such as number of hours in a shift (8, 10, 12 h), job rotation schedule if applicable, and pay system (hourly, incentive, etc.). These data may be examined relative to existing research findings, regarding levels of exposure associated with elevated risk, or they may be used as input to tools such as the SI (Moore and Garg, 1995), HAL (ACGIH, 2002), or others, to determine the degree of risk posed by the hazards (risk factors). The website of the Washington State Department of Labor and Industries provides assessment tools as well (http://www.Ini.wa.gov/Safety/Topics/Ergonotnics/Services Resources/Tools/default.asp).

The job analysis should be performed at a sufficient level of detail to identify potential work-related risk factors associated with WMSDs and include the following steps: (1) collection of pertinent information about the job (number of employees on the job, which jobs precede and follow it, cycle time, tools used, etc.), (2) interview of a representative sample of workers, (3) breakdown of the job into tasks or elements, (4) description of the component actions of each task or element, (5) measurement and quantification of WMSD risk factors, (6) identification of the risk factors for each task element, (7) identification of the problems contributing to risk factors (root-cause analysis), and (8) summary of the problems and needs for intervention for the job. If intervention is required, once it has been developed, with input from workers and others, and put in place, follow-up assessments should be performed to ensure that the intervention is effective in dealing with the former problem and that no new problems are inadvertently introduced with the intervention. It is also important to document all of these steps within the analysis process in order to track progress, provide justification for changes, and share information with others about successful interventions.

## 6.8  Medical Management

Both scholarly academic work and various federal agencies and their activities recognize that WUEDs are responsible for a significant proportion of loss of work and also the fact that not all WUEDs that manifest at work can be prevented. Thus, it is extremely important that the management of WUEDs takes the appropriate approach.

### 6.8.1  Basic Activities

The primary objective of medical management in occupational health and safety programs is the prevention of work-related disorders and injuries (Hagberg et al., 1995). The specific goals of occupational health programs relevant to prevention of musculoskeletal

disorders were specified by the American Medical Association (AMA, 1972) as follows: (1) protecting employees against health and safety hazards in their work situation; (2) evaluating workers' physical, mental, and emotional capacity before job placement; (3) ensuring that employees can perform the work with an acceptable degree of efficiency and without endangering their own health and safety or that of others; (4) ensuring adequate medical care and rehabilitation for the occupationally ill or injured: and (5) encouraging and assisting with measures for personal health maintenance, including the acquisition of a personal physician whenever possible.

Medical management of WUEDs includes medical diagnosis, treatment, rehabilitation and return to work, and work hardening (Karwowski and Kasdan, 1988). In addition to these activities, medical management should also be involved in both passive and active health surveillance, job skills training programs, and ergonomic task force activities (Hagberg et al., 1995). As discussed in Section 6.1, the use of injury reports for health surveillance purposes is a form of passive health surveillance. The effective passive health surveillance requires data that have a high sensitivity for WUEDs. Injury reports should be followed up by workplace visits and an evaluation. In a population of workers or in a specific job category where there is a high risk of WUEDs, it may be necessary to perform the active health surveillance (i.e., periodic medical evaluations to identify workers in the early stages of a disease) and to target these workers for early secondary prevention efforts (i.e., medical treatment).

### 6.8.2 Medical Treatment

In general, the medical treatment efforts for WUEDs in the acute phase are similar to the treatments used for non-work-related disorders. As discussed by Hagberg et al. (1995), the general therapeutic objectives for WUEDs should include the following: (1) promotion of rest for the anatomical structures affected, (2) diminished spasms and inflammation, (3) reduction of pain, (4) increase in strength and endurance, (5) increase in range of motion, (6) alteration of mechanical and neurological structures, (7) increase in functional and physical work capacity, and (8) modification of work content and social environment.

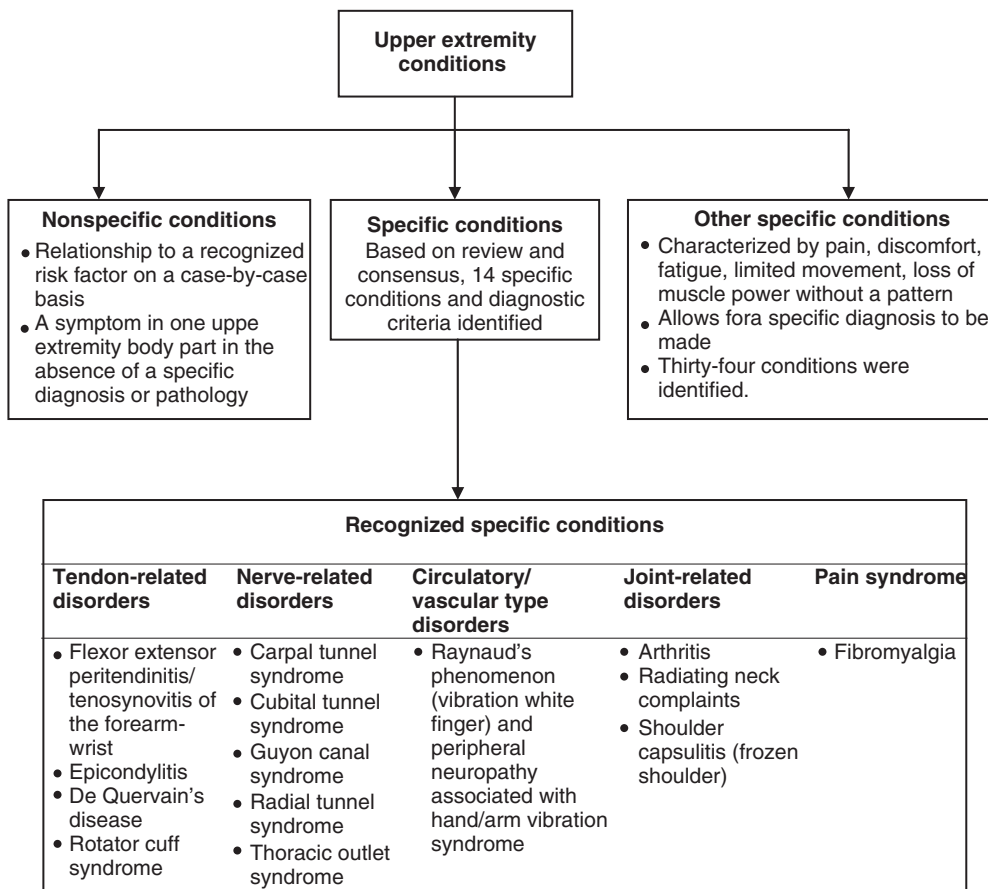

**Figure 7** Proposed model for classifying work-related upper extremity conditions.

**Table 23 Strength of Various WMSD Management Components**

| Criterion | Evidence | Strength of Evidence | Source |
|---|---|---|---|
| Classification and diagnosis | Classification and diagnosis are problematic. Lack of agreement on diagnostic criteria, even for the specific conditions (e.g., tenosynovitis, epicondylitis and rotator cuff syndrome), and Inconsistent application, both in the clinic and in the workplace, lead to misdiagnosis, incorrect labeling, and difficulties in interpretation of research findings. | Strong | Beaton et al. (2007) Huisstede et al. (2006) Van Eerd et al. (2003) Walker-Bone et al. (2003) |
| | The scientific basis for descriptive classification terms implying a uniform etiology is weak or absent (e.g., RSI or CTD). They are inconsistently applied/understood, and there is an argument that such terms should be avoided. | Moderate | Szabo (2006) Hagberg (2005) Lucire (2003) Bonde et al. (2003) |
| Epidemiology | There is a very high background prevalence of upper limb pain and neck symptoms in the general population (e.g., the 1-week prevalence in general population can be as high as 50%), Estimates of the prevalence rates of specific diagnoses are less precise but are considerably lower than for nonspecific complaints, and rates vary depending on region, population, country, case definition, and question asked. | Strong | Huisstede et al. (2006) Palmer and Smedley (2007) Eltayeb et al. (2007) Silverstein et al. (2006) |
| | Upper limb pain is often recurrent and frequently experienced in more than one region at the same time (both bilaterally and at anatomically adjacent sites). | Moderate | Macfarlane et al. (2000) Walker-Bone et al. (2004a) Silverstein et al. (2006) |
| | WUEDs often lead to difficulty with normal activities and to sickness absence, yet most workers with WUEDs can and do remain at work. | Strong | Walker-Bone et al. (2004b) Silverstein et al. (2006) Lee et al. (2006) Baldwin and Butler (2006) |
| Association and risks | Published scientific reviews (which included much cross-sectional data) concluded that there were strong associations between biomechanical occupational stressors (e.g. repetition, force) and WUEDs. Supported by plausible mechanisms from the biomechanics literature, the association was generally considered to be causative, particularly for prolonged or multiple exposures (however, a dose–response relationship generally was not evident). | Moderate | NIOSH (1997) NRC (1999) Industrial Injuries Advisory Council (2006) |
| | More recent longitudinal epidemiological studies also suggest an association between physical exposures and development of WUEDs, but they report the effect size to be rather modest and largely confined to intense exposures. The predominant outcome investigated (primary causation, symptom expression, or symptom modification) is inconsistent across studies and remains a subject of debate. This is true for regional complaints and (with few exceptions) most of the specific diagnoses. | Strong | Walker-Bone and Cooper (2005) Palmer and Smedley (2007) Coggon et al. (2000) Ijmker et al. (2007) |
| | The evidence that cumulative exposure to typical work is the cause of most reported upper limb injury is limited and inconsistent. | Weak | Macfarlane et al. (2000) NIOSH (1997) Hadler (2005) Dembe (1996) |

**Table 23  (Continued)**

| Criterion | Evidence | Strength of Evidence | Source |
|---|---|---|---|
| | Workplace psychosocial factors (beliefs, perceptions, and work organization) have consistently been found to be associated with various aspects of WUEDs, These include symptom expression, care seeking, sickness absence, and disability. | Strong | Walker-Bone and Cooper (2005) Bongers et al. (2006) Woods (2005) Burton et al. (2005) |
| | Individual psychological factors (such as anxiety, distress, and depression) have consistently been found to be associated with various aspects of WUEDs, including symptom expression, care seeking, sickness absence, and disability. | Strong | Mallen et al. (2007) Alizadehkhaiyat et al. (2007) Coutu et al. (2007) Henderson et al. (2005) |
| Interventions for MSDs in general | General management principles are to provide advice that promotes self-management, such as staying active and engaging in productive activity (with appropriate modifications). Pain modulation and control should be directed toward allowing appropriate levels of activity. | Weak | ARMA (2007) Breen et al. (2007) |
| | Programs using cognitive–behavioral approaches are effective and cost-effective at reducing pain and increasing productive activity in both the earlier and the later phases. | Strong | Hanson et al. (2006) Meijer et al. (2005) Marhold et al. (2001) |
| | Multimodal integrated interventions that address both biomechanical and psychosocial aspects at the same time should be useful for managing musculoskeletal problems in the workplace. | Weak | Waddell and Burton (2004) Cole et al. (2006) Selander et al. (2002) Feuerstein et al. (2003) |
| Interventions specifically with respect to WUEDs | Pain management programs using cognitive behavioral principles and multidisciplinary occupational rehabilitation for people with WUEDs can improve occupational outcomes in the short term and significantly reduce days away from work in the longer term. Earlier intervention appears to yield better results. | Moderate | Crawford and Laiou (2007) Feuerstein et al. (1999) |
| | There is a conceptual case that rehabilitation should be started early and that long periods of rest or sick leave are generally counterproductive. | Weak | Hagberg (2005) Helliwell and Taylor (2004) NHMRC (2004) Waddell and Burton (2004) |
| | Ergonomic work redesign directed at equipment or organization has not been shown to have a significant effect on incidence and prevalence rates of WUEDs. Ergonomic interventions can improve worker comfort that can in principle contribute positively to multimodal interventions. | Moderate | Boocock et al. (2007) Szabo (2006) Hadler (2005) Pransky et al. (2002) |
| | There is limited evidence that ergonomic adjustments (e.g., mouse/keyboard design) can reduce upper limb pain in display screen workers Insufficient evidence for equipment interventions among manufacturing workers. | Weak | Boocock et al. (2007) Verhagen et al. (2006) Williams et al. (2004) |
| | In general resting injured upper limbs delays recovery, | Weak | Nash et al. (2004) Melhorn (2005) |

**Table 23** (*Continued*)

| Criterion | Evidence | Strength of Evidence | Source |
|---|---|---|---|
| | Early activity improves pain and stiffness and can speed return to work yet does not increase complications or residual symptoms and may lead to less treatment consumption. | | Haahr and Andersen (2003) Cheng et al. (2007) |
| | There is wide consensus that early return to work is an important goal which should be facilitated by multimodal interventions, including provision of accurate information, pain relief, and encouragement of activity. An integrative approach by all the players (i.e., employer, worker, and health professional) is conceptually a fundamental requirement. | Weak | Cheng and Hung (2007) Lee and Higgins (2006) Breen et al. (2007) Meijer et al. (2005) |
| | Although the components of return-to-work interventions vary, there is emerging evidence that integrative approaches can be effective for MSDs in general and possibly for WUEDs. Facilitation of return to work through temporary transitional work arrangements (modified work) seems to be an important component. | Moderate | Breen et al. (2007) McCluskey et al. (2006) Cole et al. (2006) Franche et al. (2005) |
| Nonspecific complaints and specific diagnoses | There is insufficient robust evidence to identify reliable prognostic indicators that are applicable across the WUED spectrum (specific diagnoses and regional complaints). | Weak | N⊘rregaard et al. (1999) Hagberg (2005) Kuijpers et al. (2004) Ryall et al. (2007) |
| | There is inconsistent and conflicting evidence on whether and to what extent certain specific diagnoses and regional complaints should be conceived differently in terms of overall management targeted at vocational outcomes. | Weak | Hadler (2005) Melhorn (2005) Derebery et al. (2006) Staal et al. (2007) |

*Source:* After Burton et al. (2009).

Medical treatment of WUEDs begins with classification and diagnosis. As Boocock et al. (2009) reviewed, to date, there is much confusion with (1) operational definition of MDSs and (2) accurate classification and diagnosis of conditions appropriate to a particular case. The problem initiates with the nomenclature of the general term of MDS that varied within and between countries with about 14 different terms. The subsequent challenge is identification of conditions. Following the review, Boocock et al. (2009) suggested three broad categories of conditions: (1) specific conditions, (2) nonspecific conditions, and (3) other specific conditions. With these three identification conditions, Boocock et al. (2009) proposed the classification model shown in Figure 7.

### 6.8.3  Rehabilitation, Return to Work, and Work-Hardening Programs

A program that promotes healing and helps an injured worker to return to work and specifies appropriate job placement conditions based on different job tasks and work requirements is called occupational rehabilitation. Since the injury may not always have only a physical basis, psychosocial (at work and outside work) and psychological disability aspects are essential parts of the rehabilitation process. According to the Commission on Accreditation of Rehabilitation Facilities (CARF, 1989), a work-hardening program is a highly structured, goal-oriented, individualized treatment program designed to

maximize a person's ability to return to work. Such a program uses a set of conditioning tasks that are graded progressively in the quest to improve biomechanical, neuromuscular, cardiovascular, and psychosocial functions with real or simulated work activities.

In a recent review, Burton et al. (2009) evaluated various components of WMSD management: (1) classification and diagnosis, (2) epidemiology, (3) association and risks, (4) generic interventions, (5) specific interventions, (6) return to work, and (7) nonspecific complaints and specific diagnoses. Three levels of strength of evidence were used: (1) strong (consistent findings provided by multiple studies), (2) moderate (consistent findings provided by fewer and lower quality studies), and (3) weak (single study, general consensus/guidance). The findings of the review are provided in Table 23.

### 6.8.4  Preemployment and Preplacement Screening

Although there is no scientific evidence that screening can predict the development of WUEDs, preemployment and preplacement screening may be an important part of medical management activities (Hagberg et al., 1995). According to the American College of Occupational and Environmental Medicine Committee on Occupational Medical Practice (ACOM, 1990), screening refers to the application of at least one test (or examination) to

workers in order to identify apparently healthy workers who are at high risk of developing a specific WUED from those workers who are not. Although the screening tests are not diagnostic, preemployment screening and examination are typically performed before any offer of employment can be made. On the other hand, a preplacement screening process is an examination of an employee who has already received an offer of employment and addresses a question of employee placement in a specific job.

## 7  SUMMARY

### 7.1  Balancing Work System for Ergonomics Benefits

As pointed out by Hagberg et al. (1995), there are no perfect jobs or perfect workplaces that are free of all work-related hazards and provide ideal psychosocial conditions for complete satisfaction for all employees. Therefore, one must consider the trade-offs between competing needs for ergonomic improvements at the workplace and establish a basis for identifying the most critical workplace characteristics for design or redesign. Such trade-offs between the biomechanical factors, personal factors, and work organizational factors, including work stress, coping strategies, and organizational practices, require one to balance various ergonomic needs to achieve the solution that will have the greatest benefits for employee health and productivity.

The balance theory-based model proposed by Smith and Sainfort (1989) takes a systems approach by focusing on the interactions between the worker, including the physical characteristics, perceptions, personality and work behavior; the physical and social environments; and the organizational structure that defines the nature and level of worker involvement, interaction, control, and supervision. The capabilities of technologies available to a worker to perform a specific job affect task performance and the worker's skills and knowledge needed for their effective use. Task requirements affect the required skills and knowledge of the worker. Both the tasks and technologies affect the content of the job and physical demands. The balance theory-based model can be used to establish relationships between interacting elements such as job demands, job design factors, and ergonomic loads. Demands that are placed on the worker create loads that can be healthy or harmful. Harmful loads may lead to physical and psychological stress responses that can produce adverse health effects such as WUEDs. It should be noted that a number of personal considerations may also contribute to the physical and psychological effects. These include the strength and health of the worker, previous musculoskeletal or nerve injury, personality, perceptual–motor skills and abilities, physical conditioning, prior experience and learning, motives, goals, and needs and intelligence.

### 7.2  Ergonomics Guidelines

The expected benefits of managing WUEDs in industry are improved productivity and quality of work products, enhanced safety and health of the employees, higher employee morale, and accommodation of people with various degrees of physical abilities. Strategies for managing the WUEDs at work should focus on prevention efforts and should include, at the plant level, employee education, ergonomic job redesign, and other early intervention efforts, including engineering design technologies such as workplace reengineering and active and passive surveillance. At the macrolevel, management of the WUEDs should aim to provide adequate occupational health care provisions, legislation, and industry-wide standardization.

Already widely recognized in Europe (Wilson, 1994), ergonomics has to be seen as a vital component of the value-adding activities of a company. Even in strictly financial terms, the benefits of an ergonomics management program will outweigh the costs of the program. A company must be prepared to engage in a participative culture and to utilize participative techniques. The ergonomics-related problems and consequent interventions should go beyond engineering solutions and must include design for manufacturability, total quality management, work organization, workplace redesign, and worker training. Only then will the promise of ergonomics in managing the WUEDs at work be fulfilled.

In the absence of generally applicable guidelines and criteria on minimizing and/or optimizing risk factor actor exposure, two complementary approaches have merit for the prevention of WUEDs: (1) general guidelines that describe in general terms the principles and policies to be adopted in preventing WUEDs and (2) specific guidelines that aim at the design and redesign of work and tasks that are known in detail (Hagberg et al., 1995). Since the specific guidelines draw on both scientific knowledge and the collective industrial experience, they may be much more detailed and often contain quantitative data.

Most of the current guidelines for control of the biomechanical risk factors for WUEDs at work aim to (1) reduce the exposure to highly repetitive and stereotyped movements, (2) reduce excessive force levels, and (3) reduce the need for sustained postures. For example, to control the extent of force required to perform a task, one should (1) reduce the force required through tool and fixture redesign, (2) distribute the application of force, or (3) increase the mechanical advantage of the (muscle) lever system. Because of the neurophysiological needs of the working muscles, adequate rest pauses (determined based on the scientific knowledge of the physiology of muscular fatigue and recovery) should be scheduled to provide relief for the most active muscles used on the job. Furthermore, reduction in task repetition can be achieved, for example, by (1) task enlargement (increasing variety of tasks to perform), (2) increase in the job cycle time, and (3) work mechanization and automation.

Finally, it should be noted that many of the recommendations offered by ergonomics may be difficult to implement in practice without full understanding of the production processes, plant layouts, or quality requirements and total commitment from all management levels and workers of the company. This is because many of the guidelines are not specific and define what to

avoid (e.g., avoid high contact forces and static loading, avoid extreme or awkward joint positions, avoid repetitive finger action, and avoid tool vibration) but do not define how to avoid these risk factors. In view of the above, involvement of professional ergonomists (i.e., those who are certified by the Board of Certification in Professional Ergonomics), along with engineering personnel and production workers in a truly participative manner, is critical to the success of ergonomic intervention efforts. Furthermore, ergonomics must be treated with the same level of attention and significance as other business functions of the plant (e.g., quality management control) and be accepted as the cost of doing business rather than add-on activity requiring action only when problems arise.

## 1 INTRODUCTION

Warnings are safety communications that are used to inform people about hazards and to provide instructions so as to avoid or minimize undesirable consequences such as injury of death. Warnings are used in a variety of contexts to address environmental and product-related hazards.

In the United States, interest in warnings is also associated with litigation concerns. The adequacy of warnings has become a prevalent issue in product liability and personal injury litigation. According to the Restatement of Torts (second) and to the Theory of Strict Liability, if a product needs a warning and the warning is absent or defective, then the product is defective (see, e.g., Madden, 1999).

Regulations, standards, and guidelines as to when and how to warn have been developed more extensively in the last three decades. Also, there has been a substantial increase in research activity on the topic during this time. Human factors specialists, or ergonomists, have played a major role in the research and the technical literature that has resulted.

This chapter reviews some of the major concepts and findings regarding factors that influence warning effectiveness. Most of the research review is presented in the context of a communication–human information processing (C-HIP) model. The model not only is useful for organizing research findings but also provides a predictive and investigative tool. Following the presentation of the model and the review of major concepts and findings, a collection of recommendations for designing warnings in applications is presented.

## 2 BACKGROUND

In this section several terms will be defined and the role of warnings in the broader context of hazard control will be discussed.

## 2.1 Definitions

It is important to establish a few definitions for terms that will be used in this chapter, particularly the concepts of hazard and danger. These terms are sometimes used in different ways with different meanings; hence, we want to be clear as to their meaning in this context.

*Hazard* is defined as a set of circumstances that can result in injury, illness, or property damage. Such circumstances may include characteristics of the environment, of equipment, and of a task someone is performing. From a human factors perspective, it is important to note that circumstances also include characteristics of the people involved. These people characteristics encompass abilities, limitations, and knowledge.

*Danger* is a term that is used in a variety of ways. In this chapter it is viewed as the product of hazard and likelihood; that is, if one has quantified values of hazard and likelihood, multiplying these quantities would give a value for danger. Note that an implication of this definition is that if either value is zero, there is no danger. If the hazard and its consequence are serious but will not occur, there is no danger. Similarly, if the probability of an event occurring is high but there will be no resulting undesirable consequences, there is no danger. Note, however, people commonly use the words hazard and danger interchangeably.

## 2.2 Hierarchy of Hazard Control

In the field of safety there is a concept of hazard control that includes the notion of a hierarchy (Sanders and McCormick, 1993). This hierarchy defines a sequence of approaches to dealing with hazards in order of preference. The sequence is (1) design it out, (2) guard against it, and (3) warn about it. The notion of a design solution is that the first preference is to eliminate the hazard through alternative designs. If a nonflammable solution can be used effectively for a cleaning task, then such a solution is preferable to wearing protective equipment or warning about avoiding an ignition source due to flammability. Of course, often it is not possible to eliminate hazards. Guarding, whether physical or procedural, is a second line of defense and has as its purpose preventing contact between people and the hazard. Barriers and protective equipment are examples of physical barriers while designing tasks in such a way as to keep people out of a hazard zone is an example of a procedural guard. However, like alternative designs, guarding is not always a feasible solution, and the third line of defense is warning. Warnings are third in the priority sequence because influencing behavior is sometimes difficult and seldom foolproof. There is another implication of this priority scheme; namely, warnings are not a substitute for good design or adequate guarding. Indeed, warnings are properly viewed as a supplement, not a substitute, to other approaches to safety (Lehto and Salvendy, 1995).

In addition to the above three-part hierarchy, there are other approaches that may be effective in dealing with hazards (see, e.g., Laughery and Wogalter, 2011). Generally, they fall into the same category as warnings in that they are means of influencing the behavior of people. Training and personnel selection are examples. Another approach that includes elements similar to procedural guarding and warnings is supervisory control. These latter approaches are particularly applicable to hazards in the context of employment and job performance.

## 3 WARNINGS

In this section the purpose(s) of warnings and some general criteria for warnings are discussed.

## 3.1 Purpose of Warnings

The purpose of warnings can be explained at several levels. Most generally, warnings are intended to improve safety, that is, to decrease accidents or incidents that result in injury, illness, or property damage. At another level, warnings are intended to influence or modify people's behavior in ways that will improve safety. At still another level, warnings are intended to provide information that enables people to understand hazards, consequences, and appropriate behaviors that in turn enable them to make informed decisions. This latter point places warnings as a type of communication.

There are two additional points associated with the purposes of warnings. First, warnings are sometimes used as a means of shifting or assigning responsibility for safety to people in the system, the product user, the worker, and so on, in situations where hazards cannot be designed out or adequately guarded. This point is not to say that people do not have safety responsibilities independent of warnings; of course they do. Rather, a purpose of warnings is to provide the information necessary to enable them to carry out such responsibilities. Whether responsibility has been shifted depends at least in part on the effectiveness of the communications. The second point regarding warnings' communication purpose concerns an issue that has received little attention in the technical literature, namely, people's right to know. This notion makes the point that, even in situations where the likelihood of warnings being effective may not be high, people have the right to be informed about safety problems confronting them. This aspect of warnings relates to personal, societal, and legal concerns.

## 3.2 General Criteria for Warnings

The most important general criterion for warnings is that their design should be viewed as an integral part of the overall system design process. Frantz et al. (1999) address this issue in a chapter on developing product warnings. While safety warnings are a third line of defense behind design and guarding, they should not be considered for the first time after the design (including guards) of the environment or product has already been set and established. Too many warnings are developed at this late stage of design, as an afterthought, and their quality and effectiveness often reflect it. Further, warnings based on unrealistic and untested assumptions or expectations about the target audience are destined to be inadequate.

### 3.2.1 When/What to Warn?

There are several principles or rules that guide when a warning should be used. They include:

1. A significant hazard exists.
2. The hazard, consequences, and appropriate safe modes of behavior are not known by the people exposed to the hazard.
3. The hazards are not open and obvious; that is, the appearance and function of the environment or product do not convey them.
4. A reminder is needed to assure awareness of the hazard at the proper time. This concern is especially important in situations of high task loading or potential distractions.

### 3.2.2 Who to Warn

The general principle regarding who should be warned is that it should include everyone who may be exposed to the hazard and everyone who may be able to do something about it. There are occasions when people in the latter category may not themselves be exposed to the hazard. An example would be the industrial toxicologist who receives warning information regarding a product to be used by employees and who then defines job procedures and/or protective equipment to be employed in handling the material. The physician who prescribes medications with side-effect hazards is another example.

There are, of course, situations and products where the target audience is the general public and that includes nearly everyone. Hazards in the public environment or products on the shelf of a drugstore or hardware store are examples. Other warnings may be directed to a very specific audience. Warnings about the risk of birth defects associated with taking a prescription medication would be directed primarily to women of child-bearing age; although others such as spouses or parents might also receive the warning (Mayhorn and Goldsworthy, 2007). Likewise, as noted above, health care professionals such as physicians or pharmacists should receive the warnings regarding potential birth defects when treating patients who are or may become pregnant. If warnings are to be effective, the characteristics of the target audience should be taken into account.

## 4 COMMUNICATION-HUMAN INFORMATION PROCESSING (C-HIP) MODEL

In this section a theoretical context is presented that will serve as an organizing framework or model for reviewing some of the major concepts and findings regarding factors that influence warning effectiveness. Specifically, a C-HIP model is described (Wogalter, 2006a). To place this model in context, a few general comments about communications and human information processing are in order.

***Communications*** Warnings are a form of safety communications. Communication models have been around for most of the last century (Lasswell, 1948;

Shannon and Weaver, 1949). A typical, very basic model shows a sequence starting with a source who encodes a message into a channel that is transmitted to a receiver who receives a decoded version of that message. Noise may enter into the system at several points in the sequence, reducing the correspondence between the message sent and the one received. The warning sender may be a product manufacturer, government agency, employer, and so on. The receiver is the user of the product, the worker, or any other person at risk. The message, of course, is the safety information to be communicated. The medium refers to the channels or routes through which information gets to the receiver from the sender. Understanding and improving these components of a safety communication system increases the probability that the message will be successfully conveyed.

However, the communication of warnings is seldom as simple as implied by a sequential communication model. Frequently more than one medium or channel may be available and/or involved; multiple messages in different formats and/or containing different information may be called for; and the receiver or target audience may include different subgroups with varying characteristics. An example of such a warning situation would occur when a product with associated hazards is being used in a work environment. Figure 1 illustrates a communication model that might be applicable. It shows the distribution of safety information from several entities to the receiver and that feedback may influence the kind of safety information given. It also shows that in addition to the sender (manufacturer) and receiver (end user), other people or entities may be involved such

**Figure 1**   Distribution of safety information and feedback.

as distributors and employers. Further, each of these entities may be both receivers and senders of safety information. There are also more routes through which warnings may travel, such as from the manufacturer to the distributor to the employer to the user, from the manufacturer to the employer to the user, or directly from the manufacturer to the user (as on a product label). The warnings may take different forms. One example includes safety rules that an employer sets to govern the behavior of employees. Thus, warnings or warning systems may be much more complex than just a sign or label. The concepts of warning systems and indirect warnings are discussed in more detail later in the chapter.

***Human Information Processing*** Cognition is a core area of psychology that is concerned with mental processes such as attention, memory, and decision making. Since the 1960s, much of the theoretical work has been described in terms of stages of processing. Numerous models have been developed and tested. In the next section, C-HIP is described as a model that incorporates some basic stages of mental processing.

***C-HIP Model*** The C-HIP model (Wogalter, 2006a) depicted in Figure 2 is a framework for showing stages

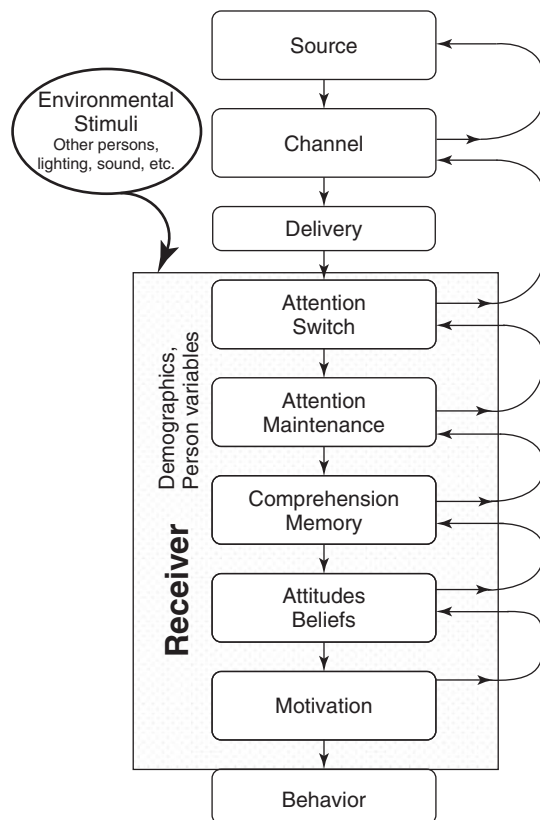

**Figure 2** The C-HIP model.

of information flow from a source to a receiver who in turn may cognitively process the information to subsequently produce compliance behavior. One of the main benefits of the C-HIP model is that it serves as a guiding framework for organizing diverse findings in the warning research literature.

At each stage of the model, warning information is processed and, if successful at that stage, "flows through" to the next stage. If processing at a stage is unsuccessful, it can produce a bottleneck, blocking the flow from getting to the next stage. If all of the stages are successful, the process ends in behavior (compliance). While the processing of the warning might not make it to the last stage, it still may be effective at influencing earlier stages. For example, a warning might positively influence comprehension but not change behavior. Such a warning cannot be said to be totally "ineffective" because it produces better understanding and can potentially lead to better, more informed decisions. However, it is ineffective in the sense that it may not curtail certain unsafe behaviors.

The C-HIP model can be particularly useful in describing the factors that influence warning effectiveness. It also can be helpful in diagnosing and understanding warning failures and inadequacies. If a source (or sender) does not issue a warning, no information will be transmitted and nothing will be communicated to the receiver. Even if a warning is issued by the source, it will not be effective if the channel or transmission medium is poorly matched with the message, the receiver, or the environment. Each of the processing stages within the receiver can also produce a bottleneck preventing further processing. The receiver might not notice the warning and thus not be directly affected. Even if the warning is noticed, the individual may not maintain attention to the warning to encode the information. If the receiver encodes the details of the warning, it still may not be understood. If understood, it still might not be believed; and so on.

Although the processing described above is linear, there are feedback loops from later stages to earlier stages as illustrated in Figure 2. For example, when a warning stimulus becomes habituated from repeated exposures over time, attention is less likely to be allocated to the warning on subsequent occasions. Here, memory (as part of the comprehension stage) affects an earlier attention stage of processing. Another example is that some people might not believe that a product or situation is hazardous, and as a consequence not look for a warning. A third example is that the person may not understand the warning and therefore might switch attention to read it again. These nonlinear effects between the stages resulting from feedback show how later stages influence earlier stages in ongoing cognitive processing.

In the sections that follow, we describe each stage of the C-HIP model and some of the factors that influence it. The purpose is to assist in analyzing how or why warnings may fail or, conversely, what they have to accomplish to succeed. In many respects the model is similar to the information processing models employed by others (Lehto and Miller, 1986; Lehto and

Papastavrou, 1993; Rogers et al., 2000). The model presented here is somewhat different than those presented in Wogalter et al. (1999b) and Wogalter and Laughery (2005). Over the years, the body of research has grown to the extent that it now requires fairly substantial books to describe and summarize the literature (e.g., Wogalter et al. 1999b; Wogalter 2006b). This chapter gives an overview of research findings relevant to each stage of C-HIP. In both Wogalter et al. (1999b) and Wogalter (2006b) there are individual detailed chapters on most of the model's stages. The model has evolved over time. The model that predated the C-HIP (Wogalter and Laughery 1996) simply presented some of the main human information processing stages (i.e., in the receiver section), in other words, only the second section of stages of the eventual C-HIP model. The Wogalter et al. (1999b) version of C-HIP added the first section from communication theory (source and channel). The most recent model from Wogalter (2006a) (shown in Figure 2) is different in four ways from Wogalter et al.'s (1999b) C-HIP model. First, in the current model the attention stage is split into two separate stages, attention switch and attention maintenance. The reason for the split is that these two stages are different and are affected by different variables. The second major difference in the models is that there is now the stage of delivery (Williamson 2006). Delivery refers to the point of warning reception where information is provided to the receiver via one or more channels. The third change in the current model is an explicit reference to the influence of other environmental stimuli. Environmental influences are aspects other than the warning itself that could affect how the warning is processed. They are extrinsic to the warning. Environmental influences can include other information on the product label, the product itself, other people's involvement, other warnings, and other aspects in the environment, including illumination and background noise (Vredenburgh and Helmick-Rich, 2006). The fourth major change from the Wogalter et al. (1999b) C-HIP model to the current model is greater emphasis on the receiver's personal characteristics (e.g., demographics) and task involvement (Smith-Jackson, 2006b; Smith-Jackson and Wogalter, 2007; Wogalter and Usher, 1999). Both the third and the fourth changes serve to emphasize how context (outside the person and warning and internal aspects of the target person) can influence the processing of warning content.

Table 1 shows a summary of some of the primary considerations associated with successful processing at each stage.

### 4.1   Source

The source is the originator or initial transmitter of the warning information. The source can be a person(s) or an organization (e.g., company or government). Research shows that differences in the perceived characteristics of the source can influence people's beliefs about the credibility and relevance of the warning (Wogalter et al., 1999c). Information from a reliable, expert source [e.g., the Surgeon General, the U.S. Food and Drug Administration (FDA)] is given greater credibility, particularly when the expertise is relevant

(e.g., the American Medical Association and the FDA for a health-related warning) (Wogalter et al., 1999c). Indeed, Internet users are more likely to believe facts they encounter on websites that have domain suffixes such as .edu and .gov than .com because they are from educational- or governmental-related sources as opposed to for-profit companies (Wogalter and Mayhorn, 2008). An important aspect that will be discussed in more detail later is that a warning attributed to an expert source may aid in changing erroneous beliefs and attitudes that the receiver may have.

A critical role of the source is to determine if there is a need for a warning and, if so, what should be warned. This decision typically hinges on the outcomes of hazard analyses that determine foreseeable ways injuries could occur. Assuming that the product or environment has been determined to need a warning, one or more communications channels must be used to reach the receiver.

### 4.2   Channel

The channel is the medium in which information is transmitted from the source to one or more receivers. In the past, most warnings have been presented on product labels, on posters, or in brochures. These traditional methods of "static" display will be enhanced through the use of technology-based dynamic displays in the future. Future warning systems will likely have properties that are different and better than those inherent in traditional static warnings [see Wogalter and Mayhorn (2005a) for a review]. For example, computers and sensors can be used to process information to enable warnings to be appropriately tailored to the situation and characteristics of the target user (Wogalter and Mayhorn, 2005a). Whether communicated via traditional static or technology-based dynamic media, warnings are often sent via the visual (printed text warnings and pictorial symbols) and auditory (alarm tones, live voice, and voice recordings) modalities as opposed to the other senses. There are exceptions: An odor added to flammable gases such as propane (LP) or natural gas can make use of the olfactory sense, and a pilot's control stick that is designed to vibrate when the aircraft begins a potentially dangerous stall makes use of the tactile, haptic, and kinesthetic senses.

***Media and Modality***   There are two basic dimensions of the channel. The first concerns the media in which the information is embedded. The second dimension of the channel is the sensory modality used to capture the information by the receiver. Media and modalities are closely tied. Some studies have examined whether presentation of a language-based warning is more effective when presented in the visual (text) versus the auditory (speech) modality. The results are conflicting (although generally either one is better than no presentation whatsoever). Some cognitive research (Penney, 1989) suggests that longer, more complex messages may be better presented visually and shorter messages auditorily. The auditory modality is usually better for attracting attention (a stage described below). However, auditory presentation can be less effective than

**Table 1 Methods and Influences of C-HIP Stages**

| C-Hip Stage | Methods and Influences |
|---|---|
| **Source** | • Determines that hazard is not designed out or guarded<br>• Credible, expert |
| **Channel** | Sensory modality<br>Visual (signs, labels, tags, inserts, product manuals, video, etc.)<br>Auditory (simple and complex nonverbal; voice; live or recorded)<br>Other senses: vibration, smell, pain<br>Generally, transmission in more than one modality is better.<br>Media<br>Print (label, manual, brochure, magazine advertisement sign)<br>Voice (radio, live), Video (TV), Internet |
| **Delivery** | Make sure message gets to target audience(s).<br>Did it arrive to one or more of the receiver's sensory modalities? |
| **Receiver** | Consider demographics of target audiences (e.g., older adults, illiterates, cultural and language differences, persons with sensory impairments). |
| **Attention switch** | Should be high salience (conspicuous/prominent) in cluttered and noisy environments (e.g., using distinctive color, motion/movement)<br>Visual: high contrast, large<br>Presence of pictorial symbols and other graphics can aid noticeability.<br>Auditory: louder and distinguishable from surround<br>Present when and where needed (placed proximal in time and space)<br>Avoid habituation by changing stimulus.<br>Measurement: recording eye and head movements |
| **Attention maintenance** | Enables message encoding by examining/reading or listening<br>Visual: legible font and symbols, high-contrast aesthetic formatting, brevity<br>Auditory: intelligible voice, distinguishable from other sounds<br>Measurement: duration of looking/listening and subsequent recall and recognition |
| **Comprehension and memory** | Enables informed judgment<br>Understandable message that provides necessary and complete information to avoid hazard<br>Try to relate information to knowledge already in users' heads.<br>Explicitness enables elaborative rehearsal and storage of information.<br>Pictorials can benefit understanding and substitute for some wording; may be useful for certain demographic groups (low literates or unskilled in language).<br>At subsequent exposures, warning can cue or remind user of information.<br>Comprehension testing needed to determine whether warning communicates intended/needed information<br>Measurement: Testing understanding of intended message after exposure: Does it communicate all of the intended necessary information? |
| **Beliefs/attitudes** | Perceived hazard and familiarity are beliefs that affect warning processing.<br>Persuasive argument and prominent warning design are needed when beliefs are discrepant with truth so as to appropriately alter those beliefs.<br>Can have influence receiver's earlier stages<br>Measurement: Determine beliefs (pre- and post-). |
| **Motivation** | Energizes person to carry out next stage (behavior)<br>Perceived low cost (time, effort, money) facilitates compliance.<br>Perceived high cost of compliance increases likelihood of noncompliance.<br>Motivation benefited by explicitness and perceived injury severity.<br>Affected by social influence, time stress, mental workload<br>Measurement: Ratings of willingness to carry out the directed behavior |
| **Behavior** | Carrying out safe behavior that does not result in injury or property damage<br>Measurement: Behavioral compliance |

visual presentation, particularly for processing lengthy, complex messages because (a) of its primary temporal/sequential nature, (b) its processing speed is slower, and (c) the ability to review previously presented material is often not possible. These characteristics tend to overload working memory (or maintenance attention, to be discussed later).

***Multiple Methods and Redundancy***   Research has generally found that presenting warnings in two modalities is better than one modality. Thus, a warning is better if the words are shown on a visual display while at the same time the same information is given orally. This provides redundancy. Together they can be beneficial as it provides a way for persons who may be occupied on a task involving attention to one or the other modality to be alerted by the warning. If an individual is not watching the display, people can still hear it. Or, if an individual is listening to something else (or is wearing hearing protection), they could potentially see the message on the visual display. Also, if the individual is blind or deaf, the information is available in the other modality. A similar concept for media is described below.

***Warning System***   The idea that a warning is only a sign or a portion of a label is too narrow a view of how safety information gets transmitted. Warning systems for a particular environment or product may consist of a number of components. In the context of the communication model presented in Figure 1, the components may include a variety of media and messages.

A warning system for a pharmaceutical product such as a prescription allergy medication may consist of several components: a verbal warning from a physician, a printed statement on the box, a printed statement on the bottle, and a printed package insert. In addition, there may be text and/or speech warnings in television and radio advertisements that specifically target consumers. In the United States, direct-to-consumer (DTC) advertisements about prescription pharmaceuticals usually include warnings about side effects and contraindications. Due to the brevity of most broadcast commercials, these DTC ads frequently direct people to other sources of information such as manufacturer websites or a toll-free telephone number (Goldsworthy and Mayhorn, 2010; Kim et al., 2010; Vigilante et al., 2007). Likewise, a warning system for pneumatic tools regarding the hazard of long-term vibration exposure causing damage to the nervous and vascular systems of the hand (vibration-induced white finger) might consist of a number of components. Examples include warnings embossed on the tool, a removable tag attached to the product when new, accompanying sheets or a stapled manual, and printing on the box. In addition, manufacturers might provide employers with supplemental materials such as videos and posters to assist in employee training sessions. Organizations including government agencies and consumer and trade groups could provide additional materials via mail or the Internet. Yet another example would be warnings for a solvent used in a work environment

for cleaning parts. Here the components might include warnings printed on labels of the container, printed flyers that accompany the product, and material safety data sheets (MSDSs) provided to employers. They might also include statements in advertisements about the product and verbal statements from the salesperson to a purchasing agent.

The components of a warning system may not be identical in terms of content or purpose. For example, some components may be intended to capture attention and direct the person to another component where more information is presented. Similarly, different components may be intended for different target audiences. In the above solvent example, the label on the product container may be intended for everyone associated with the use of the product, including the end user, while the information in the MSDS may be directed more to fire personnel or to an industrial toxicologist or safety engineer working for the employer (Smith-Jackson and Wogalter, 2007).

***Direct and Indirect Communications***   The distinction between direct and indirect effects of warnings concerns the routes by which information gets to the target person. A direct effect occurs as a result of the person being directly exposed to the warning. That is, he or she directly reads or hears the warning. But warnings can also accomplish their purposes when delivered indirectly (Wogalter and Feng, 2010). One example gleaned from research by Tam and Greenfield (2010) suggests that the indirect effects associated with alcoholic-beverage warnings may explain gender differences in the likelihood to intervene to prevent others from driving while intoxicated. The employer or physician who reads warnings and then verbally communicates the information to employees or patients is also an example. Moreover, the print and broadcast news media may present information that is given in warning labels. The point is that a warning put out by a manufacturer may have utility even if the consumer or user is not directly exposed to the warning.

An example of where an indirect effect was considered in the design of a product warning concerned a herbicide used in agricultural settings. Given that significant numbers of farm workers in parts of the United States read Spanish but not English, there was reason to put the warning in both languages. However, there are sometimes space constraints on product containers. One suggested strategy was to include a short statement on the label in Spanish indicating that the product was hazardous and that the user should get someone to translate the rest of the label before using the product. There are also other ways to increase surface area to print additional warning material, some of which are described later.

There are situations where we rely on indirect communications to transmit warning information. Employers and physicians are examples already noted; however, adults who have responsibility for the safety of children are another important category (Mayhorn et al., 2006). In the design of warning systems, empowering indirect warnings could enhance the spread of warning information to relevant targets.

## 4.3 Delivery

While the source may try to disseminate warnings in one or more channels, the warnings might not reach some of the targets at risk. For example, a safety brochure that is developed and produced by a governmental agency that is never distributed is not very helpful. Purchasers of used products are at risk because the manufacturer's product manual is frequently not available or is not transferred to new owners at resale (Rhoades et al., 1991; Wogalter et al., 1998b). For example, without the manual, the user may not know what the correct and incorrect uses of the product are or what the maintenance schedule is, which could impact safety. Williamson (2006) describes issues associated with communicating warnings on the flash-fire hazard associated with burning plastic-based insulation. Although there are some warnings accompanying bulk lots of the insulation when shipped from the manufacturer/distributor to job sites and some technical warnings that may be seen by architects and high-level supervisors, the warnings infrequently make it downstream to construction workers who may be working with or around the product. Likewise, prescription medications that are shared with others may not be seen in the original containers that include warnings regarding side effects (Goldsworthy et al., 2008b). The point here is that while a warning may be put out by a source (through some channel) it may have limited utility if it does not reach the targets at risk either directly or indirectly.

## 4.4 Receiver

In this section the focus is on the receiver, that is, the person(s) or target audience to whom the warning is directed. As noted earlier, the primary theoretical context for presenting this analysis is an information processing model. This model with respect to the receiver, shown in Figure 2, defines a sequence of processing stages through which warning information flows. By examining each of the stages and the factors that influence success or failure at each stage, a better understanding of how warnings should be designed and whether they are likely to be effective can be attained.

For a warning to effectively communicate information and influence behavior, attention must be switched to it and then maintained long enough for the receiver to extract the necessary information. Next, the warning must be understood and must concur with the receiver's existing beliefs and attitudes. If there is disagreement, the warning must be sufficiently persuasive to evoke an attitude change toward agreement. Finally, the warning must motivate the receiver to perform proper compliance behavior. The next several sections are organized around these stages of information processing.

### 4.4.1 Attention

One of the goals of a warning is to capture attention and then hold it long enough for the contents to be processed. The following sections address these two attention issues.

*Attention Switch* The first stage in the human information processing portion of the C-HIP model concerns the switch of attention. An effective warning must initially attract attention. Often this attraction must occur in environments where other stimuli are competing for attention.

For a warning to capture attention it must first be available to the recipient. As noted earlier, warning messages will not have direct effects if they are not received by the end user. Assuming the warning is present, it needs to be sufficiently salient (conspicuous or prominent) to capture attention. Warnings typically have to compete for attention, and several design factors influence how well they compete.

*Size and Contrast* Bigger is generally better. Increased print size and contrast against the background have been shown to benefit subsequent recall (Barlow and Wogalter, 1993). Young and Wogalter (1990) found that print warnings with highlighting and bigger, bolder print led to higher comprehension of and memory for owner's manual warnings.

Context plays an important role with regard to size effects on salience. What is important is not just the size of the warning but also its size relative to other information in the display. A bold warning on a product label where there are other informational items in larger print is less likely to be viewed than those larger items.

For some products, the available surface area on which warnings can be printed is limited. This is particularly true for small product containers such as pharmaceuticals. Methods available to increase the surface area for print warnings include adding tags or peel-off labels (Barlow and Wogalter, 1991; Wogalter et al., 1999d). Another method is to put some minimum critical information on a primary label and direct the user to additional warning information in a secondary source, such as available in a well-designed owner's manual or website. Wogalter et al. (1995) have shown such a procedure can sometimes be effective.

*Color* While there are some problems with the use of color such as color blindness, fading, and lack of contrast with certain other colors, good use of color can benefit warnings. Coloration can help a warning attract attention more effectively than a warning that is the same color as its surroundings, including other text around it (e.g., Laughery et al., 1993b). The ANSI(2006) Z535.2 and Z535.4 standard for signs and labels uses color in the signal word panel.

*Pictorial Symbols* Pictorial symbols and icons can be useful for attracting attention (Bzostek and Wogalter, 1999; Jaynes and Boles, 1990; Kalsher et al., 1996; Mayhorn et al., 2004b; Mayhorn and Goldsworthy, 2009; Young and Wogalter, 1990). A common icon used in warnings that can help attract attention is the alert icon (triangle enclosing an exclamation point) (Laughery et al., 1993a) that is found in the signal word panel in the ANSI Z535 style warnings.

*Placement* A general principle is that warnings located close to the hazard both physically and in time

will increase the likelihood of a proper attention switch (Frantz and Rhoades, 1993; Wogalter et al., 1995). A warning on the battery of a car regarding a hydrogen gas explosion hazard is much more likely to be effective than a similar warning embedded somewhere in the middle of a vehicle owner's manual. A verbal warning given two days ago before a farm worker uses a hazardous pesticide is less likely to be remembered and effective than one given immediately prior to using the product.

A warning, even a good one that is located in an out-of-view location, drastically reduces its likely effectiveness. In general, placement of warnings directly on a hazardous product is preferred (Wogalter et al., 1987). However, this cannot always be done given the product and the circumstances of use. There are several factors to be considered in warning placement. One is visibility; a warning should be placed so that users are likely to see it (Frantz and Rhoades, 1993). For example, a warning on a hard drive installed inside a computer will not be seen if the user does not open the interior panel of the computer. People generally do not read owner's manuals of cars they rent; thus, unless warned some other way, such as on a dashboard placard or in a quick-tip chart, drivers will not be made aware of certain safety information. Manufacturers need to consider how their product may be used, so they can select proper locations for warnings. In general, warnings should be located near where they are needed both in proximal location and in time. Task analyses are likely to be beneficial here.

Warnings should preferably be placed before or above the instructions for use. Warnings should not be buried in the middle of other text or on a later page. Wogalter et al. (1987) showed warnings in a set of instructions for mixing chemicals were more likely to be noticed and complied with if placed before the task instructions than following them.

Sometimes practical considerations limit the available options. A small container for some over-the-counter medications may simply not have the space for all of the necessary warning information. Some options for addressing this problem are discussed later.

**Formatting**    Another factor that can influence attention is formatting. Aesthetically pleasing warning text, with plenty of white space and coherent information groupings (Hartley, 1994), are more likely to attract and hold attention (Wogalter and Vigilante, 2003). If a warning contains a large amount of dense text, individuals may decide too much effort is required to read it and thus may decide to direct their attention to something else.

**Repeated Exposure**    A related issue is that repeated and long-term exposure to a warning may result in a loss of attention capturing ability (Wogalter and Laughery, 1996). This habituation can occur over time, even with well-designed warnings. Where feasible, changing a warning's format or content can slow the habituation process (Wogalter and Brelsford, 1994). Such efforts to combat habituation may be accomplished through the use of technology-based dynamic warnings where warning content and format can be changed as needed (Wogalter and Mayhorn, 2005a). For example, electronic highway safety signs that change to dynamically report on actual specific information about real-time traffic flow and the presence of construction, vehicular crash, or flooding ahead are probably much more effective in eliciting more informed and better decisions than a general static sign saying "Traffic Congestion Ahead." More about habituation will be described in a later section.

**Other Environmental Stimuli**    Other stimuli in the environment may compete with the warning for attention capture. These stimuli may include the presence of other persons, various objects that comprise the context, and the tasks being performed. Thus, the warning must stand out from the background (i.e., be salient or conspicuous) to be more likely noticed. This factor is particularly important because people typically do not actively seek hazard and warning information. Usually people are focused on the tasks they are trying to accomplish. Because safety considerations are not always on one's mind, warnings need to be prominent.

**Auditory Warnings**    Auditory warnings are frequently used to attract attention. Auditory signals are omnidirectional, so the receiver does not have to be looking at a particular location to be alerted. Like print warnings, their success in capturing attention is largely a matter of salience. Auditory warnings should be louder and distinctively different from expected background noise. Auditory warnings are sometimes used in conjunction with visual warnings, with the auditory warning serving to call attention to the need to examine a visual warning with more specific information.

**Sensor Technology**    In some instances, hazards or indications of hazards are outside the range of human sensory perception, leaving persons at risk unaware of the danger without some additional means of detection. One example is detecting carbon monoxide gas; it its pure form, it has no odor. Technology has enabled sensors capable of detecting the presence of carbon monoxide gas as well as other gases such as propane and natural gas. There are numerous other kinds of detection systems available that can "sense" a variety of indicators such as motion, temperature, and weight. These sensors can provide input into systems that could, in turn, provide a perceptible and informative warning.

**Attention Maintenance**    Individuals may notice the presence of a warning but not stop to examine it. A warning that is noticed but fails to maintain attention long enough for its content to be encoded is of little direct value. Attention must be maintained on the message for some length of time to extract meaning from the material (Wogalter and Leonard, 1999). During this process, the information is encoded or assimilated with existing knowledge in memory.

With brief warnings the message information may be acquired very quickly, sometimes at a glance. For longer warnings to maintain attention, they need to

have qualities that generate interest and do not require considerable effort. Some of the same design features that facilitate the switch of attention also help to maintain attention. For example, large print not only attracts attention but also increases legibility, thus making reading less effortful and more likely.

*Legibility*   If the warning has very small print, it may not be legible, making it difficult to read. Some persons may not be able to read it even with visual correction and some who might be able to read it with some effort will not. Older adults with age-related vision problems are a particular concern (Wogalter and Vigilante, 2003). Distance and environmental conditions such as fog, smoke, and glare can negatively affect legibility.

Sanders and McCormick (1993) give data on legibility of fonts developed for military applications. Legibility of type can be affected by numerous factors, including choice of font, stroke width, letter compression and distance between them, case, resolution, and justification. There is not much research to support a clear preference for certain fonts over others; the general recommendation is to use relatively plain, familiar fonts. It is sometimes recommended that a serif font, with embellishments in the lettering, such as Times Roman be used for small point sizes containing message text and sans serif font (plain fonts without embellishments) such as Helvetica be used in applications requiring larger point size headline-type text. The American National Standards Institute's (ANSI, 2006) Z535.2 and Z535.4 warning sign and label standard include a chart of print size and expected reading distances in good and degraded conditions.

Contrast and color are other considerations. Black on white or the reverse has the highest contrast, but legibility can be adequate with other combinations such as black print on yellow and white print on red. The selection of color should also be governed by the context in which the warning is presented (Young, 1991). One would not want to use a red warning on a largely red background.

*Formatting*   Visual warnings formatted to be aesthetically pleasing are more likely to hold attention (and thus examined and the information extracted) than a single chunk of dense text (Vigilante and Wogalter, 2003). Formatting can show the organization of the warning material, making it easier to assimilate or accommodate into memory. In general, the use of generous white space and bold bulleted lists are preferred to long, dense prose text (e.g., Desaulniers, 1987; Wogalter and Post, 1989). While aesthetically pleasing at a distance, full justification (straight alignment at both margins) is more difficult to read than "ragged right" justification (straight alignment only at the left margin) because the spacing between letters and words is consistent, thus aiding saccadic movement during reading.

*Pictorial Symbols*   Interest is also facilitated by the presence of well-designed pictorial symbols. Further, research indicates people prefer warnings that have a pictorial symbol to warnings without one (Kalsher et al.,

1996; Mayhorn and Goldsworthy, 2009; Young et al., 1995).

*Auditory*   Simple nonverbal auditory warnings are often used as alert (attention-getting) signals. Frequently, these signals carry very little information other than an attention-switch cue. After the alert is given, the visual modality is usually used to access further information (Sanders and McCormick, 1993; Sorkin, 1987).

### 4.4.2   Comprehension

Warning comprehension concerns understanding its meaning. Some comprehension may derive from subjective understanding such as its hazard connotation given it appearance and presentation and some from the specific language and the symbols used. The processes involve people's existing memory and knowledge together with the warning and contextual stimulation.

*Hazard Connotation*   The idea of hazard connotation is that certain aspects of the warning may convey some level or degree of hazard. It is an overall perception of risk, a subjective understanding of the danger conveyed by the warning components. A similar type of connoted hazard was shown in research by Wogalter et al. (1997) for various container types.

In the United States, current standards such as ANSI (2006) Z535 and guidelines (e.g., FMC Corporation, 1985; Westinghouse Electric Corporation, 1981) recommend that warning signs and labels contain a signal word panel that includes one of the terms DANGER, WARNING, or CAUTION. According to ANSI Z535, these terms are intended to denote decreasing levels of hazard, respectively. Figure 3 shows two ANSI-type warning signal word panels. According to ANSI Z535, the DANGER panel should be used for hazards where serious injury or death *will* occur if warning compliance behavior is not followed, such as around high-voltage electrical circuits. The WARNING panel (not pictured) is used when serious injury *might* occur, such as severe chemical burns or exposure to highly flammable gases. The CAUTION panel is used when less severe personal injuries or damage to property might occur, such as getting hands caught in operating

**Figure 3**   Examples of two signal word panels including alert symbol and color. Note that the DANGER panel is white print on red background and the CAUTION is black print on yellow background. Not shown is the WARNING panel, which is black print on orange background.

equipment. Research shows that lay persons often fail to differentiate between CAUTION and WARNING, although both are interpreted as connoting lower levels of hazard than DANGER (e.g., Wogalter and Silver, 1995). The term NOTICE is intended for messages that are important but do not relate to injuries. The term DEADLY, which has been shown in several research studies to connote hazard significantly above DANGER, has not been adopted by the ANSI, yet it might be considered for hazards that are significantly above those connoted by the term DANGER.

Different characteristics of sounds can lead to different hazard connotations. Higher frequency (higher pitch) and greater amplitude (louder), which have faster repetitions, are perceived as more urgent (Edworthy et al., 1991). Similar effects have been shown with verbal speech (Barzegar and Wogalter, 1998; Hellier et al., 2002; Hollander and Wogalter, 2000; Weedon et al., 2000).

In the ANSI warning's top panel, the signal words DANGER, WARNING, AND CAUTION are assigned to a paired color (red, orange, and yellow, respectively). This assignment is a method of redundancy, which is useful if one cannot read or cannot perceive the color. However, the colors for WARNING (with its color pair orange) and CAUTION (with its color pair yellow) are not readily distinguished with regard to hazard connotation. Nevertheless, DANGER (with its color pair red) is consistently judged as having a higher hazard connotation (as measured by ratings) than the other two signal word–color combinations (e.g., Chapanis, 1994; Mayhorn et al., 2004c).

*Competence*   There are many dimensions of receiver competence that may be relevant to the design of warnings. For example, sensory deficits might be a factor in the ability of some special target audiences to be directly influenced by a warning. A blind person would not be able to receive a written warning, nor would a deaf person receive an auditory warning. A person who is illiterate would not be able to read the warning text.

At the opposite end of the sequence of events is behavior. If special equipment is required to comply with the warning, it must be available or at least easily obtainable. If special skills are required, they must be present in the receiver population. It is not difficult to find examples of warnings that violate considerations of people's limitations. One example is the common warning instruction found on containers of solvents: "Avoid breathing fumes." This might be difficult to carry out for several reasons. One reason is difficulty in detecting fumes, particularly if one cannot see or smell them (e.g., if one has nasal congestion). A second reason pertains to behavior with respect to personal protection equipment. If a respirator with an independent air supply is not available, then avoidance may be difficult.

Three characteristics of receivers related to cognitive competence are important in warning design: technical knowledge, language knowledge, and reading skill. The communication of hazards associated with medications, chemicals, and mechanical devices is complex and technical in nature. If the target audience does not have the relevant technical competence needed to interpret the information, a warning concerning hazards in these domain is likely to be unsuccessful. The level of knowledge and understanding of the audience must be taken into account. This point will be discussed further in a later section.

The issue of language is straightforward, and it is increasingly important. Subgroups in the United States speak and read languages other than English, such as Spanish. As trade becomes increasingly international, requirements for warnings to be directed to users of different languages will increase. Potential ways to deal with this problem include use of multiple languages and pictorials (Lim and Wogalter, 2003).

Reading skills and capabilities in the population vary from illiteracy to graduate-level skills. Yet, high reading levels such as a grade 12 (high school graduation level) are common in warnings that are also intended for individuals who have low-level reading skill. In general, the reading level of at least the most important parts of the warning should be as low as feasible. For general target audiences, the reading level might need to be in the fourth- to sixth-grade levels (education of children 10–12 years old). Clearly, some warnings may be directed at professionals such as licensed health care professionals who have some expected level of training and can therefore be more technical. The reading levels should be matched with the intended target audience. There are readability formulas based on word frequency of use, length of words, number of words in statements, and so on, that are used to estimate reading grade level (Duffy, 1985). These formulas have limitations and are notorious for giving inaccurate estimates on comprehensibility. However, they could be useful in analyzing the text while trying to achieve a comprehensible warning. A discussion of reading level measures and their application to the design of instructions and warnings can be found in Duffy (1985).

An additional point on reading ability concerns illiteracy. Even in the richest countries of the world there are a substantial number of functional illiterates. There are estimates that over 16 million functionally illiterate adults exist in the U.S. population. Therefore, successfully communicating warnings may require more than simply keeping reading levels to a minimum. While simple solutions to this problem do not exist, well-designed pictorials, speech warnings, special training programs, and so on, may be important components of warning systems to accommodate these groups.

*Message Content*   The content of the warning message should include information about the hazard, the consequences of the hazard, and instructions on how to avoid the hazard.

*Hazard Information*   The point of giving hazard information is to tell the target audience about potential safety problems. Example hazard statements are:

Toxic vapors
Slippery floor
High voltage (7200 volts)

A general principle is that the hazard should be spelled out clearly in a warning. The exceptions pertain to when the hazard is (a) generally known by the population, (b) known from previous experience, or (c) "open and obvious." (The latter two concepts will be described in more detail in a subsequent section). Other than these exceptions, hazard information is an important component of most warnings (Wogalter et al., 1987).

**Consequences**   Consequences information concerns the nature of the injury, illness, or property damage that could result from the hazard. Hazard and consequence information is usually closely linked in the sense that one leads to the other; or, stating it in the reverse, one is the outcome of the other. Statements regarding these two elements are sometimes purposely sequenced in this way such as in "Toxic Vapor, Severe Lung Damage."

Sometimes, however, it is desirable to put consequences information near the beginning of the warning for the purposes of getting and holding the receiver's attention (Young et al., 1995). This is particularly true for severe consequences such as death, paralysis, and severe lung damage. So the appropriate sequence of statements is the opposite of that mentioned above, as in "Severe Lung Damage, Toxic Vapor."

There are also situations when the hazard information in a warning is presented and understood, where it may not be necessary to state the consequences in the warning. This point is related to the open and obvious aspects of hazards. For example, a sign indicating "Wet Floor" probably does not need to include a consequence statement "You Could Fall." It is reasonable to assume that people will correctly infer the appropriate consequence. Nevertheless, the hazard statement could be improved with including "Slippery" instead of "Wet" so as to include consequences in with the statement. Although this is a simple example, it shows how consequence information can be included together with a hazard statement relatively easily without appearing superfluous.

An important reason why consequences information is needed is that warning recipients may not make the correct inference regarding injury, illness, or property damage outcomes with more complex hazards than a wet floor. Previous research with older adults indicates that people aged 65+ years often have difficulty comprehending warning content when inferences are required (Hancock et al., 2005). Thus, it is important in designing warnings to assess, if necessary, whether people correctly infer the consequences and, if not, then to reword or redesign the warning so it is more specific and informative.

The lack of specificity is a shortcoming in many warnings. They often fail to provide important details. The statement "May be hazardous to your health" in the context of a toxic vapor hazard does not tell the receiver whether he or she may develop a minor cough or suffer severe lung damage (or some other outcome). Also giving only general information frequently fails one of the main purposes of warnings—to give "informed consent" about risks. As will be discussed later, knowledge about severe consequences can motivate attention to and compliance with the warning message (see section on motivation).

Pictorials can also be used to communicate consequence information. Some pictorials (e.g., for a slippery floor hazard) convey both hazard and consequence information without it being stated separately. Figure 4 contains some example industrial safety symbols that convey hazard and consequence information. Pictorial warnings that illustrate both hazard and consequence information are preferred (Goldsworthy et al., 2008a; Mayhorn and Goldsworthy, 2007, 2009).

**Instructions**   In addition to getting people's attention and telling them about the hazard and potential consequences, warnings should also instruct people about what to do or not do in order to stay safe and/or prevent property damage. Typically, but not always, instructions in a warning follow the hazard and consequence information. An example of an instructional statement is "Must Use Respirator Type 1234," which could be included in the context of hazard and consequence statements, as in "Severe Lung Damage, Toxic Vapors, Must Use Respirator Type 1234." The instruction assumes, of course, that the receiver will know what a type 1234 respirator is and have access to one.

Pictorials can be used to communicate instructions. Figure 5 shows examples of instructional information used in warnings. Note that some pictorials use a prohibition symbol, a circle containing the pictorial with a slash through it. Both the circle and slash are usually red, although sometimes they are black.

Sometimes a distinction is made between warnings and instructions. Warnings are communications about

(a)                    (b)

(c)                    (d)
**Figure 4**   Examples of pictorials conveying hazard information: (a) slippery floor; (b) electrical shock; (c) toxic gas; (d) pinch point.
**Figure 5** Examples of pictorials conveying instructions/directions information: (*a*) wash hands; (*b*) wear hard hat; (*c*) do not drink water; (*d*) no forklifts in area.

safety, while instructions may or may not concern safety. "Keep off the grass" is an instruction that generally has nothing to do with safety (unless the grass is infested with fire ants, in which case the statement alone clearly would not be an adequate warning). When instructions are concerned with safety information or safe behavior, then they can be viewed as part of a warning. In short, warnings include instructions, but not all instructions are parts of a warning.

***Explicitness*** Previously, it was mentioned that specificity is generally preferred over generalities. An important design principle relevant to warning comprehension is explicitness (Laughery et al., 1993a; Laughery and Paige-Smith, 2006). Explicit messages contain information that is sufficiently clear and detailed to permit the receiver to understand at an appropriate level the nature of the hazard, the consequences, and the instructions. The key here is the word "appropriate." A classic example is "Use with adequate ventilation." Does this statement mean open a window, use a fan, or something much more technical in terms of volume of air flow per unit time? Obviously the instruction is not clear. Warnings are frequently not detailed or specific enough. However, sometimes, as stated earlier, technical details are not necessary and could be detrimental in certain instances. The following two examples of warnings, each with hazard, consequence, and instructional statements, are inadequate with regard to explicitness: (a) "Dangerous Environment, Health Hazard, Use Precautions" and (b) "Mechanical Hazard, Injury Possible, Exercise Care." Explicit alternatives might be (a) "Severe Lung Damage, Toxic Chlorine

Vapor, Must Use Respirator-Type 123" and (b) "Pinch Point Hazard—Moving Rollers, Your Hand/Arm May Be Severely Crushed or Amputated, Do Not Operate without Guard X89 in Place."

***Pictorial Symbols*** Pictorial symbols are used to communicate hazard-related information, often in conjunction with a printed text message. Guidelines such as ANSI (2006) Z535.3 and FMC Corporation (1985) place considerable emphasis on the use of safety symbols. Pictorials are particularly useful in helping to increase comprehension (Boersema and Zwaga, 1989; Collins, 1983; Dewar, 1999; Lerner and Collins, 1980; Laux et al., 1989; Wolff and Wogalter, 1993, 1998; Zwaga and Easterby, 1984). Well-designed symbols can be useful to low literates or to persons who do not use the regional language (Mayhorn and Goldsworthy, 2007, 2009). Well-designed pictorials can potentially cue large amounts of knowledge at a glance.

Clearly comprehension is a primary concern for pictorials. In some pictorials, the depiction directly represents the information or object being communicated and will be understood if the person recognizes the intended depiction. Figure 6 shows two examples of direct representation. One shows both a hazard and consequences by depicting a raging fire, and the other shows both the hazard and the instructions, depicting the need for an eye shield. In other pictorials, the symbol may be recognized, but its meaning has to be learned. People may recognize a skull and crossbones, but the fact that it represents a poison hazard would have to be learned. Nowhere is this more apparent than the instance cited by Casey (1998) where hundreds of Kurdish farmers in Northern Iraq died when they consumed grain treated

**Figure 6** Examples of pictorials showing a direct representation: (*a*) raging fire and (*b*) wear eye shield.

**Figure 7** Examples of pictorials that can be recognized only after learning: (*a*) do not enter and (*b*) biohazard.

with alkyl mercury fungicide because they did not recognize the skull and crossbones symbol as meaning "poison." Reports following the incident suggest that the Kurd farmers believed the skull and crossbones symbol to be a piece of artwork associated with a corporate logo. This example clearly illustrates that cultural differences can also affect warning comprehension (Smith-Jackson and Wogalter, 2000). Other pictorials are completely abstract, such as the symbols for the "do not enter" (shown in Figure 7) and biohazard concepts. Symbols such as these also must be learned to be understood. As a general principle, pictorials that directly represent the information, such as a the "wash hands" symbol showing two hands under a faucet, are recognized at a higher rate than pictorials representing abstract concepts.

What is an acceptable level of comprehension for pictorials? This question has been addressed in the ANSI (2006) Z535.3 standard, which suggests a goal of 85% comprehension by the target audience. There are two criteria that seem relevant here. The first is simply that pictorial symbols should be designed to accomplish the highest level of comprehension attainable. If 85% cannot be achieved, the symbol may still be useful if it is better than alternative designs. A second criterion is that the pictorial not be misinterpreted or communicate incorrect information. According to the ANSI (2006) Z535.3 standard, an acceptable symbol must have less than 5% critical confusions (opposite meaning or a meaning that would produce unsafe behavior). Research by Mayhorn and Goldsworthy (2007) illustrates an example of a misinterpretation of a pictorial that was part of a warning for the drug Accutane. This drug is used for severe acne but causes birth defects in babies of women taking the drug during pregnancy. The pictorial shows a side-view outline shape of a pregnant woman within a circle-slash prohibition symbol. The intended meaning of the pictorial is that women should not take the drug if they are pregnant or plan to become pregnant. However, some women incorrectly interpreted the symbol to mean that the drug might help in preventing pregnancy.

**Habituation**    Repeated exposure to a warning over time may result in its being less effective in attracting attention. Even a well-designed warning will eventually become habituated if repeatedly encountered. Sometimes the warning may become habituated with only partial knowledge. While there are no easy solutions to the habituation problem, one approach is to use attention-related features described in this chapter to slow the progress of habituation or to cause dishabituation compared to warnings without the features (Kim and Wogalter, 2009). However, there may be some utility in varying the warnings from time to time. Rotational warnings such as on cigarette packages in the United States were intended to serve this purpose. However, these warnings have not changed in content or appearance in several decades and regular smokers have likely habituated to them. Cigarette warnings in countries like Australia and Canada also have rotating warnings but also have large, highly explicit color pictured ones depicting severe consequences that are more likely to capture attention and reduce warning habituation relative to U.S. cigarette packages. Legislation regarding a U.S. Food and Drug Administration proposal is being considered to update cigarette package warnings to be similar in type to Australia's and Canada's.

**Memory and Experience**    There are several ways to enhance safety knowledge. Employer training, mentioned earlier, is one method. Experience is another way that people acquire safety knowledge. "Learning the hard way" by having experienced an incident (or knowing someone who did) can certainly result in knowledge. Older adults commonly cite personal experience as a source of knowledge regarding hazards associated with household products such as cleaners and appliances (Mayhorn et al., 2004a). However, such experiences are not good experiences to have (!), and they do not necessarily produce accurate perceptions of risk. More on this topic will be given later in the section on beliefs and attitudes.

**Warnings as Reminders**    Although individuals may have knowledge about a hazard, they may not be aware of it at the time they are at risk. In short, there is a distinction between awareness and knowledge. This distinction is analogous to the short-term and long-term memory distinction in cognitive psychology. Short-term, or working, memory is sometimes thought of as conscious awareness, which is known to have limitations. Long-term memory is the vast contents of one's knowledge of the world. The point is that people may have information or experience in their overall knowledge base, but at a given time, it is not in their current awareness—or what they are thinking about. It is not enough to say that people know something. Rather, it is important that people be aware of the relevant information at the critical time. No one knew better than the three-fingered punch press operators of the 1920s that their hand should not be under the piston when it stroked, but such incidents continued to occur. Warnings are insufficient solution in this case. A better solution was a procedural guard requiring the two hands to simultaneously activate separate controls for the press to punch. A similar example comes from hazards associated with farm equipment. Experienced farm workers are quite knowledgeable when asked about the dangers of power take-off (PTO) machinery on tractors, yet a large number of farmers interviewed in a recent study reported knowing someone that had gotten hurt or killed while using this device (McLaughlin and Mayhorn, 2011). Thus, the distinction between knowledge and awareness has implications for the role of warnings as reminders. Potentially warnings could serve to cue information in long-term memory to bring forth related and previously dormant knowledge into conscious awareness (Smith and Wogalter, 2010).

There are several circumstances in which warning reminders are useful and/or needed. Some of the more noteworthy are:

1.   A hazardous situation or product (that is not open and obvious) is encountered infrequently where forgetting may be a factor.

2. Distractions occur during the performance of a task or the use of a product (e.g., environmental stimuli) that will compete for attention.

3. High task loads which exceed attentional capacity, limiting access to related knowledge (high mental workload and task involvement).

When warnings are intended to function only as reminders, it is not always necessary to provide the same information usually required as a full warning. With reminders, getting the person's attention is emphasized. The automobile driver who forgets to fasten the seat belt might be reminded by the buzzer and light warning. (Persons already habituated to cues may need the cues changed.) Another example is the personal digital assistant that can assist users in adhering to medication regimens by sounding an auditory signal when it is time to take a particular medication (Mayhorn et al., 2005). Technology provides the cues to prompt memory.

***"Open and Obvious"***   A source of information about dangers is the situation or product itself. In U.S. law there is a concept of "open and obvious." This concept means that the appearance of a situation or product or the manner in which it functions may communicate the nature of the safety problem. That a knife can cut is apparent to all people except young children. The hazard and consequence of a fall from a height in a construction setting is considered open and obvious unless there are special circumstances. Many hazardous situations are not open and obvious. Some are associated with chemical hazards where labeling and warnings are necessary because the chemical itself might not make the hazard known. Another issue is an attentional one, in which one hazard attracts more attention than another. Hidden hazards have been documented in the agricultural context. Farmers working to repair tractors may actively work to avoid the dangers of moving parts but in doing that succumb to another hazard such as carbon monoxide in an enclosed space (McLaughlin and Mayhorn, 2011).

***Technical Information***   Many warnings require an appreciation of technical information for full and complete understanding of the material. Examples include the chemical content of a toxic material, the maximum safe level of a substance in the atmosphere in parts per million (ppm), and the biological reaction to exposure to a substance. While there are circumstances where it is appropriate to communicate such information (e.g., to the toxicologist on the staff of a chemical plant or the physician prescribing medicine), as a general rule it is neither necessary nor useful to communicate such information to a general target audience. Indeed, it may be counterproductive in the sense that encountering such information may result in the receiver not attending to the remainder of the message. The end user of the toxic material typically does not need to know technical chemical information such as its density in the atmosphere. Rather, he or she needs to be informed that the substance is toxic, what it can do in the way of injury or illness, and how to use it safely. Different

components of the warning system can and often should be used to communicate to the different groups in the target audience.

***Auditory***   Besides simple auditory alerts described earlier in the section on attention, auditory warnings may be used for the specific purpose of conveying particular meanings. These auditory warnings may be nonverbal (distinguishable sounds to cue different things) or verbal (voice).

***Nonverbal Warnings***   Nonverbal auditory warnings can be further divided into simple and complex. Such simple warnings were mentioned in the context of the attention switch stage. Complex nonverbal signals are composed of sounds differing (sometimes dynamically) in amplitude, frequency, and temporal pattern. Their purpose is to communicate different levels or types of hazards. They can transmit more information than simple auditory warnings, but the listener must know what the signal means. Some form of education and training is necessary. Only a limited number of different nonverbal auditory signals should be used to avoid problems in discriminating and cuing their associated meaning (Banks and Boone, 1981; Cooper, 1977).

***Voice Warnings***   Auditory warnings are also transmitted via voice (speech) as in a child being warned from afar by a caretaker. In recent years, voice chips and digitized sound processors have been developed, making voice warnings feasible for a wide range of applications. Under certain circumstances, voice warnings can be more effective in transmitting information than printed signs (Wogalter et al., 1993b; Wogalter and Young, 1991). Additionally voice modifications and manipulations can produce different levels of perceived urgency (Edworthy and Hellier, 2000; Hollander and Wogalter, 2000). Thus there is great promise for voice warnings as they will be increasingly incorporated into daily life. There are, however, some problems inherently associated with voice warnings. Transmitting speech messages requires longer durations than simple auditory warnings or reading an equivalent message. Comprehension can also be a problem with complex voice messages. To be effective, voice messages should be intelligible and brief.

One example of previous research that has successfully demonstrated the utility of voice warnings is Conzola and Wogalter's (1999) "talking box" study. When participants opened the box, a miniaturized voice system delivered a sequence of precautionary steps to be performed before installing a computer disk drive in the box. With safety instructions that require numerous complex steps, working memory could be overloaded if the sequence is provided in one continuous presentation. A system that provides cognitive support by giving carefully timed or user-prompted instructions might be effective in reducing the likelihood of overloading the cognitive system.

### 4.4.3   Beliefs and Attitudes

If a warning successfully captures and maintains attention and is understood, it still might fail to elicit safety

behavior due to discrepant beliefs and attitudes held by the receiver. Beliefs refer to an individual's knowledge of a topic that is accepted as true. Attitudes are similar to beliefs but have greater emotional involvement (DeJoy, 1999). According to the C-HIP model, a warning will be successfully processed at the beliefs-and-attitudes stage if the information concurs with the receiver's current beliefs and attitudes. The warning message is easily processed as this stage if it matches up (and concurrently reinforces) what the receiver already knows. In the process, it will tend to make those beliefs and attitudes stronger and more resistant to change. If, however, the warning information does not concur with the receiver's existing beliefs and attitudes, the beliefs and attitudes must be altered by the warning for it to be effective. The warning must be salient and the message must be strong and persuasive to override preexisting beliefs and motivate compliance.

People's experiences with a situation or product can result in their believing it is safer than it is. It can also be a problem when people believe that their own abilities or competence will enable them to overcome the hazard, such as the drivers who believe their skills with driving will not suffer when they divide their attention by using cellular telephones (Strayer et al., 2003; Wogalter and Mayhorn, 2005b).

*Risk Perception*  One of the important factors in whether people will read and comply with warnings is their perception of the level of hazard and consequences associated with the situation or product. The greater the perceived level of hazard and consequences, the more responsive people will be to warnings (Wogalter et al., 1991, 1993a). Persons who do not perceive products as being hazardous are less likely to notice or read an associated warning (Wogalter et al., 1991; Wogalter et al., 1993a). Perceived hazard is also closely related to the expected injury's severity level. The greater the potential injury, the more hazardous the product is perceived (Wogalter et al., 1991). Even if the warning is read and understood, compliance may be low if the consequence is believed to be low.

*Familiarity*  Familiarity beliefs are formed from past similar experience where at least some relevant information has been acquired and stored in memory. Familiarity may produce a belief that everything that needs to be known about a product or situation is already known (Wogalter et al., 1991, 1993a). A person who is familiar with a piece of equipment might assume that a new, similar piece of equipment operates in the same way as their previous equipment. This may not actually be true, but due to their belief, the person does not read the product manual and as a result could be seriously injured. Numerous studies have explored the effects of people's familiarity/experience with a product on how they respond to warnings associated with the product. Results indicate that the more familiar people are with a product, the less likely they are to look for, notice, or read a warning (Godfrey et al., 1983; Godfrey and Laughery, 1984; LaRue and Cohen, 1987; Otsubo, 1988; Wogalter et al., 1991). Some research has also examined the effects of familiarity on compliance (Goldhaber and deTurck, 1988; Otsubo, 1988). The results have shown that greater familiarity is associated with a lower likelihood to comply with warnings.

This notion of "familiarity breeds contempt," however, should not be overemphasized for at least two reasons. First, people more familiar with a situation or product may have more knowledge about the hazards and consequences as well as an understanding about how to avoid them. Second, with increased use of the product, people are exposed more frequently to the warnings, which can increase the opportunity to be influenced by them. Of course, warnings in tiny dense print may never be read even over many cycles of use. When there is a potential for the negative effects of familiarity to be a factor, stronger warnings may be needed or other efforts required. Clearly, hazardous products that are used repetitively pose special challenges.

Prior experience can be influential in other ways. Having experienced some form of injury or having personal knowledge of someone else being injured has been shown to lead to overestimation of the degree of danger. Similarly, the lack of such experiences may lead to underestimation of danger or not thinking about them at all (Wogalter et al., 1991, 1993a).

A related point concerns the problem of overestimating what people know. Experts in a domain may be so facile with that knowledge that they fail to realize that nonexperts do not have similar skills and knowledge. To the extent it is incorrectly assumed that people have information and knowledge, there may be a tendency to provide inadequate warnings. Fewer cues are necessary for experts to enlist large stores of knowledge relative to the general public. Thus, an important part of the job, environment, and product design is to take into account the target audience's understanding and knowledge of hazards and their consequences [see Laughery (1993) for a discussion of this topic].

### 4.4.4 Motivation

Even if people see, understand, and believe a warning, they may not comply with it. Motivation is very closely tied to behavior because it can serve to energize individuals to carry out activities that they might not otherwise do. Among the most influential factors for motivation with respect to warnings are the cost of compliance and the cost of noncompliance (severity of the potential injury, illness, or property damage). If the warning calls for actions that are inconvenient, time consuming, or costly, there is an increased likelihood that it will not be effective unless the consequences of noncompliance are perceived as highly undesirable.

*Cost of Compliance*  The cost associated with compliance can be a strong motivator. Generally, compliance with a warning requires that people take some action. Usually there are costs associated with taking action. Cost of complying may include time, effort, or even money to carry out the behavior instructed by the warning. When people perceive the costs of compliance to be greater than the benefits, they are less likely to perform the safety behavior. This problem

is commonly encountered in warning analyses, when the instruction statement requires an inconvenient, difficult, or occasionally impossible behavior to carry out. "Always have two or more persons to lift [box or object]" cannot be done if no one else is around. "Wear rubber gloves when handling this product" is inconvenient to do if the user does not have easy access to appropriate gloves and a hardware store is not nearby.

Thus, the requirement to expend extra time or effort can reduce motivation to comply with a warning (Dingus et al., 1991; Wogalter et al., 1987, 1989). A primary way of reducing the cost of compliance is to make the directed behavior easier to perform. For example, if hand protection is required when using a product, gloves might accompany the product. The general rule is that safe use of a product should be as simple, easy, and convenient as possible.

Also, the costs of noncompliance can affect compliance motivation and behavior. This effect is particularly true when the possible consequences of the hazards are severe. Injury associated with noncompliance should be explicitly stated in the warning (Laughery et al., 1993a). Explicit injury–outcome statements such as "Can cause liver disease—a condition that almost always leads to death" provide reasons for complying and are preferred to general, nonexplicit statements such as "Can lead to serious illness." In a sense, compliance decisions can be viewed in part as a trade-off between the perceived costs of compliance and noncompliance.

***Severity of Consequences*** A related issue to costs of noncompliance is severity of consequences. Perceived severity of injury is intimately tied to risk perception, as discussed in the the section on beliefs and attitudes. Severity of injury is a major factor in people's reported willingness to comply with warnings. People's notions of hazardousness are almost entirely based on the seriousness of the potential outcome (Wogalter et al., 1991, 1993a). The likelihood of such events, however, is considered less readily in people's hazard-related judgments (Wogalter and Barlow, 1990; Young et al., 1990, 1992). These findings emphasize the importance of clear, explicit consequence information in warnings. Such information can be critical to people's risk perception and their evaluation of trade-offs between cost of compliance and cost of noncompliance.

***Social Influence and Stress*** Another motivator of warning compliance is social influence. Research (Wogalter et al., 1989) has shown that if people see others comply with a warning they are more likely to comply themselves. Similarly, seeing that others do not comply lessens the likelihood of compliance. Social influence is an external factor with respect to warnings in that it is not part of the warning design. An example of a risky behavior that is strongly influenced by social interaction is the "sharing" of prescription medications by teenagers (Goldsworthy and Mayhorn, 2009; Goldsworthy et al., 2008b). Explicit warnings are needed to counteract misconceptions exacerbated by social factors.

Other factors that influence motivation to comply with a warning are time stress (Wogalter et al., 1998a)

and mental workload (Wogalter and Usher, 1999). In high-stress and high-workload situations, competing activities distribute away some of the cognitive resources available for processing warning information and carrying out compliance behavior.

### 4.4.5 Behavior

The last stage of the sequential process is to carry out the warning-directed safe behavior. Determining what people will do in the context of a warning is a very desirable measure of its effectiveness. Behavioral compliance research shows that warnings can change behavior (e.g., Laughery et al., 1994; Cox et al., 1997; Wogalter et al., 2001). The main issue in contemporary research is to determine the factors and conditions that underlie whether a warning will be effective in producing compliance or not. Silver and Braun (1999) and Kalsher and Williams (2006) have reviewed published research that has measured compliance with warnings under various conditions. Wogalter and Dingus (1999) showed indirect measures may also be useful where a residual outcome of the behavior is examined (e.g., whether a pair of protective gloves have been used according to its stretch marks). Due to the ethical concerns associated with exposing research participants to real hazards, many researchers have measured intentions to comply as a proxy for compliance behavior. Recently, Duarte et al. (2010) described the potential for virtual reality technology to enable the exploration of behavioral compliance without placing users at risk from physical harm, which is one of the main difficulties in doing research that measures actual behavioral compliance.

### 4.4.6 Demographic Factors

The above sections have provided a review of major concepts and findings organized on the basis of the C-HIP model. Newer versions of C-HIP (Wogalter, 2006a) give greater emphasis on demographics differences of receivers. There are also relevant demographic characteristics of receivers. Receivers differ and such differences must be considered in warning design. Laughery and Brelsford (1991) discussed a number of relevant dimensions along which intended receivers may differ. Several such factors have already been discussed, including experience and competence. A number of studies have shown that gender and age may be related to how people respond to warnings. With regard to gender, results suggest a slightly greater tendency for women to be more likely than men to look for and read warnings (Godfrey et al., 1983; LaRue and Cohen, 1987; Young et al, 1989). Similarly, there are research results that show women are more likely to comply with warnings (Goldhaber and deTurck, 1988; Viscussi et al., 1986). However, many other studies either do not report or do not find a gender difference.

Regarding age, the results are mixed. There are results suggesting that people older than 40 are more likely to take precautions in response to warnings (Hancock et al., 2005; Mayhorn et al., 2004a; Mayhorn and Podany, 2006). However, some research (Wogalter and Vigilante, 2003; Wogalter et al., 1999d) has shown that

older adults have more difficulties reading small print on product labels than younger adults. Other research (Collins and Lerner, 1982; Easterby and Hakiel, 1981; Ringseis and Caird, 1995; Schroeder et al., 2001; Shorr et al., 2009) has shown that older subjects had lower levels of comprehension for safety-related symbols than younger adults. Results such as these suggest that older adults may be more influenced by warnings, but legibility and comprehension need to be considered in their design.

Other potentially important demographics include locus of control (Laux and Brelsford, 1989; Donner, 1991) and self-efficacy (Lust et al., 1993). Persons who believe that they can control their destiny and/or who are less confident in a situation or task are more likely to read available warnings than persons who believe that fate controls their lives and/or who are more confident in a situation or task. When designing warnings for the general population, it may not be possible to address all of the needs of different people with a single warning; thus, a multimethod systems approach may be needed to meet the needs of the varying target audience.

### 4.4.7 Summary and Benefit of C-HIP

The above review of factors influencing warning effectiveness was organized around the C-HIP model. This model divides the processing of warning information into separate stages that must be completed successfully for compliance behavior to occur. A bottleneck at any given stage can inhibit processing at subsequent stages. Table 1 summarizes some of factors that influence the processing at each stage.

The basic C-HIP model can be a valuable tool in developing and evaluating warnings. Identifying potential processing bottlenecks can be useful in determining why a warning may or may not be successful. The model, in conjunction with empirical data obtained in various types of testing, can identify specific deficiencies in the warning system. Suppose a manufacturer finds that a critical warning on their product label is not working to prevent injury. The first reaction to solving the compliance problem might be to increase the size of the font so more people are likely to see it. But noticing the warning label (the attention switch stage) might not be the problem. Product testing might instead reveal that virtually all users report having seen the warning (attention switch stage), having read the warning (attention maintenance stage), having understood the warning (comprehension and memory stage), and having believed the message (the beliefs and attitudes stage). Thus, the problem with the manufacturer's warning in this case is likely to be at the motivation stage—users may not be complying because they believe the cost of complying with the warning (e.g., wearing uncomfortable personal protection equipment) did not outweigh the small perceived risk about getting injured. The point here is that one could use the model to pinpoint the causes of the warning not working and try to remedy it by targeted means. By using the model as an investigative tool, one can determine the specific causes of a warning's failure and not waste resources trying to fix a wrong aspect of the warning's design.

For the practitioner, the model has utility in determining the adequacy and potential effectiveness of a warning. To the extent that a warning fails to meet various design criteria, the model can be a basis for judging adequacy. The lack of signal words, color, and pictorials or a poor location can be a basis for judging its adequacy regarding attention. A high reading level, the use of technical terminology, or the omission of critical information may be the basis of a warning's comprehension inadequacy. The failure to give a persuasive statements and a conspicuous presentation could result in low effectiveness. The failure to provide explicit consequences information when the outcome of noncompliance is catastrophic is inconsistent with warning adequacy criteria regarding motivation. Considerations such as these can be useful in formulating opinions and addressing issues on why a warning was not successful.

## 5 DESIGNING FOR APPLICATION

It is important to design warning systems that will maximize their effectiveness. This section considers basic guidelines and principles to assist in the design and production of warnings.

### 5.1 Standards

A starting point in designing warnings is to consider existing guidelines such as the ANSI (2006) Z535, FMC Corporation (1985), or Westinghouse Electric Corporation (1981). ANSI Z535 is currently a six-part standard which includes descriptions of safety colors, signs, symbols, labels, tags, and ancillary materials. ANSI standards are voluntary standards; that is, they are only recommendations and are generally considered "minimums." We believe that blindly following the ANSI standard will not lead to great warnings. There is a need for some human factors judgment and testing to fine tune the warning for the particular product or situation. In the ANSI Z535 standard, there is an emphasis on a standardized way to format signs (Z535.2) and product labels (Z535.4). According to these standards, warning signs and labels should possess the following components: (1) a signal word panel such as DANGER, WARNING, or CAUTION (with corresponding red, orange, or yellow color) and an alert symbol (triangle enclosing an exclamation mark) to attract attention to the warning and connote levels of hazard, (2) a hazard statement that briefly describes the nature of the hazard, (3) a description of the possible consequences associated with noncompliance, and (4) instructions for how to avoid the hazard. Research indicates that each of these four components can provide benefit to warning efficacy. There may be exceptions when one (or more) of the message components are clear or redundant from the other statements (Wogalter et al., 1987; Young et al., 1995) or from the presence of a pictorial symbol. Pictorial symbols can provide information on the hazard, consequences, or appropriate (or inappropriate) behavior and so can be used in lieu of some of the component text, assuming understandable symbols are used. Safety symbols should meet certain comprehension criteria to be acceptable for use by itself (without words). Both

the ANSI (2006) Z535.3 and the International Organization for Standardization (ISO, 2001) 9186 symbol standards provide guidelines and methods to assess symbol comprehension.

## 5.2  Checklist of Potential Warning Components

Use of only standards and guidelines may not always produce an effective warning. Table 2 presents a checklist of factors that should be considered in designing warnings. These factors are based not only on standards and guidelines but also on empirical research. Examples of measurement methods are also provided in the table. While not an exhaustive list, the table contains a set of factors that the warning literature indicates should be considered in warning design. Thus, one method of assessing warning quality is simply to determine the extent to which the design meets appropriate criteria such as those given in Table 2. With respect to attention, the effectiveness of the warning might be questioned if

**Table 2  Warning Design Guidelines**

| Warning Components | Design Guidelines |
|---|---|
| **Signal words** | DANGER — Indicates immediately hazardous situation that will result in death or serious injury if not avoided; use only in extreme situations. Use white print on a red background (ANSI Z535).<br>WARNING — Indicates a potentially hazardous situation that may result in death or serious injury if not avoided. Use black print on an orange background.<br>CAUTION — Indicates a potentially hazardous situation that may result in minor or moderate injury. Use black print on a yellow background.<br>NOTICE — Indicates important nonhazard information. Use white print on a blue background.<br>Although not in ANSI Z535, the term DEADLY connotes higher-level hazard than DANGER.<br>On the left side of the signal word is the alert symbol (triangle surrounding an exclamation mark). |
| **Format** | Text should be high contrast, e.g., black print on white or yellow background, or vice versa.<br>Left justify message text although headings can be centered.<br>Orient messages to read from left to right.<br>Each statement starts on its own line (list or outline format).<br>Use white space or bullet points to separate statements or sets of statements.<br>Give priority most important warning statements, e.g., position at the top. |
| **Wording** | Use as little text as necessary to clearly convey the message.<br>Give information about the hazard, instructions on how to avoid hazard, and consequences of failing to comply.<br>Be explicit — tell exactly what the hazard is, what the consequences are, and what to do or not do.<br>Use short statements rather than long, complicated sentences.<br>Use concrete rather than abstract wording.<br>Use short, familiar words.<br>Use active voice rather than passive voice.<br>Remove unnecessary connector words, e.g., prepositions, articles.<br>Avoid using words or statements that might have multiple interpretations.<br>Avoid using abbreviations unless they have been tested on the user population.<br>Use multiple languages when necessary. |
| **Pictorial symbols** | When used alone, acceptable symbols should have at least 85% comprehension scores, with no more than 5% critical confusions (opposite or very wrong answers).<br>Comprehension test — use open ended with relevant context.<br>Pictorials not passing a comprehension test should be accompanied by words, but critical confusions should still be avoided.<br>Use bold shapes. Avoid including irrelevant details.<br>Prohibition (circle slash should not obscure critical elements of symbol).<br>Should be legible under degraded conditions, e.g., distance, size, abrasion. |
| **Font** | Text should be legible enough to be seen by the intended audience and expected viewing distance and angle.<br>Use mixed-case letters. Avoid using all caps except for signal words or for specific emphasis.<br>Use san serif fonts (Arial, Helvetica, etc.) for signal words and larger size text.<br>Use serif (Times, Times New Roman, etc.) fonts for smaller size text.<br>Use plain, familiar, nonfancy font.<br>Do not have letters too close to or touch each other. |
| **Other** | Located/positioned so presentation is where it will be seen or heard.<br>Test to assure message fulfills C-HIP stages in Table 1. |

no signal word is used, no color is employed, the print is small, the message is embedded in other types of information, and so on. With respect to comprehension, if the reading level is high, technical language is used, or the statements are vague and not explicit, then the warning may not be interpreted as intended. Similar considerations can be applied with respect to the criteria for the other stages.

Implementation of specific factors may also depend on situational-specific considerations such as target audience knowledge and/or characteristics of the product. For example, some warning components may not be necessary if the target audience consists of trained experts or if the information is apparent from other aspects of the situation.

## 5.3 Principles

In addition to the factors specified in Table 2, there are several other important principles or general guidelines that should be considered when designing warning systems. These principles are described in the following sections.

### 5.3.1 Principle 1: Brief and Complete

As a general rule, warnings should be as brief as possible. Two separate statements should not be included if one will do, such as in the slippery floor example cited earlier. Longer warnings or those with nonessential information are less likely to be read, and they may be more difficult to understand. Thus, the brevity criterion conflicts to some extent with the explicitness criterion. Being explicit about every hazard could result in very long warnings. Obviously, the brevity criterion should not be interpreted as a license to omit important information. A "happy medium" between brevity and completeness is discussed in the next section on prioritization.

A concept related to completeness is overwarning. The term overwarning is sometimes used to label the extent to which our world is filled with warnings. The negative cited from overwarning is that people may not attend to them or may become highly selective, attending only to some warnings. The notion is that if warnings were to be placed on everything, people would simply ignore them. While this notion has face validity, there has been little empirical data assessing the limits implied. Nevertheless, overwarning may be a valid concern, and unnecessary warnings should be avoided.

An important issue related to overwarning that frequently arises in litigation is the absence of certain information. An argument that is sometimes made is that information being left off was somehow a benefit to consumers because its inclusion would hurt the likelihood of other important information being read. However, this is often just a post hoc defense and it does not comport with "right to know." The notion of informed consent says that warnings should provide to people the opportunity to know about hazards. Indeed, research indicates that people want to know about hazards even if is difficult to give definitive risk information (Freeman and Wogalter, 2002; Cheatham and Wogalter, 2003). Prioritization, discussed in the next

section, is a useful approach in dealing with warnings for products and equipment that have multiple hazards.

### 5.3.2 Principle 2: Prioritization

Prioritization concerns what hazards to warn about and to emphasize when multiple hazards exist. How are priorities defined in deciding what to include/delete, how to sequence items, or how much relative emphasis to give them? The criteria overlap the rules about what and when to warn. According to Vigilante and Wogalter (1997a, 1997b), considerations include:

1. *Likelihood*. The more frequently an undesirable event occurs, the greater the priority it should be given as a warning.

2. *Severity*. The more severe the potential consequences of a hazard, the greater priority it should be warned. If a chemical product poses a skin contact hazard, a higher priority would be given to a severe chemical burn consequence than if it were a minor rash.

3. *Known (or Not Known) to Target Population*. If the hazard is already known and understood or if it is open and obvious, warnings may not be needed (except as a possible reminder).

4. *Importance*. Is it important for individuals to know? In most cases, people want the opportunity to know about risks. Some hazards may be more important to people than others.

5. *Practicality*. There are occasions when limited space (a small label) or limited time (a television commercial) does not permit all hazards to be addressed in a single component of the warning system.

As a general rule, unknown and important hazards leading to more severe consequences and/or those more likely to occur should have higher priority than less severe or less likely hazards. Higher priority warnings should be placed on the product label. If not practical to place them all on the label, those with lower priority might go on other warning system components such as package inserts, manuals, websites, or other media.

### 5.3.3 Principle 3: Know the Receiver

Gather information and data about relevant receiver characteristics. To illustrate such an effort, Goldsworthy et al. (2010) describe an analytic technique known as latent class analysis (LCA) to facilitate the tailoring of warning content designed to prevent the sharing and exchanging of prescription medications. Receiver-centered testing of the target audience was particularly important because of the complex risk-related scenarios involved.

A related way to meet the needs of receivers is to purposely tailor for the warning as appropriate to the person, product, and/or situation. One approach to tailoring warnings can be accomplished through the use of technology, such as using sensors, computers, software, and displays (Wogalter and Mayhorn, 2005a). To

provide such customization, data must be collected and quickly processed to anticipate and present the needed warning information at the appropriate time. Users could carry relevant data with him or her. Currently, there are "smart" credit cards that contain user information and wireless electronic tags that can transmit information within a short proximity (e.g., ExxonMobil's Smart Pass, which identifies credit customers by passing an electronic key near the face of the gas pump). Advanced warning systems would be able to supply information tailored to meet people's particular needs.

### 5.3.4 Principle 4: Design for Low-End Receiver

When there is variability in the target population, which is almost always the case with the general public, design for the low-end extreme. Safety communications should not be written at the level of the average or median percentile person in the target audience. Such warnings will present comprehension problems for people at lower competence, experience, and knowledge levels. Likewise, formatting and presentation should take into consideration those who are older, perceptually disabled, and otherwise unable to access the warning information. An added benefit of designing warning systems for the low-end user is the realization that these solutions typically result in more user-friendly products and environments that benefit all consumers regardless of ability and demographic differences (Vanderheiden, 1997).

### 5.3.5 Principle 5: Warning System

When the target audience consists of subgroups that differ on relevant dimensions or when they may be involved under different conditions, consider employing a warning system that includes different components for the different subgroups. Do not assume that everything will be accomplished with a single warning or warning method.

### 5.3.6 Principle 6: Durability

Warnings should be designed to last as long as needed. There are circumstances where durability is typically not a problem. A product purchased off the shelf of a drug store that will be completely and immediately consumed is an example. On the other hand, products with a long lifespan, such as cars and lawn mowers, may present a challenge (Glasscock and Dorris, 2006). Similarly, in situations where warnings are exposed to weather such as on construction sites or extensive handling such as on some containers, durability problems can influence comprehension (Shorr et al., 2009). Some products have manuals that list warning labels with part numbers, presumably to enable ordering label replacements when needed. Undoubtedly replacement labels are not frequently ordered, a factor that suggests the original labels should be as durable as possible so as to last to the high-end range of the expected life of the product.

Related to durability is ancillary material that accompanies the product when originally purchased as new. Warnings may be printed on a an outer container box or packaging and on an insert or in an owner's manual. These ancillary materials may not be available at later uses of the product. The box or packaging may be discarded (Cheatham and Wogalter, 2003) or the owner's manual may be discarded or misplaced (Wogalter et al., 1998b) or never transferred to subsequent owners or users of a product (Mehlenbacher et al., 2002). This is why consideration of what warnings to place directly on a product (or on a container) is critical because they may be the only ones available to users at later points in time.

### 5.3.7 Principle 7: Test the Warning

In addition to considering design criteria, it is frequently necessary to carry out some sort of testing to evaluate a particular warning or several prototype warnings. This approach may entail using small groups of people to give ideas for improvement and/or formal assessments involving larger numbers of people giving independent evaluations. Of course, the sample should be representative of the target audience while also considering practicality and feasibility.

To assess attention, a warning could be placed on a product and have people carry out a relevant task using the product to determine if they look at or notice it. Regarding comprehension, conducting studies to assess the extent to which a warning is understood probably has one of the best cost–benefit ratios of any procedure in the warnings design process. Relative to behavioral studies, comprehension can be assessed easily and quickly and at low cost. Well-established methodologies involving memory tests, open-ended response tests, interviews, and so on, are applicable. While the qualitative data that result from open-ended and interview methodologies can be problematic, such studies can be exceptionally valuable in determining what information in the warning was or was not understood as well as what might be done in the way of redesign to increase the level of comprehension.

Studies can also be carried out to determine the extent to which members of the target audience accept the warning information as true and to be applicable to them (beliefs and attitudes). Negative results on these dimensions would indicate the warning lacks sufficient persuasiveness. Motivation can be assessed by obtaining measures of compliance intentions. While such intention measures will generally reflect higher levels than actual compliance, they can be useful for determining whether or not the warning is likely to be effective as well as for comparing warnings to determine which would likely be more effective.

While behavioral compliance studies are generally difficult to execute, in situations where negative consequences of an ineffective warning are high, the effort may be warranted. As mentioned earlier, a possible alternative is to utilize virtual reality methodology to avoid such ethical issues (Duarte et al., 2010). If such technology is not available, behavioral intentions can be measured as a proxy for behavioral data. Poor warnings tend to result from no testing whatsoever.

Studies carried out to evaluate the potential effectiveness of a warning must, of course, incorporate appropriate principles of research design. The selection of

subjects to be representative of the target population, avoiding confounding by extraneous variables, guarding against contamination by expected outcomes, and determining the best coding rubric to assess qualitative comprehension data from open-ended assessments are a few of the more salient factors that must be considered. For a more complete discussion of approaches to evaluating warning effectiveness, see Frantz et al. (1999), Kalsher and Williams (2006), Mayhorn and Goldsworthy (2009), Wogalter and Dingus (1999), Young and Lovvoll (1999), and Wogalter et al. (1999a).

## 6 SUMMARY AND CONCLUSIONS

Warning design and effectiveness are comprised of many factors and considerations. In this chapter we have presented an overview of the current status of research, guidelines, and criteria for designing warnings.

Approaches to dealing with environmental or product hazards are generally prioritized such that the first one tries to solve the problem by design, then by guarding, then by warning. Thus, in the domain of safety, warnings are viewed as a third but important line of defense.

Warnings can be properly viewed as communications whose purposes include informing and influencing the behavior of people. Warnings are not simply signs or labels. They can include a variety of media through which various kinds of information get communicated to a broad spectrum of people. The use of various media or channels and an understanding of the characteristics of the receivers or target audiences to whom warnings are directed are important in the design of effective warnings. The concept of a warning system with multiple components or channels for communication to a variety of receivers is central in this regard.

The design of warnings can and should be viewed as an integral part of systems design. Too often it is carried out after the environment or product design is essentially completed, a kind of afterthought phenomenon. Importantly, warnings cannot and should not be expected to serve as a cure for bad design.

In this chapter, the C-HIP model was described. It involves processing stages based on communication theory and human information processing theory. As part of this discussion, relevant factors influential at each stage were presented. In addition, guidelines and principles for warning design in application were presented. Its potential use as an investigative tool was also discussed.

Determining whether or not a warning will influence behavior is often a difficult assignment. In addition to ethical problems of exposing people to hazards, actual field studies testing warnings are likely to be time consuming and costly. Certainly, where feasible, such studies are desirable. Also, while laboratory or other controlled simulations of warning situations can be useful in assessing behavioral effects, such approaches leave open questions of generalizability. Studies that examine the effects of warnings on attention, comprehension, beliefs and attitudes, and motivation to comply can be valuable as part of the

process of designing and assessing warnings. Such studies can help in isolating why a warning is not effective. A behavioral study that shows people do not comply with a warning may not tell us if it failed because it was not noticed, because it was not understood, because it was not believed, or because it was unable to motivate. Studies employing attention, comprehension, risk perception, or behavioral intention measures can provide information that, in turn, can be useful in developing improved warning designs.

The issue of warning effectiveness has received a great deal of attention in recent years, especially the means by which effectiveness is assessed. Several criteria can be employed in assessing warnings, including whether they capture and maintain attention, are understood, are consistent with or capable of modifying beliefs and attitudes, motivate people to comply, and result in people behaving safely. The assessment of warning effectiveness employing approaches provides useful input toward the goal of providing effective warnings.

## 1 INTRODUCTION

Personal protective equipment (PPE) belongs to a group of equipment that protects employees against dangers in the workplace. The decision to use such equipment must be preceded by all possible actions, both technical and organizational, aimed at eliminating or reducing the hazard to an admissible level. Despite the above rule, the use of PPE is still very common in many workplaces. This includes, in particular, mining, construction, transportation, and working in rooms with small capacity, for example, containers, manholes, and canals, and refers to all types of emergency actions.

A frequent cause of accidents in the workplace is failure to use PPE by the workers or their wrong selection for the level of risk connected with the occurring hazards. Workers' reluctance to use PPE may result from the equipment not being well fitted to the needs of a user and additional conditions connected with work organization in a specific workplace.

In this chapter, issues concerning the safety of specific protection equipment will be discussed with special attention on their types, considering their correct selection for the type of hazard, ergonomics, and rules of application in workplaces.

Awareness of the discussed issues will make it possible to prepare a management system for protection equipment in companies which should include the following elements:

- Risk evaluation that enables selection of equipment and protection class (i.e., hazard identification, the way it influences the body, the set hygienic norms exceeded)
- Workplace characteristics, including the type of occupational activities of a worker, microclimate, space limitation, necessity to move and communicate, speed of potential evacuation from a dangerous zone, additional hazards, for example, fire or explosion
- Participation of workers using this equipment in the process of selecting construction solutions
- Permanent training for the users, with particular stress placed on workers' motivation, increasing their awareness concerning not using protection, understanding the manufacturer's instructions, practical fitting and application, time limitations, and problems that may occur during use
- Selection of workers on the basis of psychomotor predispositions with particular emphasis on their current health
- Marking the zones where it is necessary to use respiratory protection equipment
- Ensuring correct maintenance and repairs
- Permanent monitoring through a system of audits in the field of appropriate selection, use, maintenance, and updating of training courses

## 2 SELECTION OF RESPIRATORY PROTECTIVE DEVICES FOR DIFFERENT TYPES OF WORKPLACES

Respiratory protective devices have a complex structure which depends on their purpose and scope of use. They protect workers against risks to life or dangers that can cause serious and irreversible damage to health and whose effects cannot be determined by users quickly enough. The need to ensure such high-performance protection imposes specific requirements for the protection parameters and on conducting proper training for users. Selecting which employees should use the equipment while working and during rescue operations is very important as well.

Because of the way they function, respiratory protective devices are divided into two main groups: purifying and isolating (breathing apparatus).

Filtering equipment cleans the air in the worker's breathing zone of the harmful substances present in the working environment in the form of aerosols (including bioaerosols), vapor, and gases.

This equipment can be divided into three main groups: particle-filtering, gas-filtering, and combined devices.

Particle-filtering respiratory devices are used in the working environment if there is pollution in the form of dust, smoke, or mist in excess of designated values corresponding to the maximum allowable concentration (MAC). They are available as filtering half masks, filters with facepiece (mask, half mask, quarter mask, mouthpiece), power-assisted devices with masks or half masks, and powered devices with loose-fitting facepieces (helmets, hoods).

Gas-filtering respiratory protective devices are used if in the working environment pollution occurs in the form of vapor and/orr gas.

The equipment is in the form of gas-filtering half masks, gas filters with facepiece (mask, half mask, quarter mask, mouthpiece), power-assisted devices with masks or half masks, and powered devices with loose-fitting facepieces (helmets, hoods).

Often the working environment may contain impurities in the form of vapor and/or toxic gases and aerosols (dust, fumes, mists). In such situations it is necessary to use the combined respiratory protective devices, which can filter both particles and gases.

Because of the way they operate and the way the air is supplied, breathing apparatus are of two types: air line and self-contained. The first group consists of compressed line and fresh-air line breathing apparatus. These apparatus may contain various types of facepieces depending on user needs and requirements: masks, hoods, face shields, helmets, and so on. The apparatus in the second group, the self-contained apparatus, operate in an open circuit (air-breathing apparatus) and a closed circuit (oxygen apparatus). Self-contained apparatus are completed only with the masks or mouthpieces. Such equipment is used in conditions of oxygen deficiency (below 19%) and in cases of unidentified air pollutants in unknown concentrations.

Efficiency of energetic processes of human being organism is only 20%. It means that 80% of energy turns into the heat and cause extra load to organism. This fact is especially important in an environment with increased humidity and temperature, where cooling of an organism is very difficult. Such ambient conditions appear in many workplaces where usage of respiratory protective devices (RPDs) is necessary. Therefore, it was necessary to conduct complex tests in the laboratory and at the workplace with selected types of respiratory protective equipment to make a complete and objective assessment of ergonomic parameters.

Practical performance tests are performed by participants wearing RPDs in accordance with instructions given by the manufacturer. Test subjects perform several exercises that simulate practical use of the device. Then participants are asked to assess the equipment and give their comments. Before and after tests carried out with and without the RPD, a psychological test is carried out to measure the mental burden resulting from the use of RPDs. Practical performance tests are performed at an ambient temperature of $16-32°C$ and relative humidity of $30-80\%$ accompanied by additional sound and light effects (simulating the real conditions of rescue operations) in order to assess the ability to communicate and the effects of light.

In both the workplace and the laboratory changes in temperature under the facepiece were found to be highest for completed half masks with combined filters, which are characterized by highest breathing resistance, and lowest for filtering half masks, which have the lowest resistance. At the same time, considerable differences in temperature were recorded in laboratory conditions as well as at workstations, which suggests that the simulation under laboratory conditions does not correspond to actual conditions. Tests on the energy expenditure of workers were also carried out at workstations and in the laboratory. In laboratory conditions, where the level of activities done was balanced, the energy expenditure reached 0.59 kcal/min and was 3.5 times less than at workplaces. In the workplace, where the energy expenditure changed depending on work methods, work intensity, work experience, and the kind of tools used, the energy expenditure value is different. The highest expenditure value was achieved for such work as pulling down walls and frameworks and the lowest by workers chrome plating ring pistons.

To comply with requirements of the quality of air inhaled by a wearer of a RPD (concentration of harmful substances below the level of the MAC, minimum 19% oxygen content in ambient air), it is necessary to evaluate the efficiency of the equipment and then estimate the multiplication factor that will reduce the contaminant concentration in the workplace environment, achieved as a result of using a any RPD device. The above task can be realized by calculating boundary values of total inward leakage for all kinds of respiratory protective equipment and then evaluating the nominal protection factor.

The protection factor can be described as the level of efficiency of a given respiratory device. It is expressed by a multiplication factor of reduction of contaminant concentration in the workplace when an adequate protective device is used. Selection of the device is based

on the assumption that the device should guarantee the wearer sufficient quantity and purity of air for breathing. The nominal protection factor (NPF) is expressed as the maximum percentage of inward leakage permitted for a given European Union (EU) standard class of RPD and is presented as a ratio:

$$\text{NPF} = \frac{100}{\text{Percent of allowable inward leakage}}$$

The NPF values for different types of respiratory protective equipment differ from actual values fixed in the workplace. Studies have shown that terms of use of RPD, such as air temperature, ambient humidity, and energy expenditure of the user, have an impact on the values of protection factors.

The Central Institute for Labour Protection— National Research Institute (CIOP-PIB) studies to determine the NPF value performed by Makowski and Majchrzycka (2004) and by Brochocka and Makowski (2005) were carried out in a climatic chamber where exercises were performed to assess the impact of ambient usage conditions on the health of workers using RPDs. The decision to keep the total inward leakage testing under conditions simulating the use of respiratory protection equipment was dictated by the need to ensure reproducible test conditions for all types of equipment, which due to the significant differences in the application (sprays, vapors, gases, oxygen deficiency) would not be possible in the workplace.

## 3 PERSONAL EYE PROTECTORS

There are four types of personal protectors for the eyes: protective glasses, protective goggles, face shields, and welding shields (the latter category includes shields, visors, goggles, and hoods).

Eye and face protectors should be used where the following dangers occur:

- Impact (e.g., splinters of solid bodies)— mechanical hazards
- Optical radiation (e.g., radiation arising from welding, solar glare, laser radiation)—a risk from physical factor; radiation

- Dust and gases (e.g., coal dust or aerosols of harmful chemicals)—risks from chemical and/or mechanical factors
- Drops and splashes of liquids (e.g., splashes resulting from flowing liquid substances)—risks from chemical and/or mechanical factors
- Molten metals and hot solids (e.g., molten metal splashes, resulting from metallurgical processes)—mechanical hazards
- Electrical arc (e.g., an electric arc formed during work under high voltage)—risk of physical factor, an electric shock and/or harmful UV rays arising from the emergence of the electric arc

Viewers, oculars, mesh, and filters are mounted in the above-mentioned categories of eye protectors (the filter category includes welding filters, ultraviolet protection filters, infrared radiation protection filters, glare protection filters, and laser radiation protection filters). Eye protectors may also be part of the RPD system (viewers in the air-cylinder apparatus) or head protector (shields mounted onto industrial safety helmets). All eye protectors consist of the viewing part (viewers, oculars, mesh, and filters) and a frame (for glasses and goggles) or a body together with the harness (for the guards).

Because many professions benefit from measures that protect the eyes, the demand for these products has resulted in upgrades to eye protector designs.

The components for the frame and temples of personal eye protectors are made of high-quality plastic, which does not cause allergic reaction when in direct contact with the user's skin. Frames and temples have numerous parts that allow adjustment to get optimal matching to the user's head.

Protective glasses that show significant improvement in ergonomics of use are systems that allowadjustment in the length and depression angle of the tamples. Such a system is shown in Figure 1.

Another feature which has had a significant impact on the ergonomics of eye protector use is resistance to fogging. The problem of creating a layer of moisture on solid surfaces, glass and plastics in particular, relates to glasses, goggles, and face shields used under conditions of high air humidity or as a result of perspiration of

(a)                    (b)
**Figure 1** Adjustment of (a) length and (b) depression angle of tample in protective glasses.

the user (the problem applies to protective goggles which tightly adhere to the user's face and ventilation systems built in goggles are not able to remove excess perspiration) and moving between areas with different temperature and humidity. Fogged viewers and oculars in the eye protectors make the work less comfortable and often impossible to do regardless of whether the moisture is deposited on the surface of glasses as liquid drops or mist.

For eye protectors where the body is mounted onto the head strip, it is very important to have the head strip well matched so that it can firmly support the eye protector and not cause too high compression. Currently widely used control systems allow a seamless fit between the head strips and the user's head.

When designing the components of eye protectors mounted onto the user's head, one must consider convenience, in terms of fitting and adjustment and ventilation systems, how perspiration is removed through materials adjacent to the user's forehead, and so on.

Another advanced technology that has improved ergonomics and safety of use is the automatic welding filter (Kubacki et al., 2001). Automatic welding filters are being increasingly used for eye protection during arc welding . They are auto darkening (transition from light to dark state) due to the initiation of the welding arc. In the light state of the filter the welder can preview welding elements. In the dark state complete protection from the harmful rays of the welding arc is assured. Automatic welding filters are mostly installed in welding masks.

Oculars and inorganic glass filters are replaced with high-quality plastic components. This substantially reduces the weight of the eye protectors. Currently one of the materials commonly used for the construction of oculars and filters is polycarbonate. This material features very high mechanical resistance and natural ability of UV absorption. Polycarbonate can also be easily colored, thus giving it good filtration properties.

To protect the eyes from the harmful optical radiation occurring in many workplaces, it is necessary to use PPE with appropriate protective filters. Modification of the spectral transmission characteristics of filters is designed to ensure an adequate level of protection while maintaining visible-light transmission properties to an extent which will allow the visual activity as defined in the work process.

Protective filters used in eye protectors are divided into welding filters (to protect against radiation emitted during welding and allied techniques), UV protection filters (to protect eyes when working with sources of ultraviolet radiation used for medical, technical, and scientific purposes), infrared radiation protection filters (to protect against glare and short-wavelength near-infrared radiation), sun glare protection filters (for protection against solar radiation, intended primarily to protect the human eye from glare; in addition to protection from required absorption of visible radiation, may also be intended to protect the eye from ultraviolet and infrared radiation), and filters for protection against laser radiation (to protect eyes from laser radiation at wavelengths from 180 to 1000 μm).

## 4   PROTECTIVE HELMETS: SELECTION

Workers are exposed to a number of hazards depending on the specific characteristics of the work site and the operations performed. The most serious and common hazards include those associated with mechanical factors, for example, a fall from a high work site; impacts caused by falling objects; impacts caused by sharp, protruding elements, which may result in punctures or cuts; impacts caused by mobile parts of machines, posing the risk of dragging into a machine and crushing; and abrasions caused by coarse, rough elements and falls on slippery and uneven surfaces.

The aforementioned factors can cause injuries to various parts of the human body. However, considering the consequences of potential accidents, the head should be treated with particular care. Hazards due to mechanical factors are present primarily in such industries as mining, civil engineering, transport, warehousing, communications, trade, energy, and gas and water supply. Taking into account the statistical data concerning accidents at work, the most frequent causes of head injuries include impacts caused by falling elements and sharp, hard objects. The consequences of such events depend mainly on the kinetic energy of the impact as well as the shape and hardness of the material making up the object which comes in contact with the head. The injuries caused by mechanical factors may involve the skin of the scalp, the cranial bones, the brain, and the cervical vertebrae. In extreme cases, such injuries may lead to permanent disability or even death.

Considering the potential consequences of head injuries, it is the duty of both the employer and the employee to eliminate the hazard. Hazards should be eliminated by appropriate safety measures taken at the work sites or by appropriate organization of work. If such solutions of the problem are impossible, the workers should be equipped with suitable PPE. However, it should be remembered that the use of such equipment, in this case protective helmets of various types, does not eliminate hazardous factors but rather only reduces the severity of their effects.

To ensure appropriate protection of the user's head against mechanical factors, a protective helmet must be selected correctly from among various types. The primary factors to be considered include:

- Specific factors against which protection is needed (e.g., central impacts, side impacts, lateral forces)

- Temperature range characterizing the usage conditions

- Regulation range as related to the user's head dimensions

- Presence of other hazards (e.g., electric shock, high temperature)

- Other personal protective devices and additional equipment to be used (e.g., eye and face shields, hearing protectors, lamps mounted on the helmet)
**Figure 2** Industrial safety helmet: 1, shell; 2, headband with nape strap; 3, cradle; 4, chin strap; 5, sweatband.

- Activities which may cause the helmet to fall off the head (e.g., use of the helmet together with fall-arresting equipment)

Industrial safety helmets (Figure 2) provide a basic and most common means of protection of workers' heads in the working environment. Irrespective of their construction, the following two elements are found in such helmets: the shell, and the harness.

The helmet shell, most often made of polyethylene or acrylonitrile butadiene styrene (ABS), constitutes its external part, which gives the helmet its characteristic shape. It is designed primarily to receive the impact, absorb part of the energy, and transfer the rest of it to the harness. The shell also prevents direct contact of a hazardous object with the user's head. Depending on the specific structural solution, the shell can be equipped with a visor, a brim, a rain gutter, vents, attachment devices for eye and face shields as well as hearing protectors.

The harness constitutes the internal part of the helmet in the form of a system of straps made of textile tapes or polyethylene which rest on the user's head. It is connected with the helmet shell by appropriate attachment devices. The main task of the harness is to absorb the energy of an impact acting on the shell and distribute the forces over as much of the head as possible. It is noteworthy that a helmet with harness connected to the shell close to its rim and not equipped with any additional shock-absorbing lining (protective padding) provides no protection against side impacts. This phenomenon was explained by Baszczyński (2002) and Korycki (2002). Helmets with appropriately stiff shells protect the head to some extent against lateral forces.

The headband, encircling the head at the level of the forehead in front and skull base at the back, together with the harness, ensures stable positioning of the helmet on the user's head. The headband is equipped with two mechanisms that allow the wearer to adjust the head circumference as well as enhance its stability on the head. In most industrial protective helmets the headband is equipped with a sweatband.

Industrial protective helmets can be equipped with additional elements, for example, a chin strap to prevent the helmet from falling off the head and attachment devices for eye and face protectors.

Numerous work sites do not pose the risk associated with impacts caused by falling objects but do pose the risk of superficial head injuries resulting from bumps against construction elements. In such a situation, industrial protective helmets should not be used. Rather what should be used are industrial bump caps, in which case the worker is not exposed to discomfort due to pressure exerted by the harness and the headband, load exerted on the muscles of the neck by additional weight on the head, and impaired ventilation of the upper part of the head.

The most important features of industrial bump caps, in comparison with industrial protective helmet structures, are significantly lower weight and smaller size.

Industrial conditions include work sites where the risk of mechanical injuries is so high that the industrial protective helmets fail to ensure an appropriate level of protection. Such work sites can be found, for example, in mining and construction sites. In such a situation, the workers should be equipped with high-performance industrial safety helmets. As far as protection against mechanical factors is concerned, these helmets have the following characteristics in comparison with industrial protective helmets:

- Provide the same level of shock absorption (i.e., force transmited to the user's head) for impacts with twice the energy
- Protect the head against both central impacts (at the highest point of the shell) and lateral impacts—from the front, back, and sides
- Provide higher level of protection against impacts exerted by sharp-tipped objects

The shell and the harness are also the main elements of high-performance industrial safety helmets. The method most commonly used to improve the shock-absorbing properties and protection against side impact involves introduction of appropriate lining materials absorbing the impact energy and thus reducing the forces acting on the user's head. Such a lining is usually made of foam possessing appropriate force deformation

characteristics, for example, high-density polyurethane and foamed polystyrene.

To ensure appropriate protection of the user's head against mechanical factors, a protective helmet must be selected, fitted, and used correctly. Selection means appropriate choice from among the three types available (industrial bump caps, industrial safety helmets, and high-performance industrial safety helmets) as well as various structural solutions. Protection against other hazardous factors, such as electric shock, molten metal splashes, and high temperatures, should also be taken into consideration. Fitting involves appropriate regulation, for example, circumference of the head band, wearing height, length of the chin strap, and adjusting the helmet to the dimensions of the user's head. Correct usage involves following the manufacturer's instructions on the conditions and modes of use, recommended maintenance and storage methods, and terms for phasing the helmets out of service.

## 5  HEARING PROTECTION DEVICES

Hearing protection devices (HPDs) should be applied in conditions in which there are no other technical means to reduce noise levels or when it is not economically feasible to reduce noise at the source according to European Directive (2003) 2003/10/EC. The HPDs are divided into two broad categories: earmuffs and earplugs. Earmuffs are placed around the ears and provide an acoustic barrier to sound. Earplugs fit into the ear canal to block its entrance and keep noise from entering. Some other head protecting devices such as military helmets and sand-blasting helmets usually include in their design parts to protect hearing.

Earplugs include foam, premolded, formable, custom molded and semi-insert earplugs (Figure 3). Foam earplugs (Figure 3a) made from slow-recovery material, usually polyurethane, have to be rolled and compressed to the diameter which would allow for easy insertion into the ear canal. Expansion of the earplug leads to a very good sealing of the ear canal against external sound.

Premolded earplugs (Figure 3b) are formed from a flexible material such as thermoplastic elastomer (TPE) in different shapes with flanges, rings, and cups on a stem that is held with the fingers while inserting the earplug into the ear canal. Formable earplugs (Figure 3c) are made from plastic materials, usually mixtures of wax with cotton and mineral wool. Such earplugs are formed by the user who inserts the material into the ear canal. These earplugs are often not used in the workplace and are more popular in the consumer market (Berger, 2000). Custom-molded earplugs (Figure 3d) are more expensive but are more comfortable. These earplugs are formed for an individual user and are separately fitted to the left and right ear canal shapes. They are often used when comfort is the primary prerequisite. Earmuffs (Figure 4) consist of rigid plastic earcups sealed around the ears by foam or, more rarely, with fluid-filled or partly fluid-filled cushions. Earmuffs are held on the ears by a plastic or a metal headband placed on top of the head (Figure 4a), behind the head (Figure 4b), or under the chin (Figure 4c) to allow for use in combination with other personal protective devices placed on the head, for example, helmets. For helmets, however, helmet mounted earmuffs (Figure 4d) are most often used integrated with the helmet by a spring. Regardless of passive designs, special kinds of HPDs are equipped with electronic circuits to control sound attenuation, provide communication, and apply active noise reduction.

Attenuation of earmuffs is affected by their cup volume, mass, headband force, diameter of opening in the cushion, and construction materials (Berger, 2000). Large volume enclosed by an earmuff improves

**Figure 3**  Earplugs: (a) foam, (b) premolded, (c) formable, and (d) custom molded.

**Figure 4**  Earmuffs: (a) top of head headband, (b) behind the head headband, (c) under the chin headband, and (d) attached to helmet.

attenuation in the low-frequency range, while dumping acoustic material in the earcup absorbs high-frequency sound energy (Berger, 2000).

HPDs currently on the market are labeled with attenuation data obtained by the real ear at threshold (REAT) method, standardized by international and national standards [e.g., International Organization for Standardization (ISO), 1990; American National Standards Institute (ANSI), 2008]. In the REAT method, HPD attenuation is determined for frequencies spanned in octaves from .125 to 8 kHz as the difference between the hearing thresholds in two conditions: When an HPD is not worn and when it is worn. The average attenuation calculated for a group of subjects and several samples of the HPD represents the attenuation. To estimate the attenuation values protecting 84 or 98% of the population one or two standard deviations are subtracted from the mean attenuation. The value obtained by subtracting one standard deviation is called the approved protection value (APV) and is used to label the HPDs according to the ISO (1994) standard.

While calculations in octave-bands are considered the most accurate method to estimate the sound level under the HPD, the ISO (1994) standard introduces a single number rating (SNR) as an index for overall HPD attenuation and H, M, and L parameters for high-, mid- and low-frequency content noise, respectively. In the United States, the noise reduction rating (NRR) is used as a single number index describing the HPD attenuation,. Despite some differences (generally the NRR is 3.5 dB lower than the SNR), the basic idea of using the NRR or SNR is to estimate the A-weighted sound level under the HPD from the C-weighted sound level of noise measured outside the HPD.

Attenuation of HPDs may also be determined with the use of various objective methods involving measurement with a microphone. In the microphone in real ear technique (MIRE; ISO, 2002), the microphone is placed in the subject's ear at the entrance to the ear canal. This method is considered an objective counterpart of the REAT method (Berger, 2000). Other technics involve the use of acoustic couplers such as an artificial test fixture (ATF; ISO, 2007) or an acoustic manikin (ISO, 2004) equipped with an internal microphone and designed to replicate with some simplification the dimensions and shape of the human head and/or the torso. Measurements with the ATFs or manikins are suitable in all conditions in which there is a risk of exposure to high-level sound such as in impulse noise measurements (Żera and Młyński, 2007).

Bone conduction is the factor limiting protection provided by earmuffs or earplugs. Even if the ear canal and air sound transmission are completely blocked by the HPD, sound reaches the inner ear through the skull at a level of 40–55 dB lower than that transmitted through the ear canal (Berger et al., 2003).

In the workplace, attenuation of an HPD may be much lower than measured in the laboratory by the REAT method. To accommodate for this, the ANSI S12.6-1997 standard (see revised version ANSI/ASA, 2008) introduced an alternative *method B* which takes into account fitting of the HPD by an inexperienced user;

also see the ISO (2006) technical specification. Participation by inexperienced subjects yields lower attenuation values, better corresponding to attenuation obtained in real-life application of HPDs.

Improper and interrupted fit of an HPD can reduce effective attenuation to 60% (earmuffs), 40% (foam earplugs), and 25% (other than foam earplugs) of the labeled value (Berger, 2000). Air leaks resulting from improper earmuff fits by users, reducing attenuation by more than 10 dB in a wide frequency range, are the major cause of the difference between attenuation measured in the laboratory and in the real world. An accepted way of estimating real-world attenuation is derating the values determined in the laboratory. For instance, in the United States, NRR values are derated to 0.75, 0.5, and 0.25 of the value measured in the laboratory for earmuffs, foam earplugs, and other earplugs, respectively. In Germany, 5 dB is subtracted from the value of attenuation on the label for earmuffs, 3 dB for foam, and 9 dB for other types of earplugs. In general, the strategy is to accept only a part of the attenuation value estimated in laboratory conditions.

Factors of primary importance in the choice of an HPD are comfort, motivation to use, conditions for speech communication, and the ability to receive auditory signals. For instance, earplugs are comfortable in hot climate owing to their small dimensions. Earmuffs are convenient for intermittent use. Small earmuffs may often provide better comfort than large earmuffs. Thus, unnecessary use of large overprotecting earmuffs [European Committee for Standardization (CEN), 2004a] should be avoided. It has to be stressed that it takes time and requires training to get used to earplugs and earmuffs. Wearing an HPD may cause a boost in low-frequency sounds, a change in the perception of a person's own voice, increased physiological noise, and changes in sound quality of speech and other sounds.

It is often of concern how the use of HPDs influences the ability to understand speech and audibility of warning signals in the work environment. For speech, excessive levels decrease speech intelligibility due to the increase of nonlinear effects in hearing. Therefore, in many cases decreasing very high levels of both speech and noise may improve intelligibility, even if the signal-to-noise ratio remains unchanged. Whether the use of HPDs improves or deteriorates the ability to understand speech and receive the warning signals depends on the level, the sound spectrum of noise, the attenuation characteristics of the HPD, and the hearing threshold of the person who uses the HPD.

## 6 INFLUENCE OF THERMAL ENVIRONMENT AND PROTECTIVE CLOTHING ON THERMAL CONDITION OF THE HUMAN BODY

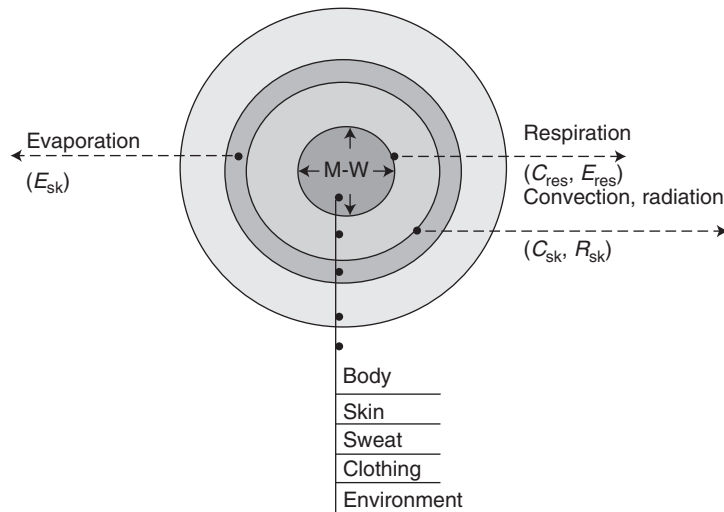
As a result of metabolic conversion, the human body produces energy that is transferred to a person's activity to maintain vital functions and warm the body (Fanger, 1970; Gagge et al., 1971). Human beings are warm-blooded organisms; therefore, the internal temperature of the body should be $37 \pm 0.3°C$. An increase in


**Figure 5**  Heat transfer processes between human and environment.

internal temperature above $1.0°C$ may cause thermal stress and consequently lead to hyperthermia, while lowering internal temperature below $36.0°C$ may lead to loss of consciousness and hypothermia. In both cases, too high/low internal temperature can lead to death; therefore, the main task for the proper functioning of the human body is to maintain a constant internal temperature. Internal temperature depends on the heat exchange between the body and the environment. A diagram of heat exchange is shown in Figure 5 and presented below in the form of an equation [American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE), 2009]:

$$M - W = C_{sk} + R_{sk} + E_{sk} + C_{res} + E_{res} + S$$

where:

$M$ = metabolic heat production, $W/m^2$
$W$ = external work rate, $W/m^2$
$C_{sk}$ = convective heat transfer from the skin, $W/m^2$
$R_{sk}$ = radiation heat transfer from the skin, $W/m^2$
$E_{sk}$ = evaporative heat transfer from the skin, $W/m^2$
$C_{res}$ = convective heat transfer from respiration, $W/m^2$
$E_{res}$ = evaporation heat transfer from respiration, $W/m^2$
$S$ = heat storage, $W/m^2$

Some of the heat produced by the body is converted to external work, especially for the performance of hard physical work. The rest of the heat is dissipated into the environment (in a quantity which depends on the cooling power of the ambient environment) from the skin surface and through the respiratory tract; the remaining portion of heat is stored in the body, which may lead to a rise or a fall in internal temperature. Heat is transferred from the body to the ambient environment through different physical phenomena: convection, radiation, and evaporation of moisture. The amount of heat exchanged between the human and the environment is affected by the following:

- Environmental conditions, corresponding to the cooling power, for example, temperature, velocity and humidity of the air, radiation temperature of the room surfaces, and water vapor pressure
- Individual conditions depending on the nature of the work and the clothing, for example, the activity (determining metabolic heat production) and the thermal insulation of clothing, which is a barrier constricting heat dissipation

At many workstations protective clothing is required to protect workers against the thermal environment but also against other physical and chemical stress factors. It is a requirement for the safety of industrial workers that protective clothing offer sufficient protection. However, it is also important that PPE meet certain ergonomics requirements so that protection is not compromised by increased physiological or mental strain, impaired performance, or increased discomfort (Holmer, 1995).

Clothing creates a kind of obstruction in the heat exchange between the human body and the environment. In moderate and cold thermal environments, in most cases clothing protects against excessive heat loss from the body and acts as a regulating mechanism that helps maintain optimal body temperature.

In each kind of thermal environment, the thermal balance of the human body depends on three basic parameters: thermal conditions, intensity of activity, and thermal insulation of clothing.

In a cold environment, clothing with required insulation should protect against hypothermia and a decrease in internal temperature of no more than $1.0°C$, which means down to $36.0°C$ (CEN, 2004b). In a cold

environment clothing should be thicker and its evaporation resistance higher. Moisture accumulation inside clothing, because of its absorption and condensation, decreases insulation. For convective heat loss from the body, maintaining a high temperature gradient between body core and skin surface is a natural strategy to keep clothing dry and perspiration to the required minimum.

In most cases protection against physical and chemical factors means using protective clothing made of fabrics that are highly impermeable to moisture. Thus, suitable protection is often achieved by disrupting the body's thermal balance. Body overheating is the result of using this kind of clothing. More impermeable clothing means there is a higher risk of discomfort and a greater thermal load for the users (White and Hodous 1987), and exposure time in this kind of clothing is from several to a few dozen minutes, depending on work intensity and the parameters of the environment (Marszałek and Sawicka, 1997).

An important condition of maintaining comfort during work in protective clothing is to eliminate condensation in underclothing and consequently perspiration on the skin and the internal layers of the protective clothing. Developments in textile production technology, including barrier materials, enabled significant progress in the construction of protective clothing. Some materials that acts as barriers to hazardous factors, are water vapor permeable, and provide removal of excessive heat from the user's body. Materials used in protective clothing include laminates of fabrics and water vapor–permeable membranes as well as microporous coatings.

Currently manufacturers of clothing that provides comfort are focusing on high-performance underwear that transfers heat and sweat from the skin to the environment. Specialized underwear can significantly reduce the discomfort of protective clothing; it is especially recommended for use under tight protective clothing (Bartkowiak, 2000).

Another method of reducing moisture under tight protective clothing and the thermal discomfort is application of nonwoven inserts with high-sorption fibers (Bartkowiak, 2006) which absorb large amounts of liquid in relation to their mass.

Improvement in the physiological parameters of tight protective clothing could result from wearing a vest with a phase change material (PCM). Cooling and ventilation systems are another way of reducing the discomfort of working in protective clothing. Two types of systems are used to cool the body in oppressive working conditions: passive systems (vests with ice) and systems with forced circulation of cooling liquid or air.

During intensive work in tight protective clothing or in protective clothing in a hot environment, proper organization of the work is very important, for example, taking breaks. The working time and duration of the breaks depend on the intensity of the work, the temperature of the working environment, and each worker's characteristics. Workers should be healthy, with correct blood pressure, high physical efficiency, and an efficient sweating system. People working in protective clothing, especially tight protective clothing, and in a hot

environment should regularly replenish the liquids in their bodies.

A new type of clothing is the subject of much research and the focus of users, that is, so-called smart or intelligent clothing. Intelligent textile fabrics may be divided into two groups:

- Those that change their properties under the influence of certain stimuli
- Those thar are integrated with electronics

The products in the first group receive stimuli directly from the human body or the environment and react with significant physical, chemical, and biological changes and in many cases are reversible. Active materials are stimulated by tension, the electromagnetic field, temperature, humidity, UV or IR radiation, or chemical substances.

The other group of intelligent textiles consists of conductive materials designed to transfer electric signals and the so-called e-textiles in which microelectronic devices are integrated with textiles, offering products with additional functions concerning information and communication.

## 6.1 Phase Change Materials

Phase change materials are able to change their phase in the phase change temperature range. They are able to absorb, store, and release large quantities of energy in the form of latent heat.

In the form of capsules, PCMs may be incorporated into a textile in various ways. Currently, fibers with microcapsules of PCM are produced. They are totally surrounded by a polymer and permanently enclosed in the fiber. PCM can also be introduced into textiles through imbuing, printing, coating, or spraying.

Because protective clothing causes heat load, attempts have been made to use PCMs in protective clothing in order to cool the user's body. Research in this field where PCM was added to the polymer coating resulted in improvement in comfort for clothing protecting against chemicals. Due to the higher physiological comfort obtained, the time that protective clothing could be used was extended.

Research on the application of PCM for thermoregulating the microclimate under tight protective clothing is being conducted at the Central Institute for Labour Protection in Poland. Two types of clothing with PCM were prepared to be used under protective clothing: waistcoats and underwear with viscous fibers including PCM and waistcoats with PCM macrocapsules placed in special channels of suitably prepared knitted material. Using waistcoats with PCM under tight protective clothing for protection against chemicals extended the time that such clothing could be worn (Bartkowiak et al., 2010).

## 6.2 Shape Memory Materials

Shape memory materials are materials that, under the influence of certain stimuli, return from their present shape to the original one, that is, the shape that has been "remembered." The effect of shape memory is seen mostly in shape memory alloys and polymers.

Shape memory alloys are a unique class of metal alloys that can change their shape when heated to a certain temperature. There were attempts to use shape memory alloys in clothing that protects against high temperature, flame, heat radiation, and cold. Using materials that at lower temperatures increase their volume enables the construction of clothing that is thinner and more ergonomic and is a better insulator.

Polyurethanes with a shape memory that have a glaze temperature greater than 55°C may be used in protective clothing, for example, in the chemical, metallurgy, and food industries. They were also found useful in intelligent waterproof and water vapor-permeable membranes for clothing protecting against bad weather.

## 6.3 Integration of Electronic Microsystems with Textiles

Integration of electronic microsystems with textiles makes it possible to create products that can be used in protecting health and in medicine, safety and rescue, industry logistics, and sport. Clothing with electronics, which monitors and registers heart rate, number of breaths, and skin temperature has been designed for athletes. Clothing with an installed GPS system and an electronic compass and altimeter has been also constructed.

Of key importance for the integration of microelectronics and textiles are technologies that enable textiles to function as electronic interfaces. Textile interfaces can be implemented into clothing together with mobile electronic equipment. E-textiles are used in medicine to monitor life functions, for example, for infants and bed-ridden patients. The lifeshirt, with sensors that enable constant monitoring of pulse, breath, and temperature while patients sleep and perform everyday activities, is an example of electronic textiles in medicine application.

Electronics finds practical use in protective clothing particularly in extreme conditions. Clothing with electronic microsystems that monitor the user's physiological parameters as well as the level of danger has been developed. Particulary it has been dedicated for rescue teams, for example, firefighters. Such clothing monitors the physiological state of a firefighter and the environment's conditions

In a cold microclimate, when a worker's activity and the amount of heat emitted increase, passive protective clothing will not provide the workers thermal comfort. Suitable protection and comfort can be obtained only through an active shield, which changes its insulation depending on changes in the outdoor environment and the user's metabolic rate. Clothing equipped with integrated heating systems ensures precise undergarment temperature regulation. The protective clothing actively reacts to temperature changes and changes its heat insulation so as to provide the user with adequate warmth (Kurczewska and Leśnikowski, 2008).

## 7 PROTECTIVE GLOVES IN THE WORKPLACE

Protective gloves are used to protect the hands in the workplace. They can protect the entire hand or part of the hand as well as the forearm and arm. Protective gloves also include gloves with no fingers and products that protect the fingers.

They can also protect against mechanical factors, heat and fire, cold, chemicals and microorganisms, electric shock (isolation while working at a voltage), ionizing radiation, radioactive contamination, and mechanical vibrations.

For protection against mechanical factors a wide range of gloves are made of chain mail (designed to protect against cuts and stabs by sharp knives); p-aramid yarns (Kevlar®, Kevlar® KleenTM, Kevlar® PlusTM, Kevlar® Amor, Twaron®, Twaron® Premium Line); core yarns where the core can be made of stainless steel or textile yarns (high resistance to cutting) and the sheath is made of textile yarn; polyethylene (Dyneema®, Spectra®, Spectra® GuardTM, Spectra® GuardTMCX); and glass fiber mixed with yarn and other materials (cotton, polyamide, polyester, polyurethane) (Stefko, 2009).

Specialized gloves should be used to protect against severe mechanical injuries such as chain mail gloves to protect the hands against cuts and punctures by hand knives.

Gloves that protect against heat are usually made of fabric or knitted from yarn or fibers, such as Kevlar®, Nomex®, Twaron®, Preox®, PBI, PBI/Kevlar®, Basofil® or cotton yarn, woolen impregnated nonflammable substances, heat-resistant leather, and fabric from glass fiber yarn. Depending on the type of yarn, weave or knit fabric, and number of layers of materials used in the construction, gloves with various protective properties are received. Examples are knit gloves that protect against burns during brief contact with flame or hot objects with a temperature of 250°C made of yarn: cotton-impregnated nonflammable substances, mixed yarns with polyester yarns, and frotte-type cotton yarns. Another example is gloves of woven fabric made of glass fiber yarn lined with nonflammable cotton that protect workers' hands in the metallurgical industry.

The outer layer of gloves that protect against cold is mostly of cow leather and fabric. Gloves made of Thinsulate® yarns and fibers also provide good thermal isolation. Gloves can also be made entirely of plastic or rubber as well as polymer covered knit and woven fabrics. Nonwoven and knit fabrics contribute to thermal insulation. Some gloves also contain waterproof or vapor-permeable membranes (GORE-TEX®, HYDROTEX®, OSMOSIS®, TEXA-POR®, NO-WET®, SYMPATEX®, POWERTECH®).

For protection against chemicals tight gloves made from various synthetic rubbers (e.g., natural rubber, synthetic rubbers, polychloroprene, polyacrylonitrile, butyl, Viton) or plastics (e.g., polyvinyl chloride, polyvinyl alcohol, polyethylene, Hypalon) should be used (Irzmańska et al., 2010).

Gloves that are not made entirely of plastic or rubber or fabric or knit fabric entirely coated with polymer should not be used for protection against chemical agents. All-polymer or all-rubber gloves may decrease perspiration and cause discomfort. Moreover, allergies

to the components of the rubber mixtures may occur as a result of direct or indirect contact with human skin.

At the same time, depending on the degree of mechanical wear and degradation of the material which is in direct contact with the chemical, the barrier of the material may weaken. In addition, gloves of the same polymer but made by different manufacturers can have—and often do have—different protective properties. The permeation time can also be different for gloves made of the same material but produced by different manufacturers. The level of protection of a material depends on many factors, factors that are sometimes not taken into account when assessing a laboratory.

When selecting the appropriate protective gloves, it is important to use the information supplied by the manufacturer. The protective properties given by the manufacturer are the result of laboratory tests of various parameters on the basis of a set of standards. It should be noted that gloves do not provide protection against all harmful and hazardous factors or for an indefinite period of time. Terms of use and storage and maintenance of gloves impact the protective properties and can reduce the amount of time that they can be used. Changes in the glove's material should be a signal to immediately stop their use.

## 8 FOOTWEAR: COMFORT OF USE

In recent years, lifestyle changes and the fact that more people are using personal protective equipment have resulted in increasing demands on their performance. The popularity of comfortable footwear has increased the demand for comfortable safety footwear. Intensive development of advanced materials that began with sports shoes has resulted in the introduction of many new foot and leg protectors. Modern protective footwear for professional usemust also meet requirements of hygiene and convenience. Used shoes often prevent the dissipation of heat and sweat which is produced in large quantities during work and other activities.

High temperatures and excessive humidity in the shoes lead to discomfort of varying intensity. If the adverse conditions of the microclimate in the shoe are present for a long time, pathogenic bacteria and fungi grow. Therefore, materials intended for construction of protective footwear should not only meet the requirements of the protection parameters but also be hygienic so that they can actively support the thermoregulatory processes of the body.

Cambrelle Extreme by DuPont and DRYZ IntelliTemp by Dicon, materials used in the manufacture of socks and footwear, combine very good thermal insulation with the ability to evaporate moisture from the immediate environment of the foot and provide active and lasting protection against microorganisms. In recent years intensive development of multifunctional membrane materials has been observed.

Breathable fabrics, such as the Coolmax lining used for LaCrosse footwear, have changed comfort in footwear today. For warmer climates where breathable materials are needed in footwear, a lining that wicks away moisture will keep feet more dry and comfortable. On the other hand, waterproof material is a necessity in wet conditions. Many manufacturers are turning to fabrics featuring new technology, such as Gore-Tex or Hyper-dri.

Proper protective toe cap is essential element of the footwear responsible for ensuring safety against mechanical risk, i.e., compression and impact. Although protective footwear does not guarantee protection from a foot injury, it can reduce the severity of an injury. Statistics have shown that three out of four people who receive a foot injury while at work did not have any protective footwear. One reason given was that the shoes were uncomfortable. The fact is it is a lot more uncomfortable to have an injured foot than it is to wear a steel-toe boot. Up-to-date toe caps in protective and safety footwear can be made with steel or polymers, for example, polycarbonate. The nonmetallic toe is lighter and more comfortable as well as electrically nonconductive and the resistance to the transmission of heat or cold can make a big difference on the job site. The other solution, using an alloy, is much lighter than a steel toe and just as strong, if not stronger.

The conclusion is that the comfort of use of footwear corresponds to protective parameters and safety. One such parameter is slip resistance. The physical parameter characterized slip resistance is the coefficient of friction (CoF). The higher the CoF, the better the slip resistance. The safety features of footwear, including slip resistance, are tested according to a set of European test standards written into EN ISO 20344:2004 (A1: 2007) (CEN, 2004c). Footwear which has passed the EN test for slip resistance will be coded SRA (tested on ceramic tile wetted with dilute soap solution), SRB (tested on smooth steel with glycerol), or SRC (tested under both conditions).

The sole tread pattern and sole compound are both important for slip resistance. Generally a softer sole and close-packed tread pattern work well with fluid contaminants and indoor environments. A more open pattern works better outdoors or with solid contaminants. Several soles that meet the requirements of the standards are shown in Figure 6.

Another modern footwear is the Shock Protection System (SPS). The combination of SPS with Blundstone's unique dual-density soling has been designed to increase comfort in safety footwear. SPS reduces workplace fatigue and orthopedic problems in the lower back,

**Figure 6**   Examples of up-to-date soles.

legs, and feet. Dynamic tests indicate an average reduction in shock transmitted to the legs of 33% at a brisk walking pace. SPS-Total includes advanced microcellular shock-absorbing material.

## 9   FALL PROTECTION SYSTEMS: SELECTION OF EQUIPMENT

The data concerning accidents at work published annually in many European countries demonstrate that work on heights still belongs to the most hazardous occupations. The practice of work on heights in such sectors as civil engineering, energy engineering, mining, and telecommunications demonstrates that in many cases it is impossible either to eliminate the risk of falls from a height or to use group protections such as barriers and protective nets. In such situations, the use of personal systems protecting against falls from a height is the only method available. To play their role correctly, such systems must be made up of appropriately selected components. The most important factors determining the selection of components for systems that protect against falls from a height include:

- Topography of the work site, including the available space which can be used for fall arrest
- Presence of construction elements which can be used to anchor the protective equipment
- Presence of other work site factors which may affect the technical efficiency of the protective equipment, for example, high temperature, molten metal splashes, aggressive chemicals
- Typical movements of the user at the work site, for example, in the vertical or horizontal direction
- Single-instance or repeated nature of tasks performed at a particular work site
- Necessity to minimize the free-fall distance
- Necessity of work positioning while performing tasks on a height

The first step in selecting systems that protect against falls from a height is type selection. Three types of systems characterized by function are available: systems designed for fall arrest, systems designed for work positioning, and systems designed for restraint of a fall from a height.

The fall arrest systems described by Sulowski (1991) are designed for work sites whose topography and workers activities required make it impossible to eliminate the risk of a fall. The main functions of such a system include fall arrest, alleviation of fall effects by reduction of forces acting on the human body, prevention of injuries caused by crashing against dangerous objects on the ground or at the work site, and maintaining the position of the user's body during and after fall arrest, allowing for assistance to arrive. An example of a fall arrest system is presented in Figure 7.

A fall arrest system consists of three basic components: an anchor component, a connecting and shock-absorbing component, and full-body harnesses. The

**Figure 7**  Fall arrest system: 1, full-body harnesses; 2, energy absorber; 3, lanyard; 4, anchor lanyard.

anchor component is the first link of the system and is connected directly with the work site, anchoring the connecting and shock-absorbing component to the work site to prevent the user from falling down. The role of universal anchor connectors can be played by various types of connectors attached to safety lanyards, wire grider grips, wire rope slings, anchor slings, and hooks.

Such components can be connected to steel constructions, beams, ties, trusses, and other work site elements of appropriate shape and mechanical strength. Such anchor elements are generally unsuitable for work where the user moves in the horizontal plane because they must be disconnected and then reconnected to the new anchor points. Horizontal flexible anchor lines and horizontal rigid anchor lines presented by Baszczyński and Zrobek (2000) can be used as the anchor components, enabling the worker to move in the horizontal plane.

To protect workers in wells (e.g., the sewage system, shafts), the best solutions for anchoring fall arrest systems include tripods or horizontal anchor beams with an anchor point.

The second component of a system protecting against falls from a height is a connecting and shock-absorbing component located between the anchor component and the full-body harness. Its main functions include fall arrest, reduction to safe values (not exceeding 6 kN) of the forces acting on the user's body during fall arrest, and reduction of falling distance. Owing to such functions, the connecting and shock-absorbing component alleviates the conditions of fall arrest and minimizes the risk of impacts caused by crashes with elements at the work site. The function of this component involves absorption of the kinetic energy of the human body falling down. This energy is converted to deformation and friction forces of the component elements. The most popular connecting and shock-absorbing components used at present include:

- Lanyards and textile energy absorbers, in which the kinetic energy is converted into the work of separation of two layers of shock-absorbing webbing

- Retractable-type fall arresters described by Baszczyński and Zrobek (2003) and Baszczyński (2006), in which the kinetic energy is converted into the work involving friction of brake disks or tearing of a textile element
- Guided-type fall arrester on a rigid or flexible anchor line, in which the kinetic energy is converted into the work involving friction between the anchor line and the self-locking mechanism and deformation of the anchor line or other elements specifically designed for that purpose

The third component of a fall arrest system, which is in direct contact with the user's body, is the full-body harness. The main functions of such equipment include:

- Distribution of the dynamic forces acting during fall arrest on the human body in a manner reducing the risk of injuries
- Appropriate positioning of the user's body during fall arrest to prevent damage to the internal organs and vertebral column
- Appropriate positioning of the user's body after completion of fall arrest to enable the user to wait for help safely as comfortably as possible

The fall arrest attachment element (usually a buckle) is an important element of the full-body harness, whose construction and positioning determine its application. Most frequently, this element is placed at the back and then the body harness can cooperate with energy absorbers with lanyards, retractable-type fall arresters, and guided-type fall arresters on flexible anchor lines. The attachment buckle placed on the chest can also be connected to the above connecting and shock-absorbing elements as well as with guided-type fall arresters on rigid anchor lines.

Work-positioning systems, presented by Baszczyński and Zrobek (2005), are the second type of system protecting against falls from a height. They are designed to position the users so that they are firmly supported and can use both hands for work. A work-positioning belt equipped with side attachment elements connected to a work-positioning lanyard with a length adjuster is an example of such equipment presented in Figure 8.

During exploitation of the equipment user's back is supported by a belt, while the legs rest on the work site construction.

The lanyard, the ends of which are connected to the attachment elements of the work-positioning belt, is tied around a work site construction element, for example, a pole. Its length is adjusted by the user so as to ensure a safe and comfortable position. The work-positioning lanyard must be tied around such an element, which will make its displacement and, consequently, the initiation of the user's fall impossible. If such conditions cannot be provided at the work site, an additional fall arrest system and work-positioning system are necessary. In such cases, full-body harnesses equipped with a work-positioning belt should be used.

**Figure 8** Work-positioning system: 1, belt for work positioning; 2, work-positioning lanyard.

The third type of system protecting against falls from a height are restraint systems. Their main task is to restrain the users' mobility, keeping them away from the dangerous area associated with the risk of falls. A restraint system consists of an anchor component allowing attachment to work site construction elements, a connecting component with one end attached to the anchor element and the other to the harness (e.g., a lanyard with adjustable length and a guided-type fall arrester on a flexible anchor line equipped with hand-operated blockade), and harnesses, such as full-body harnesses, work-positioning belts, and sit harnesses.

Fall restraint systems are designed primarily for large-space gentle-slope work sites. Such systems can be used only at the work sites where the user does not have to stay in places associated with the risk of a fall.

The selection of components to be used in a system protecting against falls from a height should take into account the factors present at the work site, which can negatively affect the protective parameters of these components. The most important of such factors include thermal factors (e.g., molten metal splashes, open flame, high temperature, aggressive chemical substances), mechanical factors (e.g., sharp and rough objects), and atmospheric factors, including in particular low and high temperatures, humidity, and rainfall/snowfall.

The comfort of use is also an important factor in the selection of elements for personal systems protecting against falls from a height. The equipment should be as lightweight as possible, cause no restraint of movements necessary to carry out the required tasks, exert no pressure causing the sensation of discomfort, and provide a feeling of safety.

## 1 UNIQUE FACTORS IN SPACE FLIGHT

The first human space flight, in the early 1960s, was aimed primarily at determining whether humans could indeed survive and function in microgravity. Would eating and sleeping be possible? What mental and physical tasks could be performed? Subsequent programs increased the complexity of the tasks the crew performed. Table 1 summarizes the history of U.S. space flight, showing the projects, their dates, crew sizes, and mission durations. With almost 50 years of experience with human space flight, the emphasis now is on how to design space vehicles, habitats, and missions to produce the greatest returns to human knowledge. What are the roles of humans in space flight in low Earth orbit, on the moon, and in exploring Mars?

The National Aeronautics and Space Administration (NASA) has captured the information about physical health and human factors in several standards and handbooks, which form the basis for design of future space missions, vehicles, and habitats. NASA-STD-3001, *Space Flight Human System Standards*, Volume 1, *Crew Health*, was approved in 2009 (NASA, 2009a).

Volume II, *Human Factors, Habitability, and Environmental Health*, was approved in 2011 (NASA, 2011). These documents capture standards and their rationale. Much more human factors information is presented in NASA/SP-2010-3407, *Human Integration Design Handbook* (NASA, 2010c). These are the successors to NASA-STD-3000, *Man-Systems Integration Standards* (NASA, 1995), which captured standards, guidelines, lessons learned, and design concepts in one document.

### 1.1 Gravity

The most obvious factor specific to space flight is gravity. Orbiting Earth, crews experience free-fall, or microgravity. This affects all aspects of life and requires special considerations when designing habitat, equipment, tools, and procedures. During launch and entry, crews experience hypergravity for short periods of time. Extensive research and experience with high-performance aircraft has provided great understanding of these environments, and indeed, the tasks to be performed are similar to aviation tasks. On the surface of the moon and Mars, gravity is substantially lower

**Table 1  U.S.-Crewed Space Programs to Date**

| Program | Dates | U.S. Crew Size | Mission Length |
|---|---|---|---|
| Mercury | 1961−1963 | 1 | Up to 34 h |
| Gemini | 1961−1962 | 2 | Up to 6 days |
| Apollo | 1968−1972 | 3 | Up to 12.5 days |
| Skylab | 1973 | 3 | Up to 84 days |
| Apollo−Soyuz (ASTP) | 1975 | 3 | Up to 9 days |
| Space Transportation System (STS) | 1981−current | 2−10 | 3−17 days |
| Shuttle−Mir | 1995−1998 | 2 Russian, 1 U.S. | Up to 6 months |
| International Space Station (ISS) | 2000−current | 2−6 (including international partners) | approx. 6 months |

than on Earth but is definitely sufficient to allow designing habitats, equipment, and tasks analogously to those on Earth.

### 1.2  Mission Constraints

Accommodations for humans in space are constrained by the three major mission drivers: mass, volume, and power, each of which drives the cost of a mission. Mass and volume determine the size of the launch vehicle directly; they limit consumables such as air, water, and propellant; and they affect crew size and the types of activities the crew performs. Power is a limiting factor for a space vehicle. All environmental features—atmosphere, temperature, lighting—require power to be maintained. Power can be generated from batteries, fuel cells, or solar panels. Each of these sources requires lifting mass and volume from Earth, driving mission cost.

### 1.3  Mission Duration

The habitability and human factors requirements for space flight are driven by mission duration. The Space Transportation System (STS) was designed for missions on the order of 2 weeks—analogous to a camping trip. With Mir and the International Space Station (ISS), mission durations of 6 months became standard, requiring far more concern for habitability and for crew efficiency, training, and sustenance. As NASA begins to plan for a mission to the Mars surface, with travel times on the order of 6 months each way and a possible surface stay of 18 months, it must address providing all support and services to crew members: health maintenance, training, recreation, food, clothing, and so on.

### 1.4  Communications

To date, the model for space exploration has had a very small crew—a maximum of seven or eight on a shuttle flight and nominally six people on the ISS—supported by a very large group of scientific and engineering experts on the ground. The crew and ground personnel are linked through the mission control center (MCC). This model has been essential because such a small crew cannot be expert in all the critical subsystems on board. There are too few people to understand the subsystems in sufficient detail to operate and maintain them under nominal circumstances, let alone when malfunctions occur. But this model depends on rapid two-way communications. Video and audio transmissions allow the MCC to see and hear the crew and to transmit questions and procedures in a short enough time to be responsive to time-critical events. Even between Earth and the lunar surface, communications lags are on the order of seconds. But with a mission to Mars, communications can take up to 20 min each way, and a "black-out" period of up to two weeks may occur when the sun is between Earth and Mars. This requires the roles of the ground and flight crews to be reexamined.

### 1.5  Crew Time

Crew time is becoming recognized as another mission driver. The size of the crew affects mass and volume requirements directly. Designing equipment and procedures to maximize returns from crew time is beginning to be considered in the earliest stages of mission planning. Detailed studies of how crew time was actually used during Skylab (Bond, 1977) showed that approximately one-third of the crew time was spent in sleep and one-third in other forms of self-sustenance such as hygiene, exercise, eating, and recreation and one-third was actually devoted to operating the spacecraft and scientific experiments. This has not changed very much on the ISS.

## 2  ANTHROPOMETRY AND BIOMECHANICS

### 2.1  Changes in Posture and Body Size

In a microgravity environment the body changes. Immediately on reaching free-fall, the body assumes a neutral posture quite different from standing or sitting postures on Earth. The neck, shoulders, elbows, hips, and knees all flex somewhat, and the shoulders also abduct and rotate with a large intersubject variability. The result affects a crew member's line of sight, height, and reach envelope (Mount et al., 2003). The range of postures observed on one Shuttle mission is shown in Figure 1. Table 2 gives the joint angles. Figure 2 illustrates reach envelopes based on a typical posture for a 95th percentile crew member. After a short while, on the order of hours, the body height changes due to spinal elongation. Standing height increases about 3% during the first day or so in microgravity. A current study (Young et al., 2010) is measuring changes in seated height, which preliminary results indicate increases about 6%, affecting seat placement and suit design. The
**Figure 1**   Neutral postures in microgravity. Bodies 1–6 are actual crew members. Body 7 is a composite posture based on Skylab data.

**Table 2   Crew Microgravity Posture Measurements (deg)[a]**

| Anthropometric Measurement Joint Angles[b] | Skylab Composite Left–Right | Crew 1 Left–Right | Crew 2 Left–Right | Crew 3 Left–Right | Crew 4 Left–Right | Crew 5 Left–Right | Crew 6 Left–Right |
|---|---|---|---|---|---|---|---|
| Hip flexion | 50 | 33 | 33–29 | 33 | 33 | 29 | 12 |
| Hip abduction | 18.5 | 6.5–5.5 | 20–16 | 13–17.5 | 15.5–16 | 3.5–4.5 | 4–9 |
| Knee flexion | 50 | 50 | 83–87 | 50 | 50 | 44 | 11–12 |
| Ankle plantar extension | 21 | 6–7 | 15–14.5 | 29–30 | 27–24 | 16–14 | 35–41 |
| Waist flexion | 0 | 13 | 0 | 1 | 0 | 0 | 2 |
| Neck flexion | 24 | 16 | 18 | 16 | 5 | 7 | 16 |
| Left neck lateral bend | 0 | 0 | 0 | 3 | 0 | 0 | 0 |
| Shoulder flexion | 36 | 49–46 | 67–64 | 29 | 33–35 | 60–57 | 36 |

| Finger flexion | 0 | 42 | 60 | 30 | 21–57 | 55–47 | 25–35 |

[a]Crews 1–6 correspond to the body positions shown in Figure 1. Skylab composite corresponds to illustration 7.
[b]Angles are based on an upright stature coordinate system.

distribution of body fluids also changes. Fluids move to the head and torso, affecting hand size, facial appearance, the voice, and perhaps the sense of smell.

## 2.2   Changes in Strength

Changes in strength over time in microgravity have been a focus of research because of the direct effect on the ability to perform physical tasks. Jaweed (1994) reports significant (10–20%) decreases between preflight and postflight strength in the antigravity muscles (back and legs) after as few as 5–10 days on orbit. This, taken with the loss of bone mass observed (Schneider et al., 1994), indicates that countermeasures must be taken for long-duration flights and that tasks that can be performed
**Figure 2**  A 95th percentile stature crew member is shown in a neutral body posture (left) and standing vertically (right). The elliptical gray shading indicates the reach envelope. The darker gray cone indicates the viewing area.

early in flight might be more difficult or dangerous after an extended time in microgravity. The most common countermeasure for strength loss is exercise, particularly of the legs and back. Typical equipment includes bicycle ergometers and treadmills. When designing spacecraft, volume must be allowed for equipment storage and deployment. Significant periods of crew time, on the order of an hour per day per person, must be reserved for exercise. Design and location of equipment must address isolation of vibration and noise.

## 3  ENVIRONMENTAL FACTORS

### 3.1  Human Factors in a Closed Environment

NASA strives to close the spacecraft environment in the sense that every effort is made to recycle air and water rather than to carry replacement oxygen and water on a mission. This greatly affects design of the habitat and equipment. Materials must not release compounds that are difficult to remove from the atmosphere; this eliminates a variety of plastics and certain types of finishes for other materials. Materials must be compatible with cleaning materials and biocides that are safe for the environment; they must be incompatible with flourishing colonies of bacteria and mold.

### 3.2  Atmosphere

Crew members in a system must be provided with an environment to enable them to survive and function as a system component in space. An artificial atmosphere of suitable composition and pressure is the most immediate need. It supplies the oxygen and the pressure their bodies require. Humans can survive in a wide range of atmospheric compositions and pressures. Atmospheres deemed sufficient for human survival are constrained by the following considerations:

- There must be sufficient total pressure to prevent the vaporization of body fluids.
- There must be free oxygen at sufficient partial pressure for adequate respiration.
- Oxygen partial pressure must not be so great as to induce oxygen toxicity.
- For a long duration (in excess of two weeks), some physiologically inert gas must be provided to prevent atelactasis.
- All other atmospheric constituents must be physiologically inert or of low enough concentration to preclude toxic effects.
- The breathing atmosphere composition should have minimal flame or explosive hazard.

Mission planning must take the foregoing considerations for atmospheric conditions and balance them with the constraints of the mission: length of mission, mission objectives, requirement for prebreathe (for extravehicular activity), research requirements for the mission, and equipment in the vehicle. Carbon dioxide levels become increased with visiting shuttle missions. Because of this increase with an additional seven crew members from the shuttle, the ISS $CO_2$ scrubbers must be adjusted by ground control during visits. In the past high $CO_2$ levels have caused headaches with the crew members. This particular fix helped with the STS-127 shuttle mission (Harwood, 2009).

### 3.3  Water

In addition to the obvious need for drinking water, water is required for a variety of other uses, including personal use, hygiene, and housekeeping. If plants are to be grown during the mission, that is an additional water requirement. Typical water requirements for drinking, hygiene, and washing for each crew member are

2.84–5.16 kg per person per day for standard operational mode (NASA, 1995). A crew depends on water that is clean and safe. The use of water that is reclaimed and stored depends on its quality.

Water management systems changed with the design of the space vehicles and life support requirements of each program. During early Mercury, Gemini, and Skylab missions, water was filled up in tanks, built into the vehicle before launch, and carried into space. However, during the Apollo missions, the water source came from the fuel cells; fuel cells convert hydrogen and oxygen to generate power with water as the by-product. This marked a major breakthrough in the water management technology because water tanks did not have to be prefilled before the launch. The shuttle orbiter uses four 168-lb-capacity steel tanks. The potable water source comes from the fuel cell by-product, water.

The ISS has a water recycling system that reclaims wastewaters from the shuttle's fuel cells, from urine, and from oral hygiene and hand washing and by condensing humidity from the air. This eliminates the need to resupply 40,000 pounds per year of water for the life of the station (NASA, 2010b).

### 3.4 Noise

Noise can affect human physiology and health in a number of ways (Wheelwright et al., 1994). From the perspective of human factors, noise can affect performance by interfering with communications, interfering with sleep, and causing annoyance. In an assessment of the SpaceHab-1 mission (STS-57), Mount et al. (1994) found that, although the measured noise levels did not generally exceed the levels permitted for the shuttle flight deck or middeck, noise levels were substantially above design limits for the SpaceHab. This is probably because of the number and nature of experiments and equipment that were located there. However, most crew members required earplugs during sleep, even though they slept in the shuttle. Crew members principally used the intercom rather than unaided voice to communicate, even when in the same area, and reported difficulty in concentration and noise-induced headaches and fatigue.

Large space vehicles present a significant acoustics challenge because of obvious difficulties with controlling a number of connected, operating modules with payloads and equipment to perform vehicle functions and experiments, sustaining crew, and keeping them in good physical condition. Modules have equipment such as fans, pumps, compressors, avionics, and other noise-producing hardware or systems to serve their functional and life support needs. Payload racks with operating equipment create continuous or intermittent noises or a combination of both. Payload rack contributions to the total on-orbit noise can be and has been shown to be significant. The crew exercises on a treadmill and with other conditioning devices that generate noise. Communications between crew and ground, which are raised to communicate over the background environment, adds to the overall crew noise exposure. The crew members have to work and live in the resulting acoustic environment. The acoustics challenge is further complicated by the fact that there are numerous suppliers of modules, hardware, and payloads from across and outside the United States (Allen and Goodman, 2003).

The ISS is a complicated and sophisticated machine. ISS hardware is divided into categories, including the module (or spacecraft), government-furnished equipment, and payloads (science experiments). These different categories of hardware are governed by different requirements. Acoustic noise emissions verification is performed through actual test measurements of the hardware to the greatest extent possible. However, in some instances a fully integrated end item is not available due to schedule mismatches or physical limitations to the hardware configuration, or the payload may be delivered to ISS and placed in a rack already onboard. An acoustic test-correlated analytical model is used to predict overall noise levels in this case so that crew safety can be ensured. Remedial actions are performed to quiet hardware when necessary (Allen and Goodman, 2003).

The astronauts of the ISS are exposed to an average noise level of 72 dBA for the entire duration of their stay on the ISS, which can last up to six months. The significant noise sources throughout the ISS are the life support system ventilation fans and include the carbon dioxide removal systems (+70 dBA), the refrigerators (70 dBA), and air conditioning and ventilation fans (69–52 dBA). Another source of noise is the treadmill and vibration isolation system with an intermittent noise level of 77 dBA during ground assessment. Countermeasures against spacecraft noise include design engineering controls (like quiet fans and use of advanced composite materials), sound insulation materials, and hearing protection (ear inserts, passive muff headsets, and active noise reduction earpieces or headsets) (Clark and Allen, 2008).

### 3.5 Lighting

Lighting is essential to performing virtually every task in space. When windows are present and unshuttered, the typical 90-min low Earth orbit of the shuttle or station causes problems with time for eyes to adapt to the rapid disappearance of sunlight. In the study by Mount et al. (1994), the most frequent report of lighting problems was that sunlight made electronic displays and video monitors difficult or impossible to read. However, some activities, such as remote manipulator operations, require out-the-window viewing, and Earth watching is a favorite crew activity in any spare time. Wheelwright et al. (1994) and the *Human Integration Design Handbook* (NASA, 2010c) provide tables and guidelines for illumination levels for various intravehicular and extravehicular tasks.

Two critical tasks requiring vision of external targets are docking the shuttle to the ISS and using remote manipulators to position space-suited crew members or large structural components. In low Earth orbit, there is a change from light to dark every 90 min. In vacuum, shadows are much sharper than in an atmosphere, where water vapor, dust particles, and other airborne particles scatter light. To ensure adequate light, tasks may be scheduled to be performed in those parts of the orbit when the combination of sunlight and artificial light are predicted to provide adequate contrast

and visibility. NASA developed software that models realistic images of complex environments. Measured data are used to develop models of shuttle and station artificial light. Natural lighting, such as sun and Earth shine, are also incorporated into the lighting analyses. By incorporating the measured reflectance of each material into the lighting models, an accurate calculation of the amount of light entering a camera can be made. Using this calculated light distribution with the model of the shuttle cameras, camera images can be simulated accurately. Use of these lighting images are essential to predict available lighting during space operations requiring camera viewing, such as the assembly of ISS components. In preparing for a shuttle visit to the ISS, mission planners simulate the lighting environment for critical tasks at 1-min intervals.

### 3.6 Dust and Debris

Debris and dust in the orbiter crew compartment of early shuttle missions created crew health concerns and physiological discomfort and were the cause of some equipment malfunctions. Debris from orbiters during flight and processing was analyzed, quantified, and evaluated to determine its source. Selected ground support equipment and some orbiter hardware were redesigned to preclude or reduce particularization/debris generation. New filters and access ports for cleaning were developed and added to most air-cooled avionics boxes. Most steps to reduce debris were completed before flight STS-26, in 1988. After these improvements were made, there was improved crew compartment habitability and less potential for equipment malfunction (Goodman, 1992).

For future lunar/Mars exploration missions, the problem of dust in these environments is recognized. However, our knowledge at this time is limited as to the specifics of the dust. We have some data from previous lunar missions and are supplementing it with derived data. Derived data from our limited but growing knowledge of Mars is forming a basis of our need for requirements for dust abatement. The dust will cause a serious problem for extravehicular activity (EVA) suits and equipment used external to the vehicle. There is also a concern for dust in the vehicle habitation area. Dust inside the vehicle could increase crew time due to more frequent filter changes and other chores to remove dust from equipment. Basic habitability could also be affected if the dust were to accumulate on display screens and cooking equipment.

## 4  HABITABILITY AND ARCHITECTURE

### 4.1  Architecture

Habitability as a discipline is concerned with providing a space vehicle that within some understandably necessary size restraints provides a comfortable, functionally efficient habitat that will support mixed crews living and working together for the duration of the mission. Attention must be given to the morale, comfort, and health of crews with differing backgrounds, cultures, and physical size. Architectural design of crew interfacing elements should be comfortable for the extremes

of any crew population. The *habitability architecture* design concerns are mainly the fixed architectural elements such as (1) the geometric arrangements of compartments, (2) passageways and traffic paths, (3) windows, (4) color, (5) workstations, (6) off-duty areas, (7) stowage, and (8) lighting (NASA, 1983).

Habitable volume is defined as free, pressurized volume, excluding the space required for equipment, fixtures, furniture, and so on. It does not include "nooks and crannies" (i.e., spaces too small for human access). Total volume requirements depend on the specific program goals of the particular mission. Volume requirements for specific workstations have to be calculated after determination of the tasks required at the workstation and number of crew involved (NASA, 1983).

### 4.1.1  Compartments

The success of an extended mission on a space vehicle depends on the crew being an integral part of the interior design. The focus of any vehicle design should be crew centered. The arrangement and design of any habitable compartment should take into account the possibility of a subsystem failure or damage that could require quick, efficient evacuation. The actual vehicle arrangement depends on the specific program's goals and definition. Based on space flight history, configuration should take into account the following:

- Sleeping and private areas should be separate from traffic paths and noise generators.
- Areas that are to be used by more than one crew member at a time should be arranged to avoid bottlenecks. These are areas such as the galley, workstations, and waste management systems.
- Traffic flow analysis should be done for crew tasks and activities.
- Switches should be located in proximity of associated equipment.
- Adequate electrical outlets should be provided to reduce the use of extension power cords and the resulting "spaghetti all over."
- A dedicated desk/work area should be provided for general paperwork associated with vehicle keeping.

Skylab experience has shown that crew members were able to operate equipment easily from any orientation. Basically, a crew member established a local orientation based on himself or herself and proceeded without difficulty. However, it was also shown that crew could much more easily orient themselves in a room with equipment oriented with consistent up and down directions. An inconsistent zero-*g* orientation of one module caused orientation problems that were time consuming. The conclusion is that a common plane for visual reference should be designated throughout each module.

### 4.1.2  Passageways and Traffic Paths

A *passageway* is defined as a pass-through area between two nonadjacent compartments. Passageways shall be kept free of sharp and protruding objects. Skylab crew

members liked the large "ship-type" doorways. They found round hatches to be much less satisfactory.

Traffic paths consist of three types. *Emergency paths* are those used for crew passage to emergency equipment such as oxygen bottle or mask, firefighting equipment, pressure controls, and escape hatches. *Primary paths* are those used for personnel and equipment transfer between major habitable compartments or between a compartment and a workstation or off-duty area. *Secondary paths* provide access behind equipment, between equipment and structural members, and around workstations. All traffic paths can be superimposed to form a total traffic pattern, which in conjunction with detailed task analysis can be used to determine the most efficient placement of mobility aids. This traffic pattern and task analysis must also be used to design out potential bottlenecks in a space vehicle.

To be avoided are the bottlenecks experienced on Skylab missions. They were insufficient passage room in areas with workstations, too much activity in one place (e.g., conflicting placement of shower and tool kit), and the inability to use the waste management equipment if there was someone using the hand-washing equipment (NASA, 1983).

### 4.1.3  Windows

All habitable volumes should include windows that are adequate for terrestrial and celestial references. Windows are necessary for observation of scientific phenomena, monitoring of EVA, observation of the vehicle exterior, photography, and general viewing. Sufficient window locations should always be provided to view Earth for both Earth observation experiments and crew recreation and well-being.

All viewing windows and the area adjacent to them should be considered a crew workstation. Sufficient workspace and restraint equipment should be provided at view ports for one or more crew members to perform assigned tasks. A window should be installed in the pressure hatch that allows the flight crew to observe the EVA crew in the airlock. Windows that are to be utilized for special photography and scientific experiments must be designed with an aperture size that is compatible with the equipment and tasks specified for that location. Space flights have shown window gazing to be the prime off-duty activity for crew members. Window viewing has been a treasured pastime on all missions to date. Astronauts use photography as a way to connect to Earth events and a challenging pastime for some crew members. Between 2001 and 2005, astronauts took 144,180 images of Earth, 84.5% of which were self-initiated (Robinson et al., 2006, 2011)).

Design of windows should provide handholds and equipment restraints. Failure to do so for a window (Figure 3) in the science module of the ISS led to crew members using a flexible air hose as a handhold. After numerous uses, a hole popped open, causing a slow air leak that took weeks to detect and repair (Banke, 2004).

The design of viewing windows should not impose difficult housekeeping tasks on the crew. Cleaning equipment should be provided for removal of fingerprints and other stains that may accumulate. The equipment must be compatible with the coating(s) on the window and not scratch or affect the optical quality of the window or disturb any surface coating.

Each window should have a sufficiently clear area around it to permit a variety of body positions for viewing. A positive means of defogging the windows should be provided. All window covers and/or shutters should be operated by a device that is easy for any crew member to use. All viewing windows should be provided with a crew-operated, opaque sunshade located

**Figure 3**  An astronaut carries out Earth observation activities through the window in the ISS science laboratory.

within the interior of the spacecraft that is capable of restricting all sunlight from entering the habitable compartments (NASA, 1983).

### 4.1.4  Color

Color should be used to provide visual stimulation for the vehicle occupants and to create different moods for relieving the monotony of prolonged confinement. Factors required in color planning are room volume, function, architecture materials, safety, and required color coding. As the Skylab mission grew in length, the interior color scheme became less acceptable. The crew of the 84-day mission felt that the color scheme was too drab and suggested that accent colors should be used more extensively. Color coding should be used as a supplement to nomenclature to enhance discrimination and to assist the crew in rapid identification of functions. Coding of EVA equipment should be used with colors that will not deteriorate from solar exposure. All EVA handrails should be a standard color. The color should have a high contrast ratio with the background (NASA, 1983).

### 4.1.5  Workstations

A *workstation* is defined as any location in the space vehicle where a dedicated task or activity is performed exclusive of the recreation, personal maintenance, and sleep areas. Tasks and activities include vehicle stabilization and control, systems management, experiments, science, and maintenance (equipment repair). With any workstation, analysis should be done to determine the tasks, operator activities, tools, and equipment necessary for each workstation. To make efficient use of space, multiuse workstation can be considered.

All necessary equipment, tools, restraints, lights, and power outlets should be provided at each workstation. Adequate space should be provided for the crew to perform the assigned tasks efficiently and safely. Where possible, workstations and associated equipment should be standardized throughout the entire vehicle to aid in the efficiency of tasks. Part of the workstation analysis should cover adjacent workstations and any impact that might arise from two crew members working at adjacent workstations at the same time. An analysis of traffic flow should be completed to determine placement of a workstation without bottlenecks.

Flight experience has shown that anything "usable" will be used as a kickoff point or as a grabbing point to change direction of travel. All workstations should be planned to limit inadvertent control activation and/or deactivation by passing crew members. A restraint system should be incorporated into a workstation design with compatibility to the task to be done (NASA, 1983).

### 4.1.6  Off-Duty Areas

There should be a dedicated area for off-duty activities, with a minimum space for the entire crew. This allows for socialization. Stowage areas should be provided in a dedicated recreation area and in the personal space area for items to be used during recreation activity and off-duty time (NASA, 1983). There has been agreement

from crew members on U.S. missions and also from crew during analog studies that they do not like to have the same table used for dining as well as a maintenance bench and/or as a biology work area (Mount, 2002). The psychological need for a separate wardroom/dining table was realized by the ISS Expedition 1 crewmembers so they built a table from scratch using sheet metal and vice grips rather than waiting the delivery of a table in a future Progress mission (Jones, 2004; NASA, 2000).

### 4.1.7  Stowage

Stowage space must be provided. For efficient use the space should be near the stations where the stowed items will be used. A method should be provided for locating stowed equipment and supplies. This is extremely important for a mission like the ISS, where crews are changed out periodically, but large quantities of the stowed equipment and supplies stay (NASA, 1983). Substantial time is spent moving and unpacking stowed supplies and equipment; containers floating in the translation pathways as shown in Figure 4 may provide a hazard if an emergency were to occur.

### 4.1.8  Ambient Lighting

For the most part, lighting follows the same requirements as for an Earth structure, but spacecraft hardware designers face a few human factors challenges not usually encountered in earthbound environments. In general, design of any space vehicle must take into account the constraints of power and weight limitations. This has an impact on the number of lights and their specifications. General lighting for all vehicles designed and built in the U.S. space program have been fluorescent luminaires. LEDs (light emitting diodes) are being considered due to reduced mass and power required for a given amount of light. Fluorescent lighting has to be sealed to contain the mercury in case of breakage. The use of fixed luminaires for general illumination within the relatively small habitable volume of a spacecraft implies that an astronaut may frequently find one or more of these light sources in her or his field of view as she or he floats in microgravity. This creates potential direct glare sources. Additionally, many astronauts are old enough to have experienced typical symptoms of presbyopia. The loss of the full range of accommodation in their viewing close and distant objects is often simply compensated for by their use of corrective eyeglasses or contact lenses. These means are not available to an astronaut during EVAs in a spacesuit, however. The dry, low-pressure, high-oxygen content environment within the spacesuit precludes the use of contact lenses, and the helmet does not provide adequate interior space for eyeglasses. If the helmet were roomy enough to allow eyeglasses to be worn, it is likely that internal light reflections between the lenses of the eyeglasses and the interior of the faceplate would prove problematic. This means that when planning an EVA task, lack of eyeglasses and light levels must be taken into account.

While in low Earth orbit there is a change from light to dark every 90 min. This affects the EVA task planning, due to the changes in light and shadows. The

**Figure 4** Astronaut Alvin Drew moves a stowage container through the laboratory, while other storage bags are temporarily tethered to walls.

Graphics Research and Analysis Facility at Johnson Space Center uses an accurate lighting model to produce realistic images of this complex, ever-changing environment. Measured data are used to develop models of shuttle and station artificial lights along with the natural lighting from sun and Earth shine. This information is incorporated into the task analysis for EVA tasks.

### 4.2 Considerations for Self-Sustenance

The spacecraft must be designed to provide for all aspects of life. For long-duration missions, private compartments are used for sleep and certain personal activities, such as recreational reading or communicating with family and friends. Since the sleep compartment is the single location in which the crew member spends the most time (presleep and sleep), it has been found to be most effective to shield the compartment heavily against radiation.

#### 4.2.1 Sleep

An individual sleep compartment should be provided for each crew member. The private sleeping accommodations should have a privacy curtain, partitions, and stowage lockers. Each sleep area should be located as far as possible from noise, activity, and public area. Since there is no up or down in weightlessness, the position of the body does not matter during sleep (Figure 5). Some astronauts have been bothered by an effect known as *head nod*. If the head is not secure when fully relaxed during sleep, the head develops a nodding motion. Astronauts can secure the sleep restraint (sleeping bag) to limit this nod. Skylab sleep restraints were similar to sleeping bags with neck holes and arm slits. Straps were on the front and back so the crew member could be tightened for a steady, snug position. The space shuttle missions sometimes split the crew into two shifts

to enable around-the-clock science. The ISS is now equipped with six individual sleep stations that have their own lighting, ventilation, and soundproofing (Figure 6). The crew members enjoy the privacy and quiet sleeping environment the sleep stations afford. Many crew members decorate the inside of the sleep station with their family pictures and personal items.

#### 4.2.2 Food

The problem of ensuring astronauts consume sufficient calories and nutrients to maintain health and performance over missions of increasing duration has been a challenge to human systems integration (Perchonok and Bourland, 2002). Since the first food was consumed in orbit in 1962, improvements and developments have been made and are continuing to be made in the food systems for manned space flight. The food system for the Mercury flights was limited in scope and purpose. Food was used in most cases to obtain general information on the effects of null gravity on food ingestion and digestion and to determine types of food and packaging for longer duration space flights. Food for Mercury flights consisted of purees in aluminum tubes, coated tubes, and rehydratables.

The Gemini food system began with an all-dehydrated food system The food consisted of bite-size cubes with an expanded variety and rehydratable foods which included beverages, pudding, soups, fruits, and vegetables. The initial Apollo food system was based on the dehydrated system used for Gemini; however, greater attention was focused on astronaut preference. The availability of hot water increased the selection of foods and enhanced the palatability. The thermostabilized food in a flexible pouch, fresh bread, canned fruit and puddings, and frozen sandwiches for launch day were some of the items introduced on Apollo. Results

**Figure 5** Two examples of using the shuttle sleep restraint while sleeping in the shuttle middeck.

**Figure 6** Astronaut Peggy Whitson straddles the doorway of the temporary sleep station on the ISS.

from Apollo proved that food could be consumed from an open container using normal utensils in microgravity.

A completely new food system was designed for the Skylab program. The new system was required because (1) the food was launched with the orbiting laboratory and would be exposed to unusual environmental extremes and long-term on-orbit storage; (2) the metabolic studies on board required precise intakes of several nutrients; (3) all water had to be launched, so rehydratables offered no weight advantage; and (4) refrigerators, freezers, and food warmers would be available. To meet the long-shelf-life requirement, all Skylab foods were packaged in full-panel pull-out aluminum cans. Cabin pressure required that the aluminum cans be "overcanned" in canisters to withstand pressure variances. This resulted in the rehydratables being packaged in three containers: a plastic pouch, a can, and a canister. Beverages were packaged in a polyethylene collapsible container which expanded on reconstitution. Menus for Skylab were repeated every six days.

The design of the shuttle package significantly reduced the production process and eliminated numerous failure points. Most of the package production steps are automated or semiautomated. At the present time, research is ongoing to look into advanced technology for future food systems for lunar and/or Mars long-term missions.

The ISS menu composition is an extension of the menu system established for the space shuttle/Mir Phase 1 program, which consisted of 50% Russian and 50% American foods (Kloeris and Bourland, 2003).

The next possible step after ISS is long-duration manned space flights beyond low Earth orbit. The duration of these missions may be as long as 2.5 years and will probably include a stay on a lunar or planetary surface. The primary goal of the food system in these long-duration exploratory missions is to provide the crew with a palatable, nutritious, and safe food system and minimize volume, mass, and waste. The paramount importance of the food system in a long-duration manned exploration mission should not be underestimated. During long-duration space missions, several physiological effects may occur, including weight loss, fluid shifts, dehydration, constipation, electrolyte imbalance, calcium loss, potassium loss, decreased red blood cell mass, and space motion sickness. The

menu will provide the crew with changes in the nutrient levels that may be required due to the longer duration mission.

The acceptability of the food system is of much greater importance due to the longer mission durations and the partial energy intake often observed in space flight. The decreased energy intake might significantly compromise the survival of the crew.

### 4.2.3  Personal Hygiene

Managing personal waste and cleaning the skin and hair are problematic because of the lack of gravity and the cost of lifting water to orbit. Except for Skylab, dedicated volumes for various activities have been very limited. Early bodily waste management systems can be described succinctly as "baggies." Since Skylab, there have been a variety of suction-based toilets for collecting fecal matter and urine. The principal systems for personal hygiene for each major spacecraft are described below.

*Skylab*  Personal hygiene for the Skylab crew members was supported in the waste management compartment (WMC). The WMC included a fecal–urine collector, a hand washer, stowage for personal hygiene items and kits, and a drying station. There was also a shower aboard the Skylab. Pressurized water flow combined with a suction device to collect the water caused the water to flow "down." It was considered a pleasant experience but was very time consuming, about 45 min from start to finish. This included cleanup activity.

*Mir*  The Mir personal hygiene subsystem consisted of toilets for body waste management, hand washing units, a shower, and personal hygiene kits. For the last two years the shower was on board, and it was used as an air shower (sauna). It was removed to make way for other required equipment.

*Shuttle*  For washing, the shuttle crew is provided with a personal hygiene system hose located in the waste collection system (WCS) compartment. Water is squirted onto a washcloth using the hose. Some crew prefer to use the hygiene port provided at the galley because it provides hot water. The hose for the galley hygiene port is long enough to be extended to the WCS for cleansing and grooming. The crew is provided with no-rinse body bath and no-rinse shampoo.

*ISS*  The Russian segment is generally the same as for Mir, without a shower. In the U.S. segment the personal hygiene subsystem provides a WMC. Wet wipes and towels are used from the Russian segment. Occasionally, ISS crew members have rigged up a bathing device for their use. There are differing opinions on the results (Mohanty, 2001).

### 4.2.4  Exercise

Exercise regimens prescribed for space missions have required gradually longer and more frequent periods of exercise, particularly as the length of missions has increased. On the first prolonged (18-day) Soviet manned flight, *Soyuz 9*, physical exercises were performed by the cosmonauts for two 1-h periods each

day. In subsequent 24-day flights, 2.5 h of exercise per day was employed, including walking and running on a treadmill. By 1975, the standard program involved three exercise periods per day, with a variety of equipment, for a total of 2.5 h, with the selection of exercises on the fourth day being optional. Over the three missions of the Skylab program a similar increase in exercise quantity was imposed, although the total amounts were less than those used by the Soviets. On the last manned Skylab mission, a treadmill was provided which allowed more vigorous exercise.

Throughout the Skylab missions, successive improvements were seen in postflight leg strength and volume changes, orthostatic tolerance and recovery time, and cardiac output and stroke volume, even though each mission lasted four weeks longer than the last. *Skylab 4* was an 84-day mission. Results of exercise on Soviet missions have shown a similar pattern of reduced physiological deconditioning in response to more strenuous exercise programs (NASA, 1982).

The exercise requirement for ISS is 2.5 h daily with 1.0 h for aerobic exercise (cycle ergometry or treadmill locomotion) and 1.5 h for resistive exercise condition. Each time segment includes 15 min for setup and 15 min for set-down of equipment. Usually astronauts exercise six days a week, with day 7 as active rest (the astronauts can exercise if they want to). They usually start exercise conditioning after space motion sickness has resolved and all transfer of payload has occurred. The Russians do not start exercise countermeasures until flight day 30. The shuttle requirements are different and depend on mission length and crew member roles. They apply only to use of the cycle ergometer.

### 4.2.5  Recreation

With any space vehicle design for a long-term mission, an area for recreation should be designated to provide for social interaction, Earth viewing, games, videotape viewing, music, and active and passive participatory activities. A quiet area should be provided for a crew member to read, listen to music, and write. Currently on the ISS astronauts and cosmonauts listen to their music on computers or personal MP3 players and uplinked streaming video has replaced videotapes and DVD movies. There is an electronic keyboard and guitar on the ISS. And some astronauts have brought their own instruments, like a trumpet and even a didgeridoo. Holiday decorations and materials are located in a specific locker to keep the morale of the crew high on their holidays. Astronauts also have access to a standard load and individual recreational software on their computers. These examples of recreation are continually being upgraded on the ISS.

### 4.3  Vehicle Maintenance

With the exception of Skylab and ISS, in-flight maintenance provisions and planning on U.S. space programs have not been supported by definitive program requirements. The Skylab mission acknowledged a substantive role for maintenance to achieve mission objectives. The wisdom of this decision was validated by the major repair and maintenance tasks required during the brief lifetime of the program. The shuttle program was to have

no in-flight maintenance, with all maintenance tasks planned to be done on the ground. Over the life of the program this has changed, due to the necessity of preventive maintenance, even on the short missions, and unanticipated problems (Mount, 1989).

On-orbit maintenance was recognized as an essential consideration within the ISS program (NASA, 2004). A three-tiered maintenance concept was adopted that is similar to that employed by military organizations. The primary mode of on-orbit maintenance was designated as organizational maintenance and consisted primarily of removal and replacement of orbital replaceable units (ORUs) (comparable to line replaceable units in military applications). This was supplemented by in situ maintenance for systems that did not lend themselves to the modular ORU design approach, such as utility lines and secondary structure. The option was retained for intermediate-level maintenance, which would consist of on-orbit repair of ORUs. Intermediate-level maintenance has been employed to a limited extent in applications such as replacement of circuit cards within avionics ORUs. Crew member training for maintenance has focused on the development of general skills and on types of maintenance tasks. However, extensive training on highly specific actions is done in some specific instances.

Future missions will be challenged by their extended duration, limited or no resupply opportunities once the mission has begun, and extended round-trip communication times (Watson et al., 2003). These factors will require such missions to be almost entirely self-sufficient. An additional constraint will be the need to carefully control and minimize the mass and volume of equipment and supplies used to support maintenance activities. It is expected that maintenance will be performed at the level of piece parts, so that the required replacement parts will be as small as possible. However, performing maintenance at this level carries significant implications from multiple perspectives.

First, hardware must be designed to enable crew members to perform the required maintenance. Not only must the equipment be accessible but also it must be possible for units to be disassembled as necessary to enable piece-part replacement. Additionally, commonality and standardization of piece parts must be imposed to obtain mass and volume benefits. If not, the number of unique piece parts could be so great as to negate any potential benefit. This maintenance concept will also require more extensive diagnostic capabilities than have been used heretofore in space. Every effort should be made to incorporate these capabilities within the systems themselves to minimize the amount of stand-alone test equipment that is required. Preparation of all potential maintenance procedures in advance will probably be prohibitively expensive, so means must be available to provide crew members with necessary information and guidance when needed. An attractive concept would be capable of automatically generating needed procedures based on input from diagnostic systems and from hardware design information stored onboard. Finally, maintenance at this level will require the ability to perform quality assurance tests (Watson, 2003).

Future missions will probably require operations in multiple gravitational environments, including the microgravity environment of Earth orbit or in-space transit, lunar gravity (approximately $0.17g$), and Martian gravity (approximately $0.38g$). Design for maintenance must take these environments into account. For example, a microgravity environment offers three-dimensional freedom of motion, facilitating access to all areas within a spacecraft volume. However, a microgravity environment introduces significant challenges from the standpoint of reacting forces that must typically be applied during maintenance tasks. Fractional-$g$ environments will restrict mobility and access to some degree (e.g., restricting access to hardware in overhead locations) but will facilitate the application of forces by crew members. Another subtle advantage to working in fractional-$g$ environments is that unrestrained parts and tools remain where placed and do not tend to float away and become lost.

With longer missions maintenance must be planned and all contingencies must be anticipated. Simple maintenance tasks take on great complexities when in microgravity. What might be considered a simple task on Earth, such as using a slot-head screwdriver, could be impossible in space. Automation is being developed to save crew time and increase productivity, but we need to know all the ramifications when the automation (and robotics) breaks down (Mount, 1989). As automated capabilities become increasingly prominent in maintenance operations, the potential for their failure and appropriate fallback positions must be considered. Tasks and hardware for which robotic intervention is planned should retain manual intervention as a backup capability. Designs should not preclude manual troubleshooting even if embedded diagnostics are planned. Interchangeability of hardware within and among spacecraft should be a key design objective.

Considerations to be given for support of maintenance in space fall into four categories (Mount, 1989):

1. Crew provisions, which includes interfaces, restraints, physical and visual access, tools and equipment, procedures and references, and personal protective equipment
2. Hardware design, which includes design for maintainability; use of common connectors, fasteners, and mounts; structural interfaces; and replacement parts
3. Software, which includes architecture design for maintainability and reconfigurability, fault detection and recovery, integrated training support, and inventory control and management
4. Supporting disciplines and processes, especially safety, reliability, and quality assurance

### 4.4 Restraints

Launch and reentry require significant structural strength; loads of up to $5g$ are experienced in nominal conditions. But once in orbit, the microgravity environment enables objects to be held in place with very little force; hook and loop fasteners dot the surfaces.

**Figure 7** Operating the remote manipulator system requires a stable restraint carefully adjusted.

**Figure 8** Brief activities can be performed with simpler restraints.

On the other hand, some force must be provided to hold anything in place. Restraints are needed for both personnel and equipment in microgravity. The most common restraint for crew members is a foot restraint. In a location where a person will be working for extended periods of time, platforms can be used that tilt to accommodate a neutral posture, with the feet angled down and with height adjustments.

Tasks of various durations requiring various degrees of force or dexterity require different types of restraints. Short, easy tasks can often be performed with toes stuck under a handle or one hand on a handhold. Tasks such as attaching a module to the ISS using the remote manipulator system, which take many hours and a high degree of hand–eye coordination, require a restraint such as that shown in Figure 7. This restraint provides support for the feet and thighs. Another example of restraints is shown in Figure 8, illustrating use of existing hardware for a temporary restraint.

## 5 SLEEP AND CIRCADIAN RHYTHM

### 5.1 Sleep Shifting and Light

Circadian and sleep components, two physiological processes, interact in a dynamic manner to regulate changes in alertness, performance, and timing of sleep. Light can aid in shifting circadian rhythms to an

earlier or later time within the biological day. Also, use of bright light during nighttime can result in significant improvement in performance and alertness levels (Campbell and Dawson, 1990). Astronauts in space are exposed to variable light levels due to the non-24-h orbital cycle (day/night) of space operations, such as the 90-min orbital cycle of the shuttle. Additionally, light levels in the space environment can be variable. Field data have shown that light levels aboard spacecraft can be as low as 10 lux during the highest activity portions of the day and as high as 79,433 lux on the flight deck (Dijk et al., 2001). The Soviets recommended 400–500 lux of full-spectrum light for work on spacecraft, and results demonstrated an improvement in performance when the location of lights on *Salyut*-7 was changed to maximize lighting (Bluth, 1984).

Barger et al. (2008) reported on their progress in collecting in-flight data about actual sleep patterns using Actiwatches and sleep logs. Preliminary results of this and other sleep studies are available in the report "Risk of Performance Errors Due to Sleep Loss, Circadian Desynchronization, Fatigue and Work Overload" (Whitmire et al., 2010).

NASA currently uses light treatment to help crew members adapt their circadian system prior to missions,

allowing the astronauts to be physiologically alert when critical tasks are required. The timed use of bright light to facilitate circadian phase shifts was effective in the STS-35 mission, the first mission requiring both dual shifts and a night launch. Subjective reports indicated that crew members were able to obtain better quality sleep during the day and remain more alert during the night after using bright-light exposure to facilitate their schedule inversion prior to the launch dates (Czeisler et al., 1999). Czeisler is currently testing the hypothesis that exposure to short-wavelength light will synchronize circadian rhythms to a shifted sleep schedule within four to five days.

Around-the-clock operational tasks for some missions have required splitting crews into two separate shifts, which required that half the crew invert their sleep–wake cycles. A procedure called *slam shifting*, which involves abrupt shifts of up to 12 h, has been used to align the sleep–wake schedules of shuttle and ISS crews upon docking, in conjunction with EVAs, and also with Progress and Soyuz dockings. The ISS crew is normally on Greenwich Mean Time (GMT) and will be shifted either to Moscow time or Houston time for activities under those perspective ground controllers and then returned to GMT after the activity is completed. Staggered sleep schedules on an eight-day mission did not work, since the crew tended to retain ground-based work–rest cycles and the schedules resulted in increased fatigue and irritability. On a one-year flight, where sleep times for docking operations were shifted by 4.5–5.0 h a total of 14 times, asthenia, end-of-day fatigue, and sleep disruptions were documented (Grigor'yev et al., 1990).

Current astronaut crew scheduling guidelines allow for astronauts' schedules to be lengthened by no more than 2 h (phase delay) and shortened by no more than 30 min (phase advance) within a given day (NASA, 1992). Schedules can be lengthened only if there is an operational requirement. For example, if the shuttle is going to dock with ISS during a time that the ISS crew is scheduled to be sleeping, operations would require the ISS crew to shift to a new schedule in the days preceding in order to be awake and alert for the docking (Mallis and DeRoshia, 2003).

### 5.2 Mars Day Circadian Entrainment

With NASA's continuing support of a manned mission to Mars, the effects of a Mars light–dark cycle must be investigated to determine a person's ability to adapt to a Mars cycle and its impact on physiological alertness. The Martian day, otherwise known as a sol, is about 39 min longer than an Earth day (a sol period is 24.6 h). Although this period length is well within the circadian range of entrainment according to previous studies conducted in relatively bright light (23–27 h) (Aschoff and Wever, 1981), preliminary laboratory results have suggested that in dim-light conditions, such as found indoors, humans cannot reliably entrain to a 24.6-h Mars sol. People differ as to their circadian rhythm, and the 25% of the population who have periods shorter than 24 h will have the greatest challenges acclimatizing to a Mars sol (Mallis and DeRoshia, 2003). Another laboratory study by Gronfler et al. (2007) showed that,

while 25 lux did not entrain subjects, 100 lux and a modulated light exposure of 25, 100, and 9500 lux did entrain the subjects to a 25-h day. This light exposure entrainment was confirmed in a study conducted in an operational environment with Phoenix Mars Lander scientists who lived on a Mars sol during their 90-day mission in 2008 (Thompson, 2008).

## 6  PERCEPTION AND COGNITION

One driver of human spaceflight is the perceptual–cognitive abilities of the crew. Perception includes both the sensing and interpreting of stimuli. Cognitive capabilities range from attention to spatial skills to executive decision making. Consideration must be given to how spacecraft architecture and design can help or hinder perceptual and cognitive capabilities across all task demands and crew capability (NASA, 2009b).

The major difference between optimal perceptual and cognitive functioning on Earth and long-duration space flight is the challenge of microgravity. Microgravity produces fluid shifts which in turn change otolith regulation and vestibulo-ocular reflexes and affect the congruence of the vestibular system to other receptors. Eye–hand coordination and gaze transitions can be temporary perceptual problems while adapting to microgravity (Paloski et al., 2008). During this time of adjustment, postural cues are disorienting and body movement may be awkward if not unbalanced. Re-entry to a $1g$ environment will also cause temporary fluid shifts as the body returns to Earth normal. Whole-body vibration, such as seen during launch or landing, hurts perceptual accuracy (Conway et al., 2006). The added component of adapting to a different gravity may lead to additional head movement hypersensitivity or illusions of self-motion (NASA, 2010d). Reduced capacity to easily make sense of perceptual cues will lead to cognitive inefficiency. Inability to perceive accurately will reduce spatial cognition, decision making, and problem solving. Attention that could be focused on other problems will be used trying to make sense of the ambiguous stimuli.

Over a decade of work on the ISS has begun to shed light on individual variations in perceptual and cognitive functioning across time in microgravity. After an individual adapts to space, the crew members can successfully complete basic cognitive tasks (Fowler et al., 2008). How long-term space flight affects an individual's complex mental functioning is being assessed by an experiment sponsored by the European Space Agency led by L. Balazs and Guy Cheron (Balazs et al., 2009). Current evidence indicates that crew members adapt and return to, or near, baseline functioning. Nonetheless, the space traveler will need easily available reviews of training in-flight for complex or seldom used procedures. The designer of robotic aids must take into account the complete isolation, autonomy, confinement, and noise that the spacefarer will endure as well as understand human problem-solving processes (NASA, 2010c). The military has Earth-based training and robotic aids that can be modified for enhanced cognitive ability in space.

In human space flight, cognition includes adapting to new situations no matter how unexpected or novel, coping with off-nominal tasks, and resolving technical and social challenges. The human will make executive decisions and must be technically competent and healthy enough to maintain cognitive skills. Poor air quality, compromised immune systems, poor task design or displays,and user-unfriendly or user-incompatible robotic aids will all decrease cognitive efficiency (Manzey, 2000).

The configuration of the ISS is such that what is "up" in one module may be down in another. Smoke or hazy conditions will exacerbate the spatial and visual challenges of working across modules, thereby increasing the need for redundant auditory aids and clear interfaces and controls. Exposure to toxins, excessive radiation, infection, or poor air quality can easily reduce cognitive clarity, making the crew member more reliant on clarity of presentation and robotic aids. Visual perception is dependent upon good lighting without ambiguous shadows or blinding glare. This is especially true in off-nominal events or in the exhaustion of EVA.

Reviews of the stressors to cognitive functioning can be found in Kanas and Manzey (2008) and Bourne and Yaroush (2003). Individual and team cognition is affected by individualistic versus collective cultures. The design of habitat and communication interfaces, training of social roles, and on-board aids for multi-cultural group or metacognition are important to avoid cognitive inefficiency. Earth-based ground crews will also be multinational, often working according to space-craft time while living on earthbound time (Schmidt et al., 2009).

Off-nominal tasks increase the cognitive workload at the same time that the crew must work under the physical demands of microgravity. On long-duration spaceflight, cognitive workload could also be minimal, easily leading to boredom and automaticity. To maintain optimal performance and safety, human factor experts need to consider task design and analysis, monitoring, and intervention for either too high or too low workload.

Spacecraft and habitat must be compatible with normal human perception and cognitive processing. Signal-to-noise clarity is increased with easily recognized, consistent orientation and location across the environment, with clear visual, sound, and tactile contrast.

Impaired perceptual or cognitive functioning because of psychiatric reasons, head trauma, or infection will require on-board medical intervention or stabilization. Early recognition or prevention of such incidents is clearly the better option. Although the same is true on Earth, there is no way to quickly extract an impaired crew member. If perceptual or cognitive impairment occurs, the system infrastructure needs to be robust enough to support the crew member during reduced functioning.

## 7 ASTRONAUT SELECTION

Today's astronauts come from an international pool of candidates, including the European Space Agency (ESA), the Russian program, Canadian Space Agency (CSA), Japanese Aerospace Exploration Agency (JAXA), and the U.S. program. Each country selects its own astronaut candidates according to its own criteria. Planning the first U.S. astronaut selection in 1958, Allen O. Gamble, one of the psychologists on the medical team, realized that there needed to be some job or task analyses—a difficult challenge, as no one had ever flown in space before. He listed the duties of the first astronauts as the following (Link, 1965):

1. To survive; that is, to demonstrate the ability of humans to fly in space and return safely
2. To perform; that is, to demonstrate the human capacity to act usefully under conditions of space flight
3. To serve as backup for automatic controls and instrumentation; that is, to add reliability to the system
4. To serve as scientific observers; that is, to go beyond what instruments and satellites can observe and report
5. To serve as engineering observers and, acting as true test pilots, to improve the flight system and its components

Since the late 1950s there has always been some system of psychological selection, although there have been many changes in criteria and procedure. Originally, psychological assessment was extensive, requiring 30 h of psychological testing, plus interviews and evaluation by a team made up of a psychiatrist, an industrial–organizational psychologist, and management. In the 1960s the Lovelace clinic tested several women; 25 female pilots completed the same psychological evaluations as those given the males chosen for the Mercury project. Of these, 13 of them enrolled in an unofficial astronaut training program; none were declared official astronaut candidates.

From 1958 through 1969, astronaut selection occurred at least four more times. Since applicants already had extensive, often hazardous, flight experience, criteria emphasized emotional stability, motivation and energy, self-concept, and quality of interpersonal relationships. Psychological testing now required only 6.5 h, and the clinical evaluation was primarily psychiatric rather than psychological. This shift toward clinical content paralleled a shift away from research, reducing the data available for systematic scientific selection into astronaut selection. By 1983, Jones and Annes (1983) could write: "Presently, no psychological testing is done." Instead, the evaluation consisted of two consulting psychiatrists who separately interviewed each candidate for 2 h. This screening, although completed by expert aviation psychiatrists, did not have specific and objective criteria by which to rate each candidate.

After a hiatus of nine years, in 1978, astronaut selection began again for the space shuttle program, including nonpilots, scientists, and women. It was not until the 1980s that NASA hired its own psychiatrist and, soon thereafter, a psychologist to work in the

operational arena. From 1988 through 1990, a newly established in-house group met to improve the selection process. This first NASA Working Group on Psychiatric and Psychological Selection of Astronauts in 1988 distinguished between the roles of psychology and psychiatry and rewrote NASA psychiatric standards to include disqualifying psychiatric disorders based on the then-current American Psychiatric Association's *Diagnostic and Statistical Manual*. In addition, the working group defined the "best" psychological make-up for the job of astronaut and the "best" crew psychological mix, particularly for extended-duration space flights. Three attributes—aptitude, motivation, and sensitivity (referred to as select-in criteria)—were defined as being of equal importance in the selection of astronauts (Santy, 1994). Aptitude includes the psychological traits of intelligence and technical aptitude, history of professional success, adaptability and flexibility, being a team player, ability to represent NASA effectively, stress or discomfort tolerance, ability to function despite personal danger, ability to compartmentalize, ability to tolerate separation from loved ones, and ability to tolerate isolation. Motivation includes the psychological traits of achievement/goal orientation, hardworking/self-starting, mastery, persistence, optimism, no unhealthy motivation, healthy sense of competition, capacity to tolerate boredom, mission orientation, and healthy risk-taking behaviors. Finally, sensitivity to self and others includes the psychological traits of overall emotional maturity and stability, self-esteem, ability to form stable and quality interpersonal relationships, expressivity, sense of humor, insight and self-awareness, appropriate assertiveness, and cultural sensitivity. These three attributes coincide with the known astronaut tasks of systems management, sequence monitoring, motor tasks like steering vehicles and remote arm activities, repair and maintenance, conduct experiments, assembly, public relation activities, and self care (Santy, 1994). Beginning in 1989, NASA began using teams of external psychiatrists and psychologists to assist with the mental health portion of astronaut selection. These teams were asked to assess the applicants from a psychiatric and psychological viewpoint with the tasks of the astronauts. Subsequent behavioral health and performance selection meetings to review and update selection procedures were convened: NASA Psychiatric Astronaut Selection Standards meeting in 2001 to review psychiatric standards, NASA Select-Out review meeting in 2003, and an Astronaut Selection Working Group in 2008.

Holland (1999) notes that, by 1989, clinical testing had returned, giving some objective data to be used by the psychiatrists, but it was still a medical model. By the 1994–1995 selection cycle, nonmedical evaluations based on industrial–organizational principles and techniques were added to the clinical and medical models. Based on these organizational studies, Galarza and Holland (1999, p. 4) have listed the critical psychological proficiencies needed for space flight: "mental/emotional stability, ability to perform under stressful conditions, group living skills, teamwork skills, ability to cope with prolonged family separations, motivation,

judgment/decision making, conscientiousness, communication skills, leadership capability." These proficiencies or critical skills have continued to be assessed in all subsequent astronaut selection cycles (Hysong et al., 2007). Between 1978 and 2010 NASA had another13 selection group cycles that selected 257 U.S. astronauts. In the same timeframe, 94 Russian cosmonauts, 38 ESA astronauts, 14 Chinese astronauts, and 11 Canadian astronauts have been selected by their respective countries using very similar techniques of psychological testing, medical physicals, interviews, and practical exercises or simulations.

Long-duration missions aboard the ISS currently last six months. Training for long-duration missions is very arduous and takes approximately two to three years. This training requires extensive travel, including long periods away in other countries training with our international partners. Travel to and from the ISS will be by space shuttle until its retirement, which is expected in 2011. Following the shuttle retirement, all trips to and from the ISS will be aboard the Russian Soyuz vehicle.

Information about applying to the NASA astronaut selection process is available at http://nasajobs.nasa.gov/astronauts/content/broch00.htm (NASA, 2010a).

## 8 CONCLUSIONS

After 50 years of human space flight and 10 years on the ISS, we have gathered great quantities of information dealing with the crew and their interfaces. With a new mission in front of us, going beyond low Earth orbit, we must learn more about the challenges of long-term missions. We must gather much more data from ISS missions. Additionally, we must take advantage of analogs that are consistent with the perceived challenges of long-term missions and glean what we can to augment our knowledge base.

## 1 INTRODUCTION

Over the past few decades, human factors and ergo-nomics practitioners have been called upon increasingly early in the system design and development process. Early inputs from all disciplines result in better and more integrated designs, as well as lower costs, than if one or more disciplines are solely in charge, find out late in the development stage that changes are required, and then call upon the expertise of the other disciplines. Our goal as human factors and ergonomics practitioners should be to provide substantive and well-supported input regarding the human(s), his or her interaction(s) with the system, and the resulting total performance. Total performance includes a number of converging measures, including task latency, type and probability of errors, quality of performance, and workload measures. Furthermore, we should be prepared to provide this input from the earliest stages of system concept development and then throughout the entire system or product life cycle.

To meet this challenge, many human factors and ergonomics tools and technologies have evolved over the years to support early analysis and design. Two specific types of technologies are design guidance (e.g., Boff et al., 1986; O'Hara et al., 1995) and high-fidelity

rapid prototyping of user interfaces (e.g., Dahl et al., 1995). Design guidance technologies, in the form of either handbooks or computerized decision support systems, put selected portions of the human factors and ergonomics knowledge base at the fingertips of the designer, often in a form tailored to a particular problem, such as nuclear power plant design or Unix computer interface design. However, design guides have the shortcoming that they do not often provide methods for making quantitative trade-offs in *system* performance as a function of design. For example, design guides may tell us that a high-resolution color display will be better than a black-and-white display, and they may even tell us the value in terms of increased response time and reduced error rates. However, this type of guidance will rarely provide good insight into the value of this improved element of the human's performance to the *overall system's* performance. As such, design guidance has limited value for providing concrete input to *system-level performance prediction*.

Rapid prototyping, on the other hand, supports analysis of how a specific design and task allocation will affect human and system-level performance. The disadvantage of prototyping, as with all human subject experimentation, is that it can be slow and costly. In particular, prototypes of hardware-based systems, such

as aircraft and machinery, are very expensive to develop, particularly at early design stages when there are many widely divergent design concepts. Despite the expense, hardware and software prototyping is an important tool for the human factors practitioner, and its use is growing in virtually every application area.

Although these technologies are valuable to the human factors practitioner, what is often needed is an integrating methodology that can extrapolate from the base of human factors and ergonomics data, as reflected in design guides and the literature, to support system-level performance predictions as a function of design alternatives. This methodology should also bind with rapid prototyping and experimentation in a mutually supportive and iterative way. As has become the case in many engineering disciplines, a prime candidate for this integrating methodology is computer modeling and simulation.

Computer modeling of human behavior and performance is not a new endeavor. Computer models of complex cognitive behavior have been around for over 20 years (e.g., Newell and Simon, 1972; Card et al., 1983) and tools for computer modeling of task-level performance have been available since the 1970s (e.g., Wortman et al., 1978). However, three trends have emerged in the past decade to promote the use of computer modeling and simulation of human performance as a standard tool for the practitioner. First is the rapid increase in computer power and the associated development of easier-to-use modeling tools. People with an interest in predicting human performance through simulation can select from a variety of computer-based tools. For a comprehensive list of these tools, see the Defense Technical Information Center (DTIC) Directory of Design Support Methods (DDSM). The DDSM contains references to human systems integration (HSI) design and interface tools, techniques, databases, guides, and standardization documents. Second is the increased focus by the research community on the development of *predictive* models of human performance rather than simply descriptive models. For example, the goals–operators–methods–selection rules (GOMS) model (Gray et al., 1993) represents the integration of research results into a model for making predictions of how humans will perform in a realistic task environment. Another example is the research in cognitive workload that has been represented as computer algorithms (e.g., McCracken and Aldrich, 1984; Farmer et al., 1995). Given a description of the tasks and equipment with which humans are engaged, these algorithms support assessment of when workload-related performance problems are likely to occur and often include identification of the quantitative impact of those problems on overall system performance (Hahler et al., 1991). These algorithms are particularly useful when embedded as key components in computer simulation models of the tasks and the environment. Third is the integration of those algorithms into cognitive architectures that integrate cognition, perception, and action into a single computational framework that can be applied to a broad range of tasks, from basic laboratory experiments used to validate the architectural mechanisms to

predicting operator performance on complex practical tasks (Gray et al., 1997).

Perhaps the most powerful aspect of computer modeling and simulation is that it provides a method through which the human factors and ergonomics team can "step up to the table" with the other engineering disciplines, which also rely on quantitative computer models. What we discuss in this chapter are the methods through which the human factors and ergonomics community can contribute early to system design trade-off decisions.

## 1.1 Chapter Objectives

In this chapter we discuss some existing computer tools for modeling and simulating human–system performance. It is intended to provide the reader with an understanding of the types of human factors and ergonomics issues that can be addressed with modeling and simulation and some of the tools that are now available to assist the human factors and ergonomics specialist in conducting model-based analyses and an appreciation of the level of expertise and effort that will be required to use these technologies. We begin with two caveats. The first is that we are not yet at a point where computer modeling of human behavior allows sufficiently accurate predictions that no other analysis method (e.g., prototyping) is needed. In the early stages of system concept development, high-level modeling of human–system interaction may be all that is possible. As the system moves through the design process, human factors and ergonomics designers will often want to augment modeling and simulation predictions with prototyping and experimentation. In addition to providing high-fidelity system performance data, these data can be used to constrain, enhance, and refine the models. This concept of human performance modeling supporting and being supported by experimentation with human subjects is represented in Figure 1. In essence, simulation provides the human factors and ergonomics practitioner with a means of extending the knowledge base of human factors and of amplifying the effectiveness of limited experimentation.

The second caveat is that the technologies discussed here are evolving rapidly. We can be certain that every tool discussed is undergoing constant change and that new modeling tools are being developed. We are discussing computer-based tools, and we expect the pace of change in these tools to mirror the pace in other software tools, such as word processors, spreadsheets, presentation and productivity tools, and Internet-based applications. These detailed discussions of several of the modeling tools are included to facilitate better understanding of human performance modeling tools. We encourage the reader to follow citations in this chapter to assess the current state of any tool. Most of these modeling tools have large, active user communities that maintain websites to provide introductory tutorials, software downloads, validated models, and published papers. These resources are invaluable both for the experienced modeler trying to stay abreast of recent developments and the novice user attempting to get up to speed on a new technology.
**Figure 1** Synergy between modeling and experimentation.

## 2 QUESTIONS ADDRESSED BY HUMAN PERFORMANCE MODELS

Below are a few classes of problems to which human–system modeling has been applied:

- How long will it take a human or team of humans to perform a set of tasks as a function of system design, task allocation, and individual capabilities?
- What are the performance trade-offs for different combinations of design, task allocation, and individual capability selections?
- What are the workload demands on the human as a function of system design and automation?
- How will human performance and resulting system performance change as the demands of the environment change?
- How many people are required on a team to ensure safe, successful performance?
- How should tasks be allocated to optimize performance?
- How will environmental stressors such as heat, cold, or vibration affect human–system performance?

The list above is a sample rather than an exhaustive list. The tools we discuss in this chapter are inherently flexible and we consistently discover that these tools can be used to solve problems that the tool developers never conceived. To assess the potential of simulation to answer questions, in every potential human performance modeling project we should first determine the specific questions that the project is trying to answer. Then we can conduct a critical assessment of what is important in the human–machine system being modeled. This will define the required content and fidelity of the model. The questions that should be considered about the system include:

1. *Human Performance Representation*. What time or duration of performance is important? How is human performance initiated, and what resolution of behavior is required? What aspects

of human performance, including task management, load management, and goal management, are expected? How much is known and constrained about the knowledge and strategies that human users bring to bear on this task?

2. *Equipment Representation*. What equipment is used to accomplish the task? To what level of functional and physical description can and should equipment be represented? Is it operable by more than one human or system component?

3. *Interface Requirements*. What information needs to be conveyed to the humans and when? Is transformation of information required? How often is information updated and monitored?

4. *Control Requirements*. What processes need to be controlled by the human and to what level of resolution? How much attention is required by the human to perform control changes?

5. *Logical and Physical Constraints*. How is performance supported through equipment operability and procedural sequences? What alarms and alerts should be represented?

6. *Simulation Driver*. What makes the system function? The occurrence of well-defined events (e.g., a procedure), the passage of time (e.g., the control of a vehicle), or a hybrid of both?

In using human performance models, perhaps the most significant task of the human factors practitioner is to determine what aspects of the human–machine system to include in the model and what to leave out. By defining the purpose of the model and then answering the questions above, the human factors practitioner will get a sense of what is important in the system and therefore what may need to be represented in a model. Many modeling studies have failed because of the inclusion of too many factors that, although a part of human–system performance, were not system performance drivers. Consequently, the models become overly complex and expensive to develop. In our experience, it is better to begin with a model with too few aspects of the system represented and then add to it than to begin a modeling project by trying to model everything. The first approach may succeed, whereas the second is often doomed. It is also important that the

level of detail is consistent with the types of data that are available.

Additionally, the human factors practitioner should consider the measures of effectiveness of the system that the model should be designed to predict. In building the model, it is important to remember that the goal will be to predict measures of human performance that will affect system performance. Therefore, a clear definition of what is important to performance is necessary. The following aspects of performance measures should be considered:

1. *Success Criteria.* What operational success measures are important to the system? Can these be stated in relative terms or must they be measured in absolute terms?

2. *Range of Performance to Be Studied.* What experimental variables are to be explored by the model? How important is it to establish a range of performance for each experimental condition as a function of the stochastic (i.e., random) behavior of the system?

By asking the foregoing questions prior to beginning a modeling project, the human factors practitioner can develop a better sense of what is important in the system in terms of both aspects that drive system performance and the measures of effectiveness that are truly of interest. Then, and only then, can a human performance modeling project begin with a reasonable hope of success.

In the remainder of this chapter we discuss two classes of modeling tools for human performance simulation, then report on recent efforts to unify those two complementary classes in order to leverage their strengths and alleviate their shortcomings. After discussing each class of modeling tool, we provide specific examples of a modeling tool and then provide case studies about how these tools have been used in answering real human performance questions.

## 3   CLASSES OF SIMULATION MODELS

Human performance can be highly complex and involve many types of processes and behavior. Over the years many models have been developed that predict sensory processes (e.g., Gawron et al., 1983), aspects of human cognition (e.g., Newell, 1990), and human motor response (e.g., Fitts' law). The current literature in the areas of cognitive engineering, error analysis, and human–computer interaction contains many models, descriptions, methodologies, metaphors, and functional analogies. However, in this chapter we are not focusing on the models of these individual elements of human behavior but rather, on models that can be used to describe human performance in systems. These human–system performance models typically include some of these elemental behavioral models as components but provide a structural framework that allows them to be integrated with each other and put in the context of human performance of tasks in systems.

**Figure 2**   Reductionist models of human performance.

We separate the world of human–system performance models into two general categories that can be described as reductionist models and first-principle models. *Reductionist models* use human–system task sequences as the primary organizing structure, as shown in Figure 2. The individual models of human behavior for each task or task element are connected to this task-sequencing structure. We refer to it as reductionist because the process of modeling human behavior involves taking the larger aspects of human–system behavior (e.g., "perform the mission") and then reducing them successively to smaller elements of behavior (e.g., "perform the function," "perform the tasks"). This continues until a level of decomposition is reached at which reasonable estimates of human performance for the task elements can be made. One can also think of this as a top-down approach to modeling human–system performance. The example of this type of modeling that we use in this chapter is *task network modeling*, where the basis of the human–system model is a task analysis.

*First-principle models* of human behavior are structured around an organizing framework that represents the underlying goals, principles, and mechanisms of human performance (Figure 3). Tools that support first-principle modeling of human behavior have structures embedded in them that represent elemental aspects of human performance. For example, these models might directly represent processes such as goal-seeking behavior, task scheduling, sensation and perception, cognition, and motor output. In turn, those processes might invoke fundamental actions such as shifts of attention, memory retrieval, and conflict resolution among competing courses of action. To use tools that support first-principle modeling, one must describe how the system and environment interacts with the human processes being modeled. In this chapter we focus on the adaptive control of thought–rational (ACT-R) cognitive architecture (Anderson and Lebiere, 1998).

It is worth noting that these two modeling strategies are not mutually exclusive and, in fact, can be mutually supportive in any given modeling project. Often, when one is modeling using a reductionist approach, one needs models of basic human behavior to represent behavioral phenomena accurately and therefore must draw on
**Figure 3** First-principle models of human performance.

elements of first-principle models. Alternatively, when one is modeling human–system performance using a first-principle approach, some aspects of human–system performance and interrelationships between tasks may be more easily defined using a reductionist approach. Both classes of model have been used to model individual and team performance. It is also worth noting that recent advances in human performance modeling tool development are blurring the distinctions between these two classes (e.g., Hoagland et al., 2001). Increased emphasis on interoperability between models has caused researchers and developers to focus on integrating reductionist and first-principle models. In the final section of this chapter we present one such attempt at integrating the ACT-R cognitive architecture with the Improved Performance Research Integration Tool (IMPRINT).

## 4 REDUCTIONIST APPROACH: TASK NETWORK MODELING

One technology that has proven useful for predicting human–system performance is *task network modeling.* In a task network model, human performance is decomposed into tasks. The fidelity of this decomposition can be selective, with some functions being decomposed several levels and others just one or two. This is, in human factors engineering terms, the task analysis. The sequence of tasks is defined by constructing a *task network*. This concept is illustrated in Figure 4, which presents a sample task network for driving while talking on a cell phone.

Task network modeling is an approach to modeling human performance in complex systems that has evolved for several reasons. First, it is a reasonable means for extending the human factors staple: the task analysis. Task analyses organized by task sequence are the basis for the task network model. Second, task network models can include sophisticated submodels of the system hardware and software to create a closed-loop representation of relevant aspects of the human–machine system. Third, task network modeling is relatively easy to use and understand. Recent advancements in task network modeling technology have made

this technology more accessible to human factors practitioners. Finally, task network modeling can provide efficient, valid, and useful input to many types of issues. With a task network model, the human factors engineer can examine a design (e.g., control panel redesign) and address questions such as "How much longer will it take to perform this procedure?" and "Will there be an increase in the error rate?" Generally, task network models can be developed in less time and with substantially less effort than would be required if a prototype were developed and human subjects used. However, as stated before, for revolutionary designs, modeling may not alleviate the need for empirical data collection.

Task network models of human performance have been subjected to validation studies with favorable results (e.g., Lawless et al., 1995; Engh et al., 1998). However, as with any modeling approach, the real level at which validation must be considered is with respect to a particular model, not with respect to the general approach.

### 4.1 Components of a Task Network Model

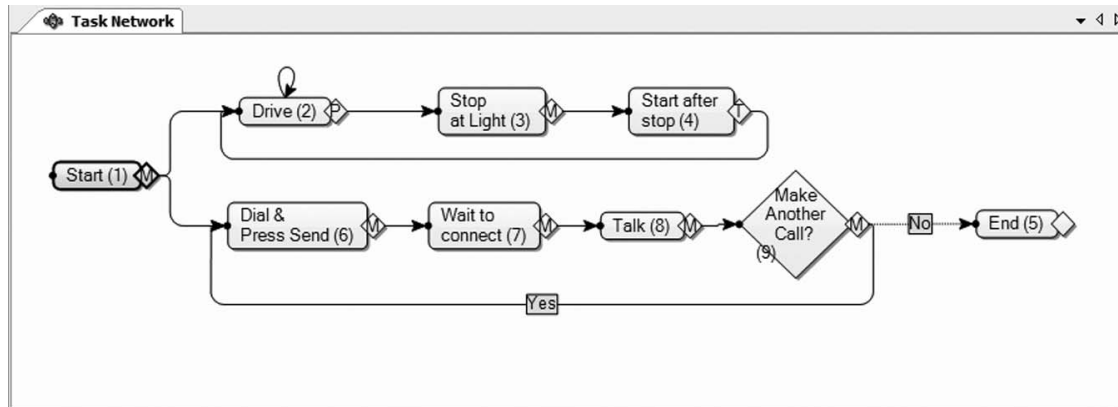
To represent complex, dynamic human–system behavior, many aspects of the system may need to be modeled in addition to simply task lists and sequence. In this section we use the task network modeling tool *Micro Saint Sharp* as an example. The basic ingredient of a Micro Saint Sharp task network model is the task analysis as represented by a network or series of networks. The level of system decomposition (i.e., how finely we decompose the tasks) and the amount of the system that is simulated depend on the particular problem. For example, in a power plant model, one can create separate networks for each of the operators and one for the power plant itself. Although the networks may be independent, performance of the tasks can be interrelated through shared variables. The relationships among different components of the system, represented by different segments of the network, can then communicate through changes in these shared variables. For example, when an operator manipulates a control, this may initiate an "open valve" task in a network representing the plant. This could ripple through to a network representing other operators and subsystems and their


**Figure 4**   Task network model representing a human driving while talking on a cell phone.

response to the open valve. This basic task network is built in Micro Saint Sharp via a point-and-click drawing palette. Through this environment, the user creates a network as shown in Figure 5. Networks can be embedded within networks, allowing for hierarchical construction. In addition, the shape of the nodes on the diagram can be chosen to represent specific types of activity.

To reflect complex task behavior and interrelationships, more detailed characteristics of the tasks need to be defined. By double clicking on a task, the user opens up the task description window, as shown in Figure 6. Below are descriptions of each of the items on the tabs in this window.

- *Task ID*. This value is an arbitrary number for task referencing.
- *Task Name*. This parameter contains a text string used to identify the task.

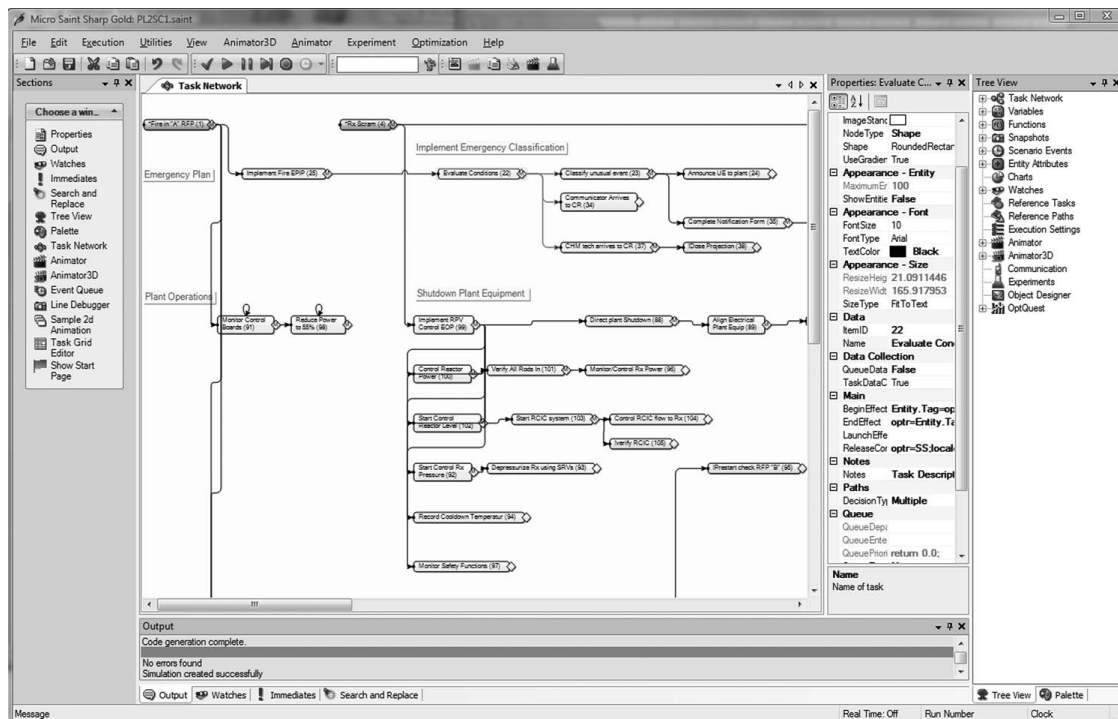

**Figure 5**   Main window in Micro Saint Sharp for task network construction and viewing.

**Figure 6** User interface in Micro Saint Sharp for providing input on a task.

- *Time Distribution*. Micro Saint Sharp conducts Monte Carlo simulations with task performance times sampled from a distribution as defined by this option (e.g., normal, beta, exponential).
- *Mean Time*. This parameter defines average task performance time for this task. This can be a number, equation, or algorithm, as can all values in the fields described below.
- *Standard Deviation*. This value contains the standard deviation of the task performance time, assuming that the user has chosen a distribution that is parameterized by a standard deviation.
- *Release Condition*. Data in this field determine when a task begins executing. For example, a condition stating that this task will not start before an operator is available might be represented by a release condition such as the following:

  OperatorBusy == false;

  In other words, for the task to begin, the value of the variable "OperatorBusy" must be false. This task would wait until the condition was true

before beginning execution, which would probably occur as a result of the operator completing the task he or she is currently performing.

- *Beginning Effect*. This field permits the user to define how the system will change as a result of the commencement of this task. For example, if this task used an operator that other tasks might need, we could set the following condition to show that the operator is unavailable while he or she performed this task:

  OperatorBusy = true;

  Assignment and modification of variables in beginning effects are one principal way in which tasks are interrelated.

- *Launch Effect*. This data element is similar to a task beginning effect but is used to launch high-resolution two- (2D) and/or three- (3D) dimensional animation of the task.
- *Ending Effect*. This field contains the definition of how the system will change as a result of the completion of this task. From the previous example, when this task was complete and the

operator became available, we could set the ending effect as follows:

$$\text{OperatorBusy} = \text{false};$$

At this point, another task waiting for an operator to become available could begin. Ending effects are another important way in which tasks can be interrelated through the assignment and modification of variables.

Another notable aspect of the task network diagram window shown in Figure 5 is the diamond-shaped icon that follows every task. This icon encapsulates data that describe the paths and the associated logic that will be executed when this task is completed. Often, this logic represents a human decision-making process. In that case, the branches align to potential courses of action that the modeled human could select. To define the decision logic, the Micro Saint Sharp user would use the "Paths" tab on the task description dialogue, as shown in Figure 7. There are three general types of decisions to model:

- *Probabilistic*. In probabilistic decisions, the human will begin one of several tasks based on a random draw weighted by the probabilistic branch value. These weightings can be dynamically calculated to represent the current context of the decision. For example, this decision type

might be used to represent human error likelihoods and would be connected to the subsequent tasks that would be performed.

- *Tactical*. In tactical decisions, the human will begin one of several tasks based on the branch with the highest "value." This could be used to model the many types of rule-based decisions that humans make, as illustrated in Figure 7.
- *Multiple*. This would be used to begin several tasks at the completion of this task, such as when one human issues a command that begins other crew members' activities.

The expression fields in Figure 7 represent the values associated with each branch. The values can be numbers, expressions, or complicated algorithms defining the probability (for probabilistic branches) or the desirability (for tactical and multiple branches) of taking each branch in the network. Again, any value on this screen can be not simply numbers but also variables, algebraic expressions, logical expressions, or groups of algebraic and logical expressions that would, essentially, form a subroutine. As the model executes, Micro Saint Sharp includes a parser that evaluates the expressions included in the branching logic when it is encountered in the task network flow. This results in a dynamic network in which the flow through the tasks can be controlled with variables that represent equipment state, scenario

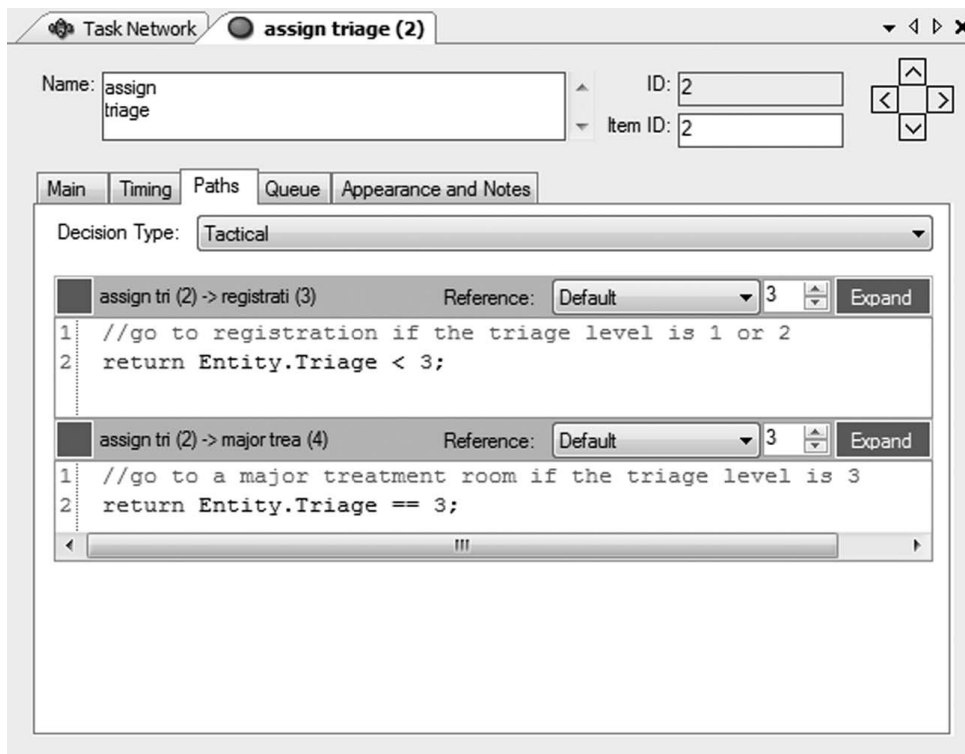

**Figure 7**   User interface in Micro Saint Sharp for defining task-branching decision logic.

context, or the task loading of the humans in the system, to name a few examples. It is the power of this parser that provides many task network models with the ability to address complex problems.

The research community has been inspired by the Micro Saint Sharp architecture, and several efforts have enhanced the capability of the task network model to more accurately represent theoretical advances. Specifically, Warwick and Santamaria (2009) extended the available decision types described above to a "recognition-primed" decision type (Klein, 1998). This new decision type represents human decisions that are experience driven and in which the subsequent action choices are driven by recognition of aspects of the scenario, rather than by a rule-based process. To implement this decision type, the model develops and maintains an ongoing representation of the human's memory, which either can be preloaded prior to model start or can be populated (i.e., trained) as the model proceeds. Preliminary validation work on this model has been encouraging and provides opportunities for more complete representations of "natural" human behavior.

The Command, Control, and Communications— Techniques for Reliable Assessment of Concept Execution (C3TRACE) tool has also expanded the available decision types to allow branching based on message communication type (digital, face to face, written, etc.) or decision quality (Plott et al., 2004).

There are other aspects of task network model development. Some items define a simulation scenario defining continuous processes within the model and queues in front of tasks. Further details of these features can be obtained from the Micro Saint Sharp *User's Guide* (Alion Science and Technology, 2009). As a model is being developed and debugged, the user can execute the model to test it and collect data. The user can rearrange, open, and close a variety of windows to represent a variety of display modes providing differing levels of information during execution. The simulation speed can also be controlled to include pausing after every simulated task. Typically, during execution the user will display the task network on the screen, and tasks that are currently executing will be highlighted. In this mode, the analyst can get a very clear picture of what events are occurring in what sequence in the model, greatly aiding debugging. Figure 8 presents a sample display during model network animation. Additionally, 2D and 3D animator modes are available. In these modes, the user can create a graphical representation of the system. Changes on the graphical background can be tied to the task flow, providing a powerful method to communicate the model's findings to stakeholders. Once a model is executed and data are collected, the analyst has a number of alternatives for data analysis. The data created during a model execution can be reviewed within Micro Saint Sharp or can be exported to statistical and graphics packages for post processing.

As stated before, the basis for task network models of human performance is the mainstay of human engineering analysis, the task analysis. Much of the information discussed above is generally included in the task analysis. Task network modeling greatly increases

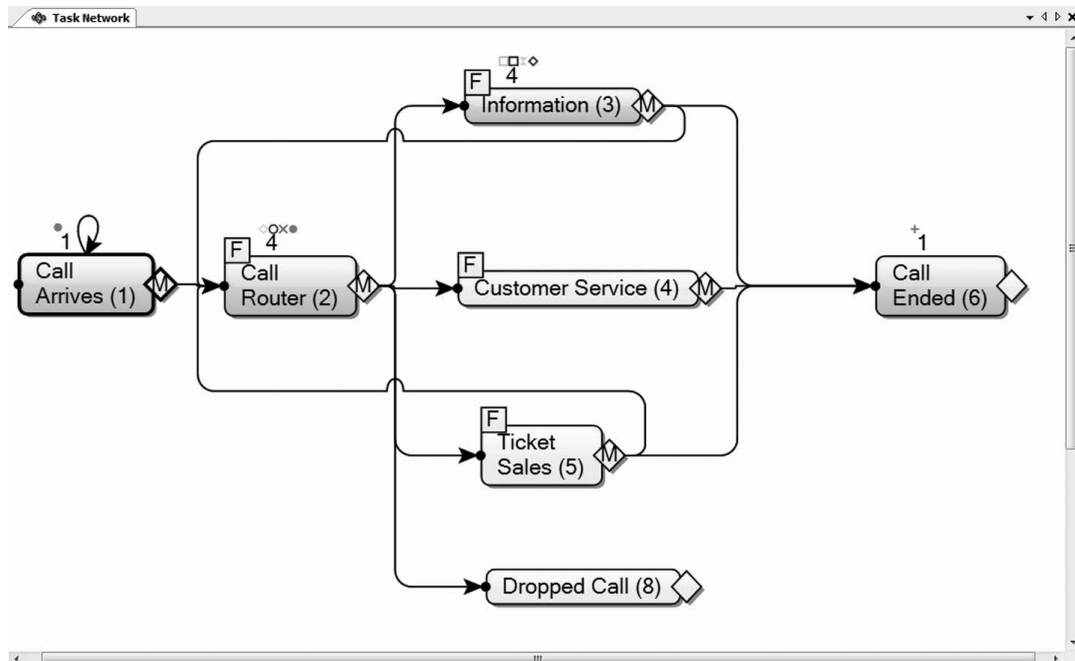

**Figure 8** Task network animation during model execution in Micro Saint Sharp.

the power of task analysis since the ability to simulate a task network with a computer permits *prediction* of human performance rather than simply the *description* of human performance that a task analysis provides. What may not be as apparent, however, is the power of task network modeling as a means of modeling human performance in *systems*. Simply by describing the system's activities in this step-by-step manner, complex models of the system can be developed where the human's interaction with the system can be represented in a closed-loop manner. The preceding discussion, in addition to being an introduction to the concepts, is also intended to support the argument that task network modeling is a mature technology ready for application in a wide range of problem domains.

### 4.2  Task Network Model of a Process Control Operator

This simple hypothetical example illustrates how many of the basic concepts of task network modeling can be applied to studying human performance in a process control environment. It is intended to illustrate many of the concepts described above. The simple human task that we want to model is of an operator responding to an annunciator. The procedure requires that the operator compare readings on two meters. Based on the relative values of these readings, the operator must either open or close a valve until the values on the two meters are nearly the same. The task network in Figure 9 represents

the operator activities for this model. Also, to allow the study of the effects of different plant dynamics (e.g., control lags), a simple one-node model of the line in which the valve is being opened is included in Figure 10.

The operator portion of the model will run the "monitor panels" task until the values of the variables "meter1" and "meter2" are different. The simulation could begin with these values being equal and then precipitate a change in values based on what is referred to as a *scenario event* (e.g., an event representing the effects of a line break on a plant state). This event could be as simple as

$$\text{meter } 1 = \text{meter } 1 + 2.0;$$

or as complex as an expression defining the change in the meter as a function of line break size, flow rates, and so on. An issue that consistently arises in model construction is how complex the plant system model should be. If the problem under study is purely operator performance, simple models will usually suffice. However, if overall plant behavior is of interest, the models of plant dynamics, such as meter values, are more important. Again, we recommend the "start simple" approach whenever possible.

When the transient occurs and the values of meter1 and meter2 start to diverge, the annunciator signal will trigger. This annunciator would be triggered in the plant

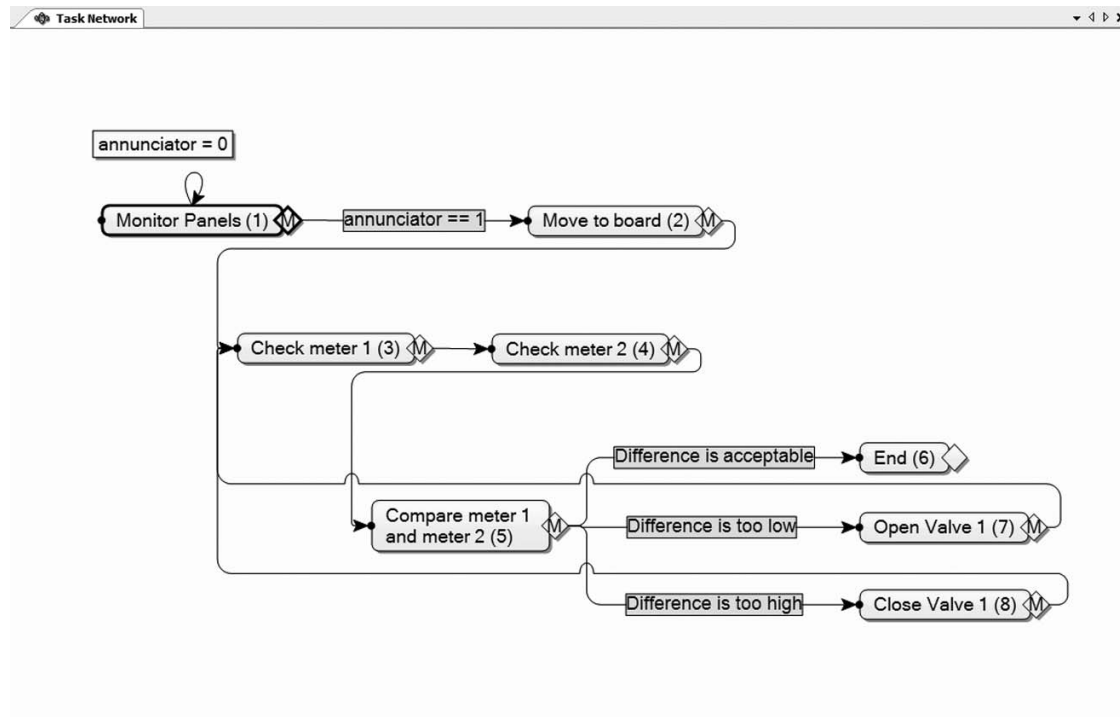

**Figure 9**　Task network model of a process control operator responding to an annunciator.
**Figure 10** Simple one-node model of the plant integrated with the detailed operator model.

portion of the model by a task-ending effect such as

if (meter 1 ! = meter 2) then annunciator = 1;

Once the plant model sets the value of the variable annunciator to 1, the operator will begin to move to the appropriate board. Then the operator will continue through a loop to check the values for meter1 and meter2 and open valve 1, close valve 1, or make no change. The determination of whether to make a control input is determined by the difference in values between the two meters. If the value is less than the acceptable threshold, the operator would open the valve further. If the value is greater than the threshold, the operator would close the valve. This opening and closing of the valve would be represented by changes in the value of the variable valve1 as a task-ending effect of the tasks open valve1 and close valve1. In this simple model, operators do not consider rates of change in values for meter1 and therefore would get into an operator-induced oscillation if there were any response lag. A more sophisticated operator model could use rates of change in the value for meter1 in deciding whether to open or close valves.

Again, this is a very small model reflecting simple operator activity on one control via a review of two displays. However, it illustrates how large models of operator teams looking at numerous controls and manipulating many displays could be built via the same building blocks used in this model. The central concepts of a task network and shared variable reflecting human–system dynamics remain the same.

Given a task network model of a process control operator in a "current" control room, how might the model be modified to address human-centered design questions? Some examples are (1) modifying task times based on changes in the time required to access a new display; (2) modifying task times and accuracies based on changes in the content and format of displays; (3) changing task sequence, eliminating tasks, and/or adding tasks based on changes in plant procedures; (4) changing allocation of tasks and ensuing task sequence based on reallocation of tasks among operators; and (5) changing task times and accuracies based on stressors such as sleep loss or the effects of circadian rhythm. This is not intended as a definitive list of all the ways that these models may be used to study design or operations concepts but should illustrate how these models can be used to address design and operational issues.

### 4.3 Use of Task Network Modeling to Address Specific Design Concerns

In this section we examine two case studies in the use of task network simulation for studying human performance issues. The first case study explores how task network modeling can be used to assess task allocation issues in a cognitively demanding environment. The second example explores how task network modeling has been used to extend laboratory and field research on human performance under stress to new task environments. We should state clearly that these examples are intended to be representative of the types of issues that task network modeling can address as well as approaches to modeling human performance with respect to these issues. *They are not intended to be comprehensive with respect to either the issues that might be addressed or the possible techniques that the human factors practitioner might apply.* Simulation modeling is a technology whose application leaves much room for creativity on the part of the human factors practitioner with respect to application areas and methods. These two case studies are representative.

#### 4.3.1 Crew Workload Evaluation

Perhaps the greatest contributor to human error in many systems is the extensive workload placed on the human operator. The inability of the operator to cope effectively with all of his or her information and responsibilities contributes to many accidents and inefficiencies. In recognition of this problem, new automation technologies have been introduced to reduce workload during periods of high stress. Some of these technologies are in the form of enhanced controls and displays, some are in the form of tools that "push" information to the operator and alert the operator in order to focus attention, and still others consist of adaptive tools that "take over" tasks when they sense that the operator is overloaded. Unfortunately, these technical solutions often introduce new tasks to be performed that affect the visual, auditory, and/or psychomotor workload of the operators.

Recently, new concepts in crew coordination have focused on better management of human workload. This area shows tremendous promise and is benefiting from efforts of human factors researchers. However, their efforts are hindered because there are limited opportunities to examine empirically the performance of different combinations of equipment and crew composition in a realistic scenario or context. Additionally, high workload is not typically caused by a single task but by situations in which multiple tasks must be performed and managed simultaneously. It is not simply that the quantity of tasks can lead to overload, but it also depends on the composition of those tasks. For example, two cognitive tasks being performed in parallel are much more effortful than a simple motor task and an oral communication task being performed together. The occurrence of these situations will not typically be discovered through normal human engineering task analysis or subjective workload analysis until there is a system to be tested. That is often too late to influence design. To rectify this problem, there has been a significant amount of

recent research and development aimed at human work-load *prediction* models. Predictive models allow the designers of a system to estimate operator workload *without human subject experimentation*. From this and other research, a solid theoretical basis for human work-load prediction has evolved, as is described in Wickens (1984).

In this section we discuss a study using task network modeling to predict the impact of task allocation on human workload. Although these examples are posed in the context of the design of a military system, the same techniques have been used in nonmilitary applications such as process control and user–computer interface design.

### 4.3.2 Modeling the Workload of a Future Command and Control Process

The Army command and control (C2) community is concerned with how new information technology and organizational changes projected for tomorrow's battle-field will affect soldier tasks and workload. To address this concern, an effort was undertaken to model soldier performance under current and future operational condi-tions. In this way, the impact of performance differences could be quantitatively assessed so that equipment and doctrine design could be influenced in a timely and effective manner.

In one C2 project, the primary concern was to deter-mine how tasks should be allocated and automated such that a C2 team could evaluate all the relevant data and make decisions within an environment with particularly high time pressure. Specifically, the effort was to address the following key questions:

- How many crew members do you need?
- How do you divide tasks among jobs?

- How does decision authority flow?
- Can the crew meet decision timeline require-ments?
- Is needed information usable and accessible?

Task network modeling was used to study crew member, task, and scenario combinations in order to examine these questions. Figure 11 shows the top-level diagram of the task network. Essentially, the crew members receive and monitor information about the system and the environment until an event occurs that pushes them out of the 10,000 and 20,000 networks into either a series of planning tasks or a series of evaluation, decision, direction, and execution tasks. The purpose of the planning task is to update tactical battle plans based on new information received from the system or the environment. Receipt of new intelligence data about the enemy's intention or capability is an example of an event that would cause crew members to undertake planning tasks. Similarly, receipt of information from the system about resource limitations might trigger the crew members to proceed down the alternative path (through evaluate to execute). Specifically, limited resources might cause crew members to evaluate whether the engagement is proceeding appropriately (30,000), decide how to adjust system parameters (40,000), direct the appropriate response to the correct level of command (50,000), and then execute the order (60,000). Upon completion, crew members would return to monitoring the system and situation.

Each rectangle in the task network shown in Figure 11 actually consists of a network of tasks. An example of the tasks that belong to network 10000 are shown in Figure 12. As described earlier, the tasks in network 10000 are linked by probabilistic and tactical decisions. Each of the tasks in the C2 task network

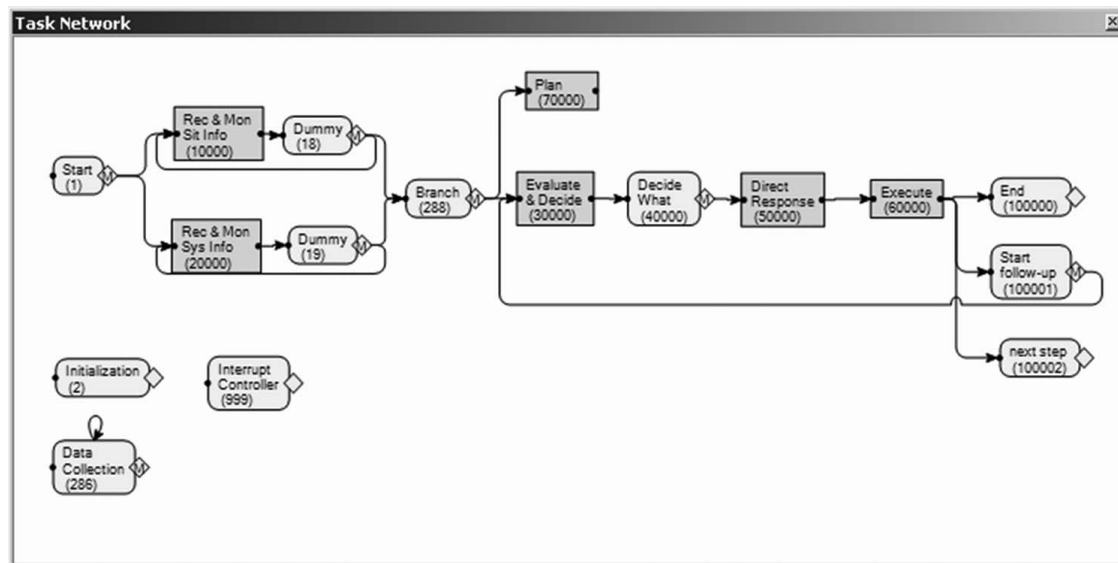

**Figure 11**  Upper level task network.
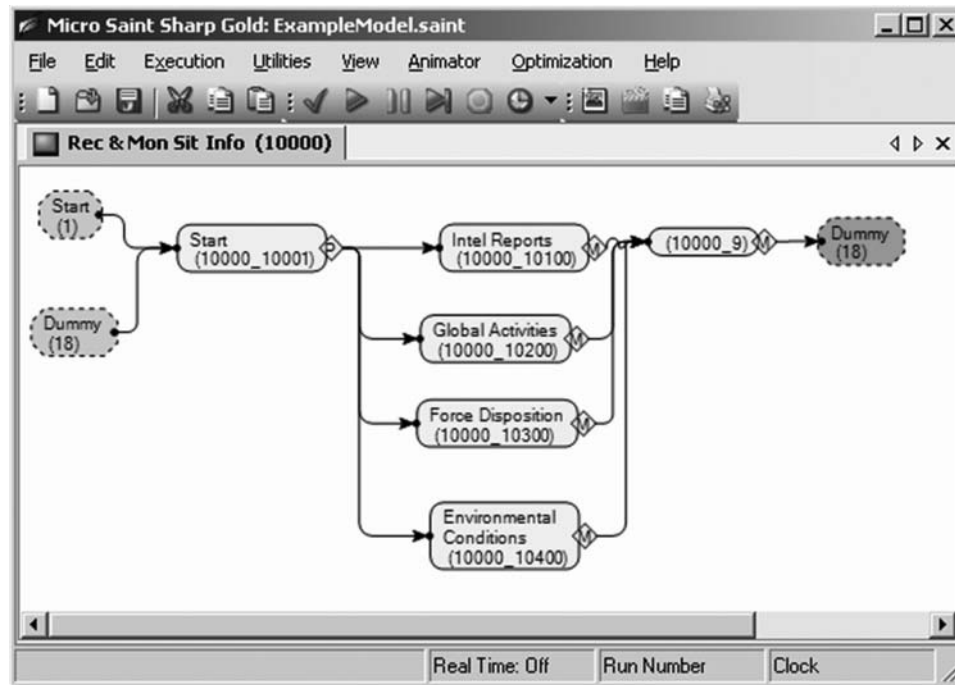

**Figure 12** Second-level task network.

is associated with several items of human performance data:

- *Task Performance Time.* These data consist of a mean, standard deviation, and distribution. The data were collected from a combination of three sources: (1) human factors literature (e.g., Fitt's law), (2) empirical studies during operator-in-the-loop simulator exercises, and (3) subject matter experts.
- *Branching Logic.* Although the task network indicates a general process flow, this particular model was designed to respond to scenario events. Because of that design decision, each task includes logic to determine the following task. For example, if the scenario is very intense and multiple target tracks are available, crew members would follow a different task flow than if they were performing routine system checks.
- *Release Rules.* Logic controlling the number and types of parallel tasks each crew member can perform is contained in each task's release condition.

Since one purpose of the model was to examine various task allocation strategies, the model was designed to incorporate several measures of crew member workload. The basis of this technique is an assumption that excessive human workload is not usually caused by one particular task required of the operator. Rather, the human

having to perform several tasks simultaneously leads to overload. Since the factors that cause this type of workload are intricately linked to these dynamic aspects of the human's task requirements, task network modeling provides a good basis for studying how task allocation and sequencing can affect operator workload.

However, task network modeling is not inherently a model of human workload. The only relevant output common to all task network models is the time required to perform a set of tasks and the sequence in which the tasks are performed. Time information alone would suffice for some workload evaluation techniques, such as Siegel and Wolf (1969), whereby workload is estimated by comparing the time available to perform a group of tasks to the time required to perform the tasks. Time available is driven by system performance needs, and time required can be computed with a task network model. However, it has long been recognized that this simplistic analysis misses many aspects of the human's tasks that influence both perceived workload and ensuing performance. At the very least, this approach misses the fact that some pairs of tasks can be performed in combinations better than other pairs of tasks.

One of the most promising theories of operator workload, which is consistent with task network modeling, is the multiple-resource theory proposed by Wickens (see Wickens et al., 1983). Simply stated, the multiple-resource theory suggests that humans have several different resources that can be tapped simultaneously and with varying levels of inter-resource conflict and competition. Depending on the nature of the information

processing tasks required of a human, these resources would have to process information sequentially (if different tasks require the same types of resources) or possibly in parallel (if different tasks required different types of resources). There are many versions of this multiple-resource theory in the workload literature (e.g., McCracken and Aldrich, 1984; Archer and Adkins, 1999). In this chapter we provide a discussion of the underlying methodology of the basic theory.

Multiple-resource workload theory is implemented in a task model in a fairly straightforward manner. First, each task in the task network is characterized by the workload demand required in each human resource, often referred to as a *workload channel*. Examples of commonly used channels include auditory, visual, cognitive, and psychomotor. Particular implementations of the theory vary in the channels that are included and the fidelity with which each channel is measured (high, medium, low vs. seven-point scale). As an example, the scale for visual demand is presented in Figure 13.

Similar scales have been developed for the auditory, cognitive, fine-motor, gross-motor, speech, and tactile channels. Using this approach, each operator task can be characterized as requiring some amount of each of the seven types of resources, as represented by a value (typically between 1 and 7). All operator tasks can be analyzed with respect to these demand values. In performing a set of tasks pursuant to a common goal (e.g., engage an enemy target), crew members frequently must perform several tasks simultaneously, or at least nearly so. For example, they may be required to monitor a communication network while visually searching a display for target track. Given this, the workload literature indicates that the crew member may either accept

the increased workload (with some risk of performance degrading) or begin dumping tasks perceived as less important. To factor these two issues into task network simulations, two approaches can be incorporated: (1) evaluate combined operator workload demands for tasks that are being performed concurrently and/or (2) determine when the operator would begin dumping tasks due to overload.

During a task network simulation, the model of the crew may indicate that they are required to perform several tasks simultaneously. The task network model evaluates total attentional demands for each human resource (e.g., visual, auditory, fine motor, gross motor, speech, tactile, and cognitive) by combining the attentional demands across all tasks that are being performed simultaneously. Intra- and interresource conflict values are then computed that indicate how much the different resources compete with each other. The conflict score is then used to increase the total attentional demand. This combination leads to an overall workload demand score for each crew member.

To implement this approach in Micro Saint Sharp, the task-beginning effect can be used to increment variables that represent the current workload score in each resource. Then, while the tasks are being performed, these variables track attentional demands. When the tasks are completed, the task-ending effects can decrement the values of these variables accordingly. Therefore, if these workload variables were recorded and then plotted as the model runs, the output would look something like as shown in Figure 14. This result can be used to identify points of high workload throughout the scenario being modeled. The human factors practitioner can then review the tasks that led to the points of

**Figure 13**  Visual workload scale.

high workload and determine whether they should be reallocated or redesigned in order to alleviate the peak. This is a common approach to modeling workload.

Once the task networks were verified with knowledgeable crew members, they became part of the human factors team's analytical test bed. Figure 15 shows the overall method that can be used to examine aspects of crew member performance across a wide variety of operational scenarios and crew configuration concepts. The center of this diagram, labeled the task network, represents the tasks that the crew performs. The network itself, representing the flow of the tasks, does not change between model runs. Rather, the model has been parameterized so that an event scenario stimulates the network. The left side of the diagram illustrates the types of data that are used to drive the task network model. In this case, those data include crew configurations, or allocations of tasks to different crew members and automation devices, as well as scenario events. The scenario events represent an externally generated time-ordered list of the events that trigger the crew members to perform tasks

in the task network. The right side of Figure 15 represents the types of outputs that can be produced from this task network model. One of the primary outputs is a crew member workload graph, such as that shown in Figure 14. Another is operator utilization, as shown in Figure 16.

### 4.3.3 Extensions to Other Environments

The workload analysis methodology described above has been developed into a stand-alone task network modeling tool by the Army Research Laboratory (ARL) Human Research and Engineering Directorate (HRED) as part of the IMPRINT (Archer and Adkins, 1999). IMPRINT integrates task network modeling software with features that specifically support the multiple-resource theory of workload discussed above. It provides the human factors practitioner with an environment that supports the analysis of task assignment to crew members based on four factors:

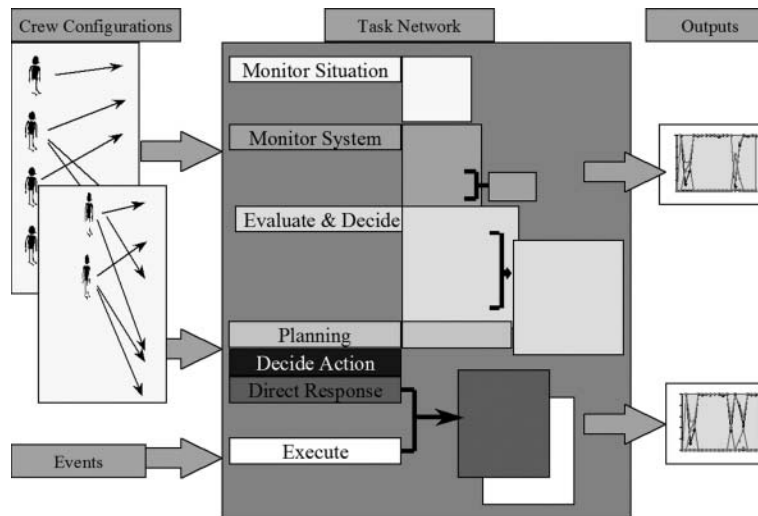
Figure 14 Workload output from a task network model.


**Figure 15**   Overall method for examining workload in a complex system.

**Figure 16**   Percent utilization taken over 10-min intervals.

1.  *Workload of Crew Members.* Tasks should be assigned to minimize the amount of time that crew members will spend in situations of excessive workload.

2.  *Time Performance Requirements.* Tasks must be assigned and sequenced so that they are completed within the available time. This consideration is essential since time constraints often will drive the need to perform several tasks simultaneously.

3.  *Likelihood of Successful Performance and Consequences of Failure.* Tasks must be assigned and sequenced so that they can be completed within a specified accuracy measure.

4.  *Access to Controls and Displays.* Tasks cannot be assigned to crew members that do not have access to the necessary controls and displays.

Of course, there are numerous theoretical questions regarding this simplistic approach to assessing workload in an operational environment. However, even the use of this simple approach has been shown to provide useful

insight during design. For example, in a study conducted by the Army (Allender, 1995), a three-man crew design was evaluated using a task network model. The three-man model was constructed using data from a prototype four-man system. From this model-based analysis, the three-man design was found to be unworkable. Later, experimentation using human subjects verified that the model's workload predictions were sufficiently accurate to point the design team in a valid direction.

IMPRINT also includes built-in constructs for simulating *workload management* strategies that operators would employ to accommodate points of high operator workload (Plott, 1995). The ultimate result of simulating the workload management strategies is that the operator task network being modeled is *dynamic*. In other words, the task sequence, operator assignments, and individual task performance may change in response to excessive operator workload as the task network model executes. These changes may be as simple as one operator handing tasks off to another operator to reduce workload to an acceptable level or as complex as the operator beginning to time share tasks in order to complete all the tasks assigned, potentially with associated task performance penalties. Ultimately, the tool provides an estimate of system-level performance as a result of these realistic workload management strategies. This innovation in modeling provides greater fidelity in efforts that model human behavior in the context of system performance, particularly in high-workload environments such as complex system control and management.

### 4.3.4 Extending Research Findings to New Task Environments

Task network modeling was used by LaVine et al. (1995) to extend laboratory data and field data collected on one set of human tasks to predicting performance on similar tasks. The problem of extending laboratory or field human performance data to other tasks has plagued the human engineering community for years. We know intuitively that human performance data can be used to predict performance for similar tasks. However, it is often the case that the task whose performance we want to predict is similar in some ways but different in others. The approach described below uses a skill taxonomy to quantify task similarity and therefore provides a means for determining how other tasks will be affected when exposed to a common stressor on human performance. Once functional relationships are defined between a skill type and a stressor, task network modeling is used to determine the effect of the stressor on performance of a complex task that uses many of these skills simultaneously.

The specific approach below is being used by the U.S. Army to predict crew performance degradation as a function of a variety of stressors. It is not intended to represent a universally acceptable taxonomy for simulating human response to stress. The selection of the best taxonomy would depend on the particular tasks and stressors being studied. What this example is intended to illustrate is another way that task network modeling can be used to predict human performance by *making a series of reasonable assumptions* that

can be played together in a model for the purpose of making predictions that would be impossible to make otherwise. The methodology for predicting human performance degradation as a function of stressors consists of three parts: (1) a *taxonomy* for classifying tasks according to basic human skills, (2) *degradation functions* for each skill type for each stressor, and (3) *task network models* for the human-based system whose performance is being predicted. Conceptually, either laboratory or field data can be used to develop links between a human performance stressor (e.g., heat, fatigue) and basic human skills. By selecting a skills taxonomy that is sufficiently discriminating to make this assumption reasonable, one can assume that the effects of the stressor on all tasks involving the skill will be approximately the same. The links between the level of a stressor (e.g., fatigue) and resulting skill performance (e.g., the expected task time increase from fatigue) are defined mathematically as the degradation function. The task network model is the means for linking these back to complex human–system performance.

***Taxonomy*** The basic premise behind the taxonomy is that the tasks that humans perform can be broken down into basic human skills or atomic tasks (Roth, 1992). The taxonomy that was used by Roth consists of five skill types described by Roth as follows:

1. *Attention:* the ability to attend actively to a stimulus complex for extended periods of time in order to detect specified changes or classes of changes that indicate the occurrence of some phenomenon that is critical to task performance
2. *Perception:* the ability to detect and categorize specific stimulus patterns embedded in a stimulus complex
3. *Psychomotor skill:* the ability to maintain one or more characteristics of a situation within a set of defined conditions over a period of time, either by direct manipulation or by manipulating controls that cause changes in the characteristics
4. *Physical skill:* the ability to accomplish sustained, effortful muscular work
5. *Cognitive skill:* the ability to apply concepts and rules to information from the environment and from memory in order to select or generate a course of action or a plan (includes communicating the course of action or plan to others)

These five skills covered most of the tasks that were of interest to the Army for this study and still provided a manageable number of categories for an analyst to use.

***Degradation Functions*** The degradation functions quantitatively link skill performance to the level of a stressor. The degradation functions can be developed from any data source, including standard test batteries or actual human tasks. Through statistical analysis, one can build skill degradation functions for each taxon. These functions map the performance decrement expected on

**Performance multipliers**
as a function of time since sleep

**Figure 17** Performance degradation functions associated with each of the human skills from the taxonomy.

a skill based on the parameters of the performance-shaping factor (e.g., time since sleep). An example of these functions is presented in Figure 17.

***Incorporating the Degradation Functions into Task Network Models to Predict Overall Human–System Performance Degradation*** The key to making this approach useful to predicting complex human performance is the task network model of the new task. In the task network model of the human's activities, all tasks are defined with respect to the percentage of each skill required from the taxonomy. For example, the following are ratings for tasks faced by a console operator responding to telephone contacts:

| Detect ring | 50% attention, 50% perception |
| Select menu item using a mouse | 40% attention, 60% psychomotor |
| Interpret customer's request for information | 100% cognitive |

In building the task network model, mathematical expressions can be developed that degrade a specific task's performance through an arithmetic weighting of skill degradation multipliers that are derived from the degradation functions. For example, if the fatigue parameter was "time since sleep" and the value of that parameter was "36 hours since sleep," the task time performance multipliers would be as follows in the example above:

| Attention performance multiplier | 0.82 |
| Perception performance multiplier | 0.808 |
| Cognition performance multiplier | 0.856 |
| Psychomotor performance multiplier | 0.784 |
| Physical performance multiplier | 0.727 |

Based on these multipliers and the task weightings above, the specific task effects would be:

● Detect ring (50% attention, 50% perception)

$$\text{Task multiplier} = 0.5 \times 0.82 + 0.5 \times 0.808$$
$$= 0.814$$

● Select menu item using a mouse (40% attention, 60% psychomotor)

$$\text{Task multiplier} = 0.4 \times 0.82 + 0.6 \times 0.784$$
$$= 0.7984$$

● Interpret customer's request for information (100% cognitive)

$$\text{Task multiplier} = 0.856$$

In a model of the complex tasks being examined by LaVine et al. (1995), the task networks consisted of several dozen or even several hundred tasks. Through the approach described above, each task in a model exhibited a unique response to a stressor depending on the particular skills that it required. The task network model then provided the means for relating the individual task performance to overall human–system performance as a function of stressor level (e.g., the time to perform a complex series of tasks involving decision making and error correction). Through this type of analysis, LaVine et al. were able to develop curves such as that shown in Figure 18 relating human performance to a stressor. These relationships would have been virtually impossible to develop experimentally.

Again, there were a number of simplifying assumptions that were made in this research. However, by being willing to accept these assumptions, LaVine et al. were able to characterize how complex human–system performance would be affected by a variety of stressors over a wide range in a relatively short time. As such, they were able to estimate the effects of stressors that would have otherwise been pure guesswork.
**Figure 18** Frequency distribution of expected human performance as a function of time since sleep that was derived using task network modeling.

### 4.3.5 Incorporation of Advanced Attention Model

In recent years advanced theories of selective attention have been advanced to the point that they can be embedded into human performance models to more accurately predict how a human might perform in a visually complex environment. As the fidelity of human performance models improve, so too does the need for integrating complex human attention models in order to predict how operators will allocate their visual attention. Attention models that have shown preliminary success when being linked to human performance models are the SEEV (salience, effort, expectancy, and value) model (Horrey et al., 2006) and the newer N-SEEV (noticing-SEEV) model (Wickens and McCarley, 2008). SEEV is a computational, plausible model that accounts for how four quantifiable elements do and/or should drive operator's attention around a complex working environment. SEEV models the operator's visual scanning pattern attending to a given "area of interest" (AOI) that supports the tasks that need to be performed. The SEEV and N-SEEV algorithms are described in detail in Chapter 5.

The Man–Machine Integration Design and Analysis System (MIDAS) has recently been updated to incorporate the SEEV algorithm (Gore et al., 2009). The integration of the SEEV model into MIDAS allows dynamic scanning behaviors by calculating the probability that the operator's eye will move to a particular AOI given the tasks the operator is engaged in within the multitask context. It also better addresses allocation of attention in dynamic environments such as flight and driving tasks. In MIDAS, effort, expectancy, and value are assigned values between 0 and 1, while salience is left unconstrained. Effort, expectancy, and value drive the human operator's visual attention around the displays. However, if a salient event occurs, then $P(\text{AOI})$ may be offset by the display exhibiting the salient event until the display location of the salient event has been

fixated and detected. The improved predictive capability of information-seeking behavior that resulted from the implementation of the validated SEEV model leaves MIDAS better suited to predict performance in complex human–machine systems.

### 4.3.6 Summary

Once again, the above are intended to serve as examples, not a catalog of problems or approaches that are appropriate for task network modeling. Task network modeling is an approach to extend task and systems analysis to make predictions of human–system performance. The creative human factors and ergonomics practitioner will find many other useful applications and approaches.

## 5 FIRST-PRINCIPLE APPROACH: ADAPTIVE CONTROL OF THOUGHT–RATIONAL COGNITIVE ARCHITECTURE

The other fundamental approach to modeling human performance is based on the mechanisms that underlie and cause human behavior. Since this approach is based on fundamental principles of the human and his or her interaction with the system and environment, we have designated them as *first-principle models*. By integrating these models with models of the system and environment, the human factors specialist can predict the full behavior of large-scale interactive human–machine systems. The ACT-R cognitive architecture (Anderson and Lebiere, 1998) is a production system theory that models the steps of cognition by a sequence of production rules that fire to coordinate retrieval of information from the environment and from memory. It is a cognitive architecture that can be used to model a wide range of human cognition. It has been used to model tasks from memory retrieval (Anderson et al., 1998) to visual search (Anderson et al., 1997). The range of models developed, from those purely concerned with internal

cognition to those focused on perception and action, makes ACT-R a plausible candidate to model complex tasks involving the interaction of one (or more) human operator with complex systems with the goal of evaluating the design of those systems. In all domains, ACT-R is distinguished by the detail and fidelity with which it models human cognition. It makes claims about what occurs cognitively every few hundred milliseconds in performance of a task. ACT-R is situated at a level of aggregation above those of basic brain processes (targeted by other modeling approaches, such as neural networks) but considerably below such complex tasks as air traffic control. The new version of the theory has been designed to be more relevant to tasks that require deploying significant bodies of knowledge under conditions of time pressure and high information-processing demand. This is because of the increased concern with the temporal structure of cognition and with the coordination of perception, cognition, and action.

## 5.1  ACT-R

ACT-R is a unified architecture of cognition developed over the last 30 years at Carnegie Mellon University. At a fine-grained scale it has accounted for hundreds of phenomena from the cognitive psychology and human factors literature. The most recent version, ACT-R 6.0 (Anderson et al., 2007), is a modular architecture composed of interacting modules for declarative memory, perceptual systems such as vision and audition modules, and motor systems such as manual and speech modules, all synchronized through a central production system (see Figure 19). This modular view of cognition is a reflection both of functional constraints and of recent advances in neuroscience concerning the localization of brain functions. ACT-R is also a hybrid system that combines a tractable symbolic level that enables the easy specification of complex cognitive functions with a subsymbolic level that tunes itself to the statistical structure of the environment to provide the graded characteristics of cognition such as adaptivity, robustness, and stochasticity.

The central part of the architecture is the production module. A production can match the contents of any combination of buffers, including the goal buffer, which holds the current context and intentions; the retrieval buffer, which holds the most recent chunk retrieved from declarative memory; the visual and auditory buffers, which hold the current sensory information; and the manual and vocal buffers, which hold the current state of the motor and speech module. The highest rated matching production is selected to effect a change in one or more buffers, which in turn triggers an action in the corresponding module(s). This can be an external action (e.g., movement) or an internal action (e.g., requesting information from memory). Retrieval from memory is initiated by a production specifying a pattern for matching in declarative memory. Each chunk competes for retrieval, with the most active chunk being selected and returned in the retrieval buffer. The activation of a chunk is a function of its past frequency and recency of use, the degree to which it matches the pattern requested, plus stochastic noise. Those factors confer memory retrievals, and behavior in general, desirable "soft" properties such as adaptivity to changing circumstances, generalization to similar situations, and variability (Anderson and Lebiere, 1998).

The current goal is a central concept in ACT-R, which as a result provides strong support for goal-directed behavior. However, the most recent version of the architecture is less goal focused than its predecessors

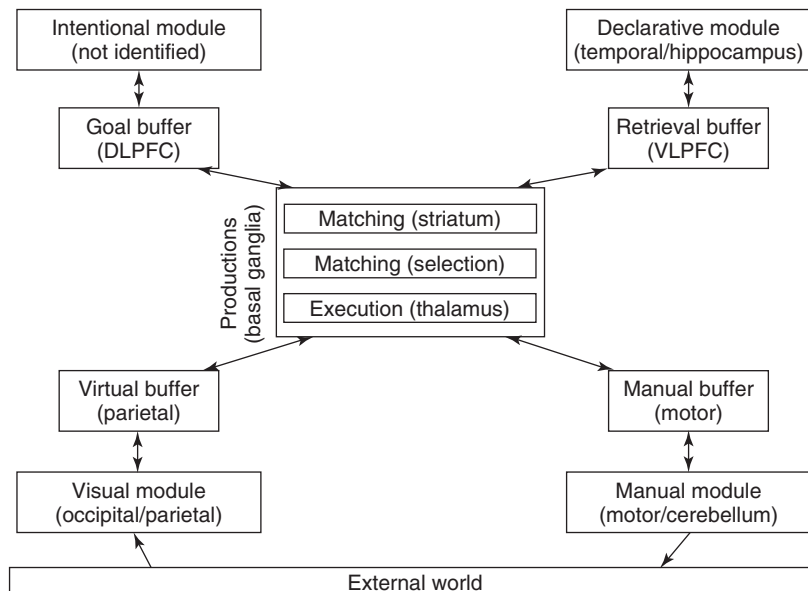

**Figure 19**  Modular view of ACT-R cognitive architecture.

by allowing productions to match to any source of information, including the current goal, information retrieved from declarative memory, objects in the focus of attention of the perceptual modules, and the state-of-the-action modules. The content of many of those buffers, especially the perceptual buffers, might have changed not as a function of an internal request but as a result of an external event happening, perhaps unexpectedly, in the outside world. This emphasis on asynchronous pattern matching of a wide variety of information sources better enables ACT-R to operate and react efficiently in a dynamic fast-changing world through flexible goal-directed behavior which gives equal weight to internal and external sources of information.

There are three main distinctions in the ACT-R architecture. First, there is the procedural–declarative distinction that specifies two types of knowledge structures: chunks for representing declarative knowledge and productions for representing procedural knowledge. Second, there is the symbolic level, which contains the declarative and procedural knowledge, and the subsymbolic level of neural activation processes that determine the speed and success of access to chunks and productions. Finally, there is a distinction between the performance processes by which the symbolic and subsymbolic layers map onto behavior and the learning processes by which these layers change with experience.

Human cognition can be characterized as having two principal components: (1) the knowledge and procedures codified through specific training within the domain and (2) the natural cognitive abilities that manifest themselves in tasks as diverse as memory, reasoning, planning, and learning. The fundamental advantage of an integrated architecture like ACT-R is that it provides a framework for modeling basic human cognition and integrating it with specific symbolic domain knowledge of the type specified by domain experts (e.g., rules specifying what to do in a given condition, a type of knowledge particularly well suited for representation as production rules). However, performance described by symbolic knowledge is mediated by parameters at the subsymbolic level that determine the availability and applicability of symbolic knowledge. Those parameters underlie ACT-R's theory of memory, providing effects such as decay, priming, and strengthening and make cognition adaptive, stochastic, and approximate, capable of generalization to new situations and robustness in the face of uncertainty. They also can account for the limitations of human performance, such as latencies to perform tasks and errors that can originate from a number of sources. Finally, they provide a basis for representing individual differences such as those in working memory capacity, attentional focus, motivation, and psychomotor speed as well as the impact of external behavior moderators such as fatigue (Lovett et al., 1999; Taatgen, 2001; Gunzelmann et al., 2009) through continuous variations of those subsymbolic architectural parameters that affect performance in complex tasks.

Because they influence quantitative predictions of performance so fundamentally, we describe in some more detail the subsymbolic level in which continuously varying quantities are processed, often in parallel, to produce much of the qualitative structure of human cognition. These subsymbolic quantities participate in neural-like activation processes that determine the speed and success of access to chunks in declarative memory as well as the conflict resolution among production rules. ACT-R also has a set of learning processes that can modify these subsymbolic quantities. Formally, activation reflects the log posterior odds that a chunk is relevant in a particular situation. The *activation* $A_i$ of a declarative chunk $i$ is computed as the sum of its base-level activation $B_i$ plus its context activation:

$$A_i = B_i + \sum_j W_j S_{ji}$$

In determining the context activation, $W_j$ designates the attentional weight given the focus element $j$. An element $j$ is in the focus, or in context, if it is part of the current goal chunk (i.e., the value of one of the goal chunk's slots); $S_{ji}$ stands for the strength of association from element $j$ to chunk $i$. ACT-R assumes that there is a limited capacity of source activation and that each goal element emits an equal amount of activation. Source activation capacity is typically assumed to be 1 (i.e., if there are $n$ source elements in the current focus each receives a source activation of $1/n$). The associative strength $S_{ji}$ between an activation source $j$ and a chunk $i$ is a measure of how often $i$ was needed (i.e., retrieved in a production) when chunk $j$ was in the context. Associative strengths provide an estimate of the log likelihood ratio measure of how much the presence of a cue $j$ in a goal slot increases the probability that a particular chunk $i$ is needed for retrieval to instantiate a production. The *base-level activation* of a chunk is learned by an architectural mechanism to reflect the past history of use of a chunk $i$:

$$B_i = \ln \sum_{j=1}^{n} t_j^{-d} \approx \ln \frac{nL^{-d}}{1-d}$$

where $n$ stands for the number of references to chunk $i$, $t_j$ stands for the time elapsed since the $j$ reference to chunk $i$, $d$ is the memory decay rate, and $L$ denotes the lifetime of a chunk (i.e., the time since its creation). As Anderson and Schooler (1991) have shown, this equation produces the power law of forgetting (Rubin and Wenzel, 1990) as well as the power law of learning (Newell and Rosenbloom, 1981). When retrieving a chunk to instantiate a production, ACT-R selects the chunk with the highest activation $A_i$. However, some stochasticity is introduced in the system by adding Gaussian noise of mean zero and standard deviation $\sigma$ to the activation $A_i$ of each chunk. In order to be retrieved, the activation of a chunk needs to reach a fixed retrieval threshold $\tau$ that limits the accessibility of declarative elements. If the Gaussian noise is approximated with a sigmoid distribution, the *probability $P$ of chunk $i$ to be retrieved* by a production is

$$P = \frac{1}{1 + e^{-(A_i - \tau)/s}}$$

where s $= \sqrt{3}\sigma/\pi$. The activation of a chunk $i$ is related directly to the latency of its retrieval by a production $p$. Formally, *retrieval time* $T_{ip}$ is an exponentially decreasing function of the chunk's activation $A_i$:

$$T_{ip} = Fe^{-fA_i}$$

where $F$ is a time scaling factor. In addition to the latencies for chunk retrieval as given by the retrieval time equation, the total time of selecting and applying a production is determined by executing the actions of a production's action part, whereby a value of 50 ms is typically assumed for elementary internal actions. External actions, such as pressing a key, usually have a longer latency determined by the ACT-R/PM perceptual–motor module (Byrne and Anderson, 2001). In summary, subsymbolic activation processes in ACT-R make a chunk active to the degree that past experience and the present context (as given by the current goal) indicate that it is useful at this particular moment.

Just as subsymbolic activation processes control which chunk is retrieved from declarative memory, the process of selecting which production to fire at each cycle, known as conflict resolution, is also determined by subsymbolic quantities called utility that are associated with each production. The utility of a production is defined as

$$U_i(n) = U_i(n-1) + \alpha[R_i(n) - U_i(n-1)]$$

where $U_i(n)$ is the utility of a production $i$ after its $n$th application, $U_i(n-1)$ is its utility after its $(n-1)$st application, $R_i(n)$ is the reward the production receives, and $\alpha$ is the learning rate. Just as for retrieval, *conflict resolution* is a stochastic process through the injection of noise in each production's utility, leading to a probability of selecting a production $i$ given by

$$Probability(i) = \frac{e^{U_i/\sqrt{2s}}}{\sum_j e^{U_j/\sqrt{2s}}}$$

where the summation is over all the productions which are currently able to fire. The production with the highest utility (after noise is added) will be the one chosen to fire. Similar computations are at work in other modules, such as the perceptual–motor modules. Especially important are the parameters controlling the time course of processing as one attempts to execute a complex action or as one shifts visual attention to encode a new stimulus (Byrne and Anderson, 2001). Recent work has simplified the process of specifying the sequence of steps for complex actions by allowing ACT-R modelers to demonstrate actions on interfaces (John et al., 2004; Matessa and Mui, 2009). ACT-R can not only predict direct quantitative measures of performance such as latency and probability of errors but, from the same mechanistic basis, can also arise more global, indirect measures of performance, such as cognitive workload. Although ACT-R has traditionally

shied away from such meta-awareness measures and concentrated on matching directly measurable data such as external actions, response times, and eye movements, it is by no means incapable of doing so. For the purpose of the task described below, Lebiere (2001) proposed a measure of cognitive workload in ACT-R grounded in the central concept of unit task (Card et al., 1983). *Workload* is defined as the ratio of time spent in critical unit tasks to the total time spent on the task. *Critical unit tasks* are defined as tasks that involve actions, such as a goal to respond to a request for action with a number of mouse clicks, or tasks that involve some type of pressure, such as a goal to scan a display result from the detection of an event onset. The ratio is scaled to fit the particular measurement scale used in the self-assessment report. Lebiere (2001) describes possible elaborations of this basic measure.

## 5.2   AMBR

In this section we describe in some detail the constraints and requirements of the process of developing an ACT-R model for a task of moderate complexity and the range of quantitative predictions that one can expect from such a model. The task is a synthetic air traffic control simulation that was developed for the agent-based modeling of behavior representation (AMBR) comparison (Pew and Gluck, 2004) that arose from a report (Pew and Mavor, 1998) that highlighted the need for more robust, realistic human performance models (HPMs) for use in simulations for training and system acquisition

The AMBR project was designed to advance the state of the art in cognitive and behavioral modeling, especially models of integrative performance, requiring the coordination of memory, learning, multitasking, interruption handling, and perceptual and motor systems in order to scale more effectively to real-world environments. The program provided a structure to gather human performance data and evaluate the accuracy and predictiveness of the models. The AMBR program was organized as a series of comparisons among alternative modeling approaches including ACT-R but also the Air Force Research Laboratory's DCOG (Eggleston et al., 2001), CHI Systems, Inc.'s COGNET/iGEN (Zachary et al., 2001), and George Mason University's EASE (Chong, 2001).

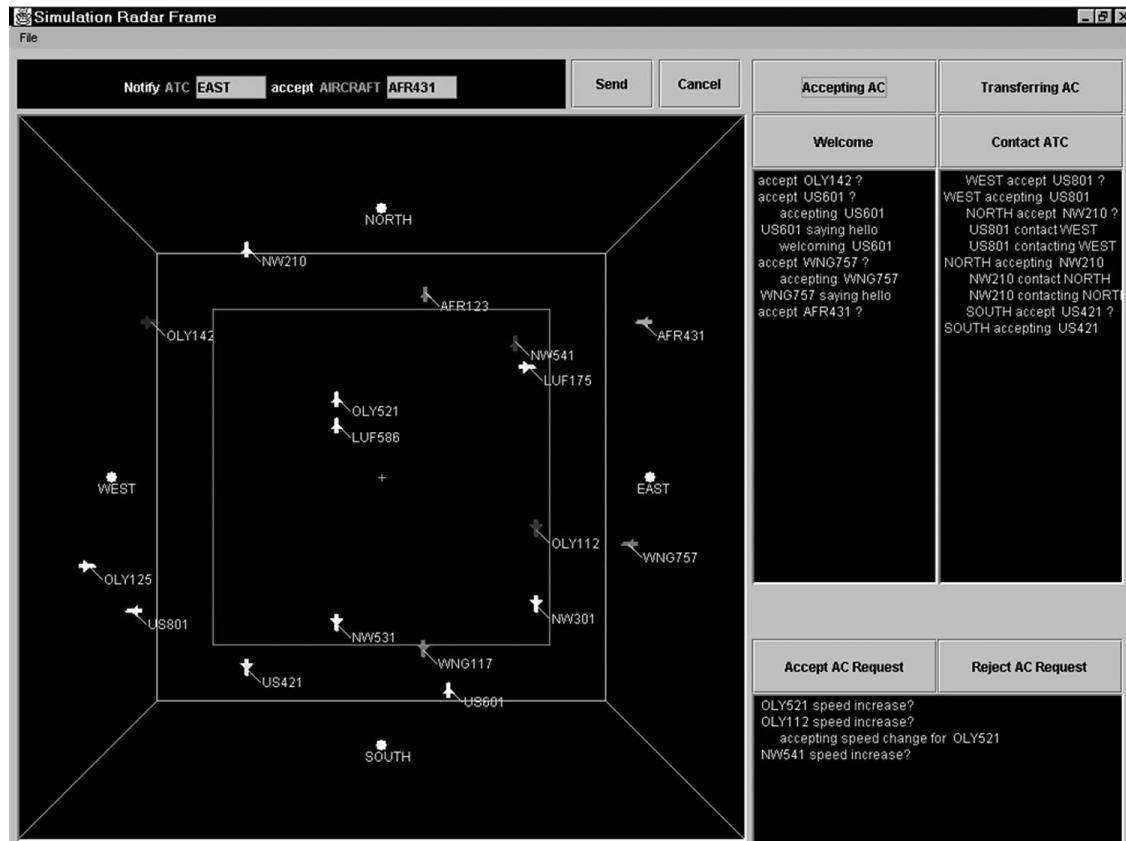
The task designed to elicit the desired behaviors is a synthetic air traffic control simulation. This domain requires a controller to manage one sector of airspace, especially the transition of aircraft into and out of the sector. Scenarios can vary the number, speed, altitude, and type of aircraft requesting access to the sector and can be complicated by having them arrive from multiple directions and adjoining sectors. This is a rich enough infrastructure to create a variety of scenarios having variable task load levels and varying levels of planning complexity. Figure 20 displays a screen shot of the simulation. The main part of the screen on the left contains a graphical representation of the entire airspace, with the part controlled by the human or model agent contained in the central yellow square. The rest of the airspace is divided by the yellow lines in four


**Figure 20** Screen shot of the AMBR simulation.

regions, north, east, south, and west, each managed by a separate controller. At any point during the simulation a number of airplanes (the exact number being a parameter controlling the difficulty of the task) are present in the airspace, flying through the central region or entering or exiting it. The task of the central controller is to exchange messages with the airplanes (each tagged with its identifying code, e.g., UAL344) and neighboring controllers to manage their traversal of its airspace. Those messages are displayed in the text windows on the right of the screen, with each window dedicated to a specific message category. The top left window concerns messages sent when a plane is entering the central controller's region, while the top right window concerns messages sent when a place is exiting the central region. Both windows include messages exchanged between controllers as well as messages between the central controller and the plane itself. The bottom window concerns messages from and to planes requesting a speed increase, which should be granted unless that plane is overtaking another plane, which is the only airspace conflict that this simplified task allows.

A single event involves a number of messages being exchanged, all of which are appended to the relevant text window. For example, in the case of a plane about

to enter the central region, a message requesting permission to enter will first be sent to the central controller from the controller of the neighboring region from which the plane originates. The central controller must reply to the other controller in a timely manner to accept the plane, then contact the plane to welcome it to the airspace. Those two cannot be performed in immediate succession but, instead, require waiting for the first party contacted (in this case the other controller) to reply before taking the final action. This delay allows for the interleaving of unit tasks but also requires the maintenance of the currently incomplete tasks in working memory. Messages from other tasks can arrive when a task is being processed, thus requiring some search of the text window to identify the messages relevant to a task. A message is composed by clicking a button above the relevant text window (e.g., accepting AC), then clicking in the graphical window on the intended recipient (e.g., another controller) and optionally the target of the message (i.e., a plane, unless it is the intended recipient, in which case this is omitted), then the send button above the graphic window. The message being composed is displayed at the top left of the display in a text window.

To measure performance on the task objectively, penalties were assessed for a variety of failures to act

in a timely manner. To evaluate the impact of system design, a decision support condition contrasted with a support condition were implemented to dissociate two aspects of multitasking behavior. In the standard condition, subjects had to parse the messages printed in the text windows on the right side of the screen to determine which planes needed attention and which functions needed to be performed on them. In the assisted condition, planes that require assistance were color coded in the graphical display on the left side of the screen according to the task that needed to be performed (green for accept, blue for welcome, orange for transfer, yellow for contact, magenta for speed change, and red for holding). This helped the subjects track visually which tasks needed to be attended to and removed any necessity to parse the text windows on the left, a complex and time-consuming task. Therefore, it dissociated the maintenance and updating of the queue of to-be-attended tasks from the resolution of conflicts between high-priority tasks. Two sets of scenarios were created: One set was provided to the developers as a model on which to base their designs, and another set was reserved to be used at the time of the competitive validation (i.e., the fly-off). Human performance data on the first set of scenarios were provided to the developers to fine-tune their model. The data from the second set of scenarios were withheld until after the fly-off for comparison with the model performance. The range of behavior requirements of both sets had the same scope, but the ways in which those behaviors were exercised were not identical, to test the robustness and predictiveness of the models.

## 5.3   Model Development

If it is to justify its structural costs, a cognitive architecture should facilitate the development of a model in several ways. It should limit the space of possible models to those that can be expressed concisely in its language and work well with its built-in mechanisms. It should provide for significant transfer from models of similar tasks, either directly in the form of code or more generally in the form of design patterns and techniques. Finally, it should provide learning mechanisms that allow the modeler to specify in the model only the structure of the task and let the architecture learn the details of the task in the same way that human cognition constantly adapts to the structure of its environment. These architectural advantages not only reduce the amount of knowledge engineering required and the number of trial-and-error development cycles, providing significant savings in time and labor, but also improve the predictiveness of the final model. If the "natural" model (derived a priori from the structure of the task, the constraints of the architecture, and the guidelines from previous models of related tasks) provides a good fit to the empirical data, one can be more confident that it will generalize to unforeseen scenarios and circumstances than if it is the result of post hoc knowledge engineering and data analysis. That is the approach that we adopted in developing a model of this task and indeed, more generally, our design and use of the ACT-R architecture.

Of course, in domains involving a large body of expertise, it makes sense to encode in the cognitive model the accepted knowledge of the field. But in synthetic tasks or in tasks involving new system design, specific established knowledge is usually inexistent or inaccessible. Thus, we did not try to reverse engineer the subjects' strategies but instead tried to develop the simplest and most natural model for the architecture. We organized the model around a few goal types with their associated productions. Goal types correspond closely to the unit tasks in human–computer interaction (Card et al., 1983) as well as to the tasks in task network models (e.g., Allender et al., 1995). Five goal types, called color-goal, text-goal, scan-text, scan-screen, and process, were defined, together with a total of 36 very simple productions. Goals were simple and would hold just a few elements, such as the aircraft currently being handled together with related information such as its position and the action to be performed, in accordance with architectural constraints. Overall, such model development need not take more than a few days. Two basic modes of human interaction with the simulation were defined: one in which the operator had to rely mostly on text messages scrolling in windows to identify events that required action (the text condition) and one in which aircraft on the radar screen that required action would turn a color corresponding to the action (the color condition). The simulation also had three speeds (low, medium, and high) that controlled how much time the subjects would have (10, 7.5, and 5 min, respectively) to perform a given number of actions.

The goal type color-goal was the top goal for the color condition. Five productions were defined that applied to that goal. They scanned the radar screen continuously, identified an aircraft that had turned color, mapped the color into the required action by relying on five simple memory chunks encoding the instructions that the subjects were given regarding the color-action mappings, then created a goal to perform the given action on the aircraft. The goal-type process executed the sequence of mouse clicks required to perform the action. Twelve productions were defined to handle the five possible actions. This required clicking on a button identifying the action, then on the aircraft, then perhaps on a neighboring controller, then finally on the send button.

As expected, the text condition was both more difficult for the subjects and slightly more complicated for the model. The goal type text-goal was the top goal for the text condition. Four productions were defined to cycle through the three text windows and the radar screen looking for aircraft requiring action by creating goals of type scan-text and scan-screen, respectively. A goal of type scan-text would handle the scanning of a single text window for a new message from another controller requesting action. A production was defined to scan the window systematically for such a message. If one was found, another production would attempt to retrieve a memory of handling such a request. Memories for such requests would be created automatically by the architecture when the corresponding goal was completed, but their availability was subject to their subsymbolic parameters, which were in turn subject to decay as well as reinforcement. If no memory could

be retrieved, the window would be scanned for another message, indicating completion. If none could be found, a process goal would be created to perform the action requested. Note that this is the same goal as in the color condition. A key component of the model was an additional production that would detect the onset of a new message in another window and interrupt the current goal to scan that window instead. This allowed the model to be sensitive to new events and handle them promptly. Scanning the radar screen was accomplished in a similar manner by goals of type scan-screen and their eight associated productions.

Finally, all the architectural parameters that control the performance of the simulation were left at their default values provided by previous models. A key aspect of our methodology, which is also pervasive in ACT-R modeling, is the use of Monte Carlo simulations to reproduce not only the aggregate subject data (such as the mean performance or response time) but also the variation that is a fundamental part of human cognition. Especially when evaluating system design, it is essential not only to capture an idealized usage scenario but as broad a range of performance as possible. In that view, the model does not represent an ideal or even average subject, but instead, each model run is meant to be equivalent to a subject run, in all its variability and unpredictiveness. For that to happen, it is essential that the model not merely be a deterministic symbolic system but also be able to exhibit meaningful nondeterminism. To that end, randomness is incorporated in every part of ACT-R's subsymbolic level, including chunk activations, which control their probability and latency of retrieval; production utilities, which control their probability of selections; and production efforts, which control the time that they spent executing.

Moreover, as has been found in other ACT-R models (e.g., Lerch et al., 1999), that randomness is amplified in the interaction of the model with a dynamic environment: Even small differences in the timing of execution might mean missing a critical deadline, which results in an error condition, which requires immediate attention, which might cause another missed deadline, and so on. To model the variation as well as the mean of subject performance, the model was always run as many times as there were subject runs. For that to be a practical strategy of model development, it is essential that the model run very fast, ideally significantly faster than real time. Our model ran up to five times faster than real time on a desktop PC, making it possible to run a full batch of 48 scenarios in about an hour an a half, enabling a relatively quick cycle of model development.

### 5.4 Modeling Results

Because the variability in performance between runs, even of the same subject, is a fundamental characteristic of this task, we ran as many model runs as there were subject runs. Figure 21 compares the mean performance in terms of penalty points for subjects and model for color (left three bars) and text (right three bars) condition by increasing workload level. The model matches the

**Figure 21** Mean performance as a function of workload and system design.

data quite well, including the strong effects of the color-versus-text condition and of workload for the unaided (text) condition.

Because ACT-R includes stochasticity in chunk retrieval, production selection, and perceptual/motor actions, and because that stochasticity is amplified by the interaction with a highly dynamic simulation, it can reproduce a large part of the variability in human performance, as indicated by Figure 22, which plots the individual subject and model runs for the two conditions that generated a significant percentage of errors (text condition in medium and high workload). The range of performance in the medium-workload condition is reproduced almost perfectly other than for two outliers, and a significant portion of the range in the high condition is also reproduced, albeit shifted slightly too upward. It should be noted that each model run is the result of an identical model that differs from another only in its run time stochasticity. The model neither learns from trial to trial nor is modified to take into account individual differences.

The model not only reproduces the subject performance in terms of total penalty points but also matches well to the detailed subject profile in terms of penalties accumulated under eight different error categories, as plotted in Figure 23. It should be emphasized that those errors were not engineered in the model but, instead, resulted directly from the limitations of the cognitive architecture applied to a demanding, fast-paced dynamic task.

The model also fits the mean response times (RTs) for each condition, as shown in Figure 24, which plots the detailed pattern of latencies to perform a required action for each condition and number of intervening events (i.e., number of planes requiring action between the time of a given plane requiring action and the time the action is actually performed). The model predicts very accurately the degradation of RT as more
**Figure 22**  Mean performance as a function of workload and system design.

**Figure 23**  Penalty points for a variety of error categories.

events compete for attention, including the somewhat counterintuitive exponential (note that RT is plotted on a log scale) increase in RT as a function of number of events rather than a more straightforwardly linear increase. The differences in RT between conditions are

primarily a function of the time taken by the perceptual processes of scanning radar screen and text windows.

Finally, the model reproduces the subjects' answers to the self-reporting workload test administered after each trial. As shown in Figure 25, the simple definition of workload described in Section 5.3 captures the main workload effects, specifically effects of display condition and schedule speed. The latter effect results from reducing the total time to execute the task (i.e., the denominator) while keeping the total number of events (roughly corresponding to the numerator) constant, thereby increasing the ratio. The former effect results from adding to the process tasks the message-scanning tasks resulting from onset detection in the text condition, thus increasing the numerator while keeping the denominator constant, thereby increasing the ratio as well. Another quantitative effect that is reproduced is the higher rate of impact of schedule speed in the text condition (and the related fact that workload in the slowest text condition is higher than workload in the fastest color condition). This is primarily a result of task embedding [i.e., the fact that a process task can be (and often is) a subgoal of another critical unit task (scanning a message window following the detection of an onset in that window)], thus making the time spent in the inner critical task count twice.

Lebiere (2004) reports the results of a second phase of the AMBR comparison in which the model had to learn how to categorize airplanes properly based
**Figure 24** Response time as a function of intervening events.

**Figure 25** Workload levels for various speed and display conditions.

on a simple pass–fail feedback. This model is similar to the one described here but leverages even more extensively the subsymbolic aspects of the architecture, especially the learning equations described in the ACT-R introductory section, to perform the learning task as a constrained component of the entire task. In summary, the advantages of this model are that it is relatively simple, required almost no parameter tuning or knowledge engineering, provides a close fit to both the mean and variance of a wide range of subject performance measures as well as workload estimates, and suggests a straightforward account of multitasking behavior within the existing constraints of the ACT-R architecture.

## 6 INTEGRATION OF APPROACHES

Because ACT-R and IMPRINT were targeted at different behavioral levels, they complement each other perfectly. IMPRINT is focused on the task level, how high-level functions break down into smaller scale tasks, and the logic by which those tasks follow each other to accomplish those functions. ACT-R is targeted at the "atomic" level of thought, the individual cognitive, perceptual, and motor acts that take place at the subsecond level. As shown in Figure 19 and in the previous example, the current goal is a central concept in ACT-R which corresponds directly to the concept of unit task. At each cycle, a production will be chosen that best applies to the goal, knowledge might be retrieved from declarative memory, and perceptual and motor actions may be taken. Those cycles will repeat until the current goal is solved, at which point it is popped and another one is selected. The ACT-R theory specifies in detail the performance and learning that takes place at each cycle within a specific goal but has comparatively little to say about the selection of those goals. Since goals in ACT-R correspond closely to tasks in IMPRINT, that weakness matches IMPRINT's strength perfectly. Conversely, since IMPRINT requires the characteristics of each task to be specified as part of the model, ACT-R can be used to generate those detailed characteristics in a psychologically plausible way without requiring extensive data collection. Thus, an integrated ACT-R/IMPRINT is structured along as pictured in Figure 26.

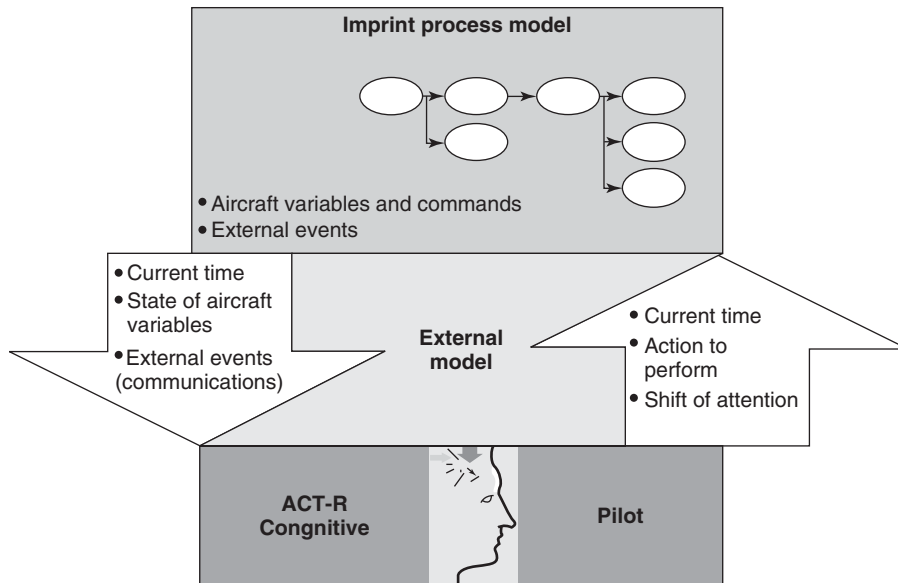
An IMPRINT model specifies the network of tasks used to accomplish the functions targeted by the model (e.g., landing a plane and taxiing safely to the gate). The network specifies how higher order functions are decomposed into tasks and the logic by which these tasks are composed together. As input, it takes the distribution of times to complete the task and the accuracy with which the task is completed. It can also take as input


**Figure 26**  Integrated ACT-R/IMPRINT model.

the workload generated by each task. Additional inputs include events generated by the simulation environment. Finally, a number of additional general parameters, such as personnel characteristics, level of training, and familiarity and environmental stressors, can be specified. IMPRINT specifies the performance function by which these parameters modulate human performance. The outputs include mission performance data such as time and accuracy as well as aggregate workload data.

An ACT-R model specifies the knowledge structures, such as declarative chunks and production rules that constitute the user knowledge relevant to the tasks targeted by the model. It also specifies the goal structures reflecting the task structure and the architectural and prior knowledge parameters that modulate the model's performance. For each goal on which ACT-R is focused (i.e., made the current goal), it generates a series of subsecond cognitive, perceptual, and motor actions. The result of those actions is the total time to accomplish the goal as well as how the goal was accomplished, including any error that might result. Errors in ACT-R originate from a broad range of sources. They include memory failures, including the failure to retrieve a needed piece of information or the retrieval of the wrong piece of information; choice failures, including the selection of the wrong production rule; and attentional failures, such as the failure to detect the salient piece of information by the perceptual modules. Although those errors could arise because of faulty symbolic knowledge (either declarative or procedural), it is often not the case, especially in domains that involve highly trained crews. More often, those errors occur because the subsymbolic parameters associated with chunks or productions do not allow the

model to access them reliably or quickly enough to be deployed in the proper situation.

Moreover, because those parameters vary stochastically and their effect is amplified by the interaction with a dynamic environment, those times and errors will not be deterministic but will vary with each execution, as is the case for human operators. Thus, the ACT-R model for a particular goal can be run whenever IMPRINT selects the corresponding task to generate the time and error distribution for that task in a manner that reflects the myriad cognitive, perceptual, and motor factors that enter into the actual performance of the task. As seen in the previous example, ACT-R can also generate workload estimates for each goal that reflect the cognitive demands of the actions taken to perform that particular subtask, then pass those estimates to IMPRINT, which can then combine them into global workload estimates for the entire task. ACT-R and IMPRINT have been unified in a single integrated development environment with the Human Behavior Architecture (HBA) tool (Warwick et al., 2008).

### 6.1  Sample Applications

As a practical application of the IMPRINT and ACT-R integration, a complex and dynamic task was selected for a modeling effort. Researchers with the National Aeronautics and Space Administration (NASA) were interested in developing models of pilot navigation while taxiing from a runway to a gate. Research on pilot surface operations had shown that pilots can commit numerous errors during taxi procedures (Hooey and Foyle, 2001). NASA was hoping to reduce the number and scope of pilot error during surface operations by

using information displays that would improve the pilots' overall situation awareness.

NASA researchers provided the IMPRINT and ACT-R modeling teams with data describing pilot procedures during prelanding and surface taxi operations. These data included videotapes of pilots in the NASA Ames Advanced Concept Flight Simulator (ACFS), which is a simulated cockpit capable of duplicating pilot taxiing operations. A detailed, scaled map of Chicago's O'Hare airport was also provided, which included runway signage. Other types of documentation were provided to give the IMPRINT and ACT-R modeling team the information necessary to duplicate runway taxiing behavior by pilots.

The IMPRINT and ACT-R modeling teams used the scaled map of Chicago's O'Hare airport to estimate the time between runway taxi turns. IMPRINT handled the higher level, task-oriented parts of the taxiing and landing operations (i.e., turning, talking on radio, looking at instrumentation), while ACT-R handled the more cognitive and decision-making parts of the task (i.e., remembering where to turn, remembering the taxi route). By using the scaled map of the airport, the IMPRINT and ACT-R teams were able to determine the amount of time between each taxi turn (based on an estimated plane speed that was correlated with the simulated speeds from the videotape data) and then use those data to estimate the decay rate for the list of memory elements (i.e., runway names) that the pilot would have to remember.

Using this integrated architecture allowed the team to represent a complex, dynamic task, and by exploiting each architecture's strengths, the modeling process was enhanced and streamlined. The resulting model could account for a broad range of possible taxiing errors within a constrained first-principle framework, as was the case for the stand-alone AMBR model, but in addition benefited by integration with the task network model, which provided a convenient task-based organizing framework to minimize the authoring requirements for the cognitive model as well as to provide a high-productivity tool to simulate the environment and aircraft with which the cognitive model interacts.

Craig et al. (2002) performed a similar integration of ACT-R into the combat automation requirements tool (CART)* model (Brett et al., 2002), a task network model used in the acquisition process of the joint strike fighter. The task to be performed was target acquisition, more specifically, management of the shoot list, which allows a pilot to select potential targets to be identified by high-resolution radar. Using a methodology similar to that described above, specific subtasks were identified for which additional cognitive fidelity was required and reimplemented in the form of ACT-R goals and associated production rules. ACT-R then interacted with the CART model, providing plausible performance for cognitive subtasks such as prioritizing targets and recalling items identified previously.

---

* The reader should note that the CART model capabilities are now subsumed into the IMPRINT tool.

## 7 SUMMARY

In this chapter we have reviewed the need for simulating performance of complex human-based systems as an integral part of system design, development, testing, and life-cycle support. We have also defined two fundamentally different approaches to modeling human performance, a reductionist approach and a first-principle approach. Additionally, we have provided detailed examples of two modeling environments that typify these two approaches along with representative case studies. Finally, we described an integrated tool that attempts to leverage the advantages of both approaches into an efficient and principled modeling package.

As we have stated and demonstrated repeatedly throughout this chapter, the technology for modeling human performance in systems is evolving rapidly. Furthermore, the breadth of questions being addressed by models is expanding constantly. Necessity being the mother of invention, we encourage the human factors practitioner to consider how computer simulation can provide a better and more cost-effective basis for human factors analysis and in turn stimulate further developments in modeling and simulation tools to better serve their needs.

## 1 INTRODUCTION

Mathematical models of human behavior serve scientific and applied functions in human factors and ergonomics and have long done so (Gray, 2008; Pew, 2008). Their bearing on the advance of theoretical behavioral science (e.g., Townsend and Ashby, 1983) is well documented, and their utility in more applied areas such as biomechanics is well established (e.g., Chaffin et al., 1999). However, their utility for the engineering psychologist is often overlooked. In fact, there is a general sense that the engineering psychologist cannot yet use mathematical models to design an actual interface. In an issue of *Human Factors*, in an article in a special section on quantitative formal models of human performance, this sense is clearly articulated: "An aim of human factors research is to have models that allow for the advance of user-friendly environments. This is still a distant dream because existing models are not yet sufficiently sophisticated" (Jax et al., 2003).

Clearly, no model or technique can handle all situations. But we believe there exist models that play and will continue to play a central role in the design of user-friendly environments (Fisher, 1993). Unfortunately, they lie scattered throughout a varied literature, one not easily accessible to many readers. Moreover, designers aspire to consider the entire task and its environment, but available models are likely to be targeted for particular aspects of the situation, thereby not coming to the attention of the design community. Finally, many models that could be useful in design are not extended in that direction, perhaps because the optimization techniques needed to make this transformation are part

of a field, operations research, which generally does not overlap with engineering psychology. One purpose of this chapter is to bring to the attention of the more general reader models and optimization techniques that allow creation of real, user-friendly environments.

Design lies at the center of the link between theory (the scientific model) and practice (the application or environment). Understanding this link makes clear the limited but essential role mathematical models play in the design process, one that many models can now play. The interface between the human operator and the environment is the design element, natural or built. This design element can be as simple as a kitchen utensil or as complex as the displays in a nuclear power plant control room. The design element is frequently constrained but within those constraints can take on an infinite or very large number of different configurations. For example, consider just the location of the keys on an automated teller machine (ATM). Suppose there are four keys positioned on the ATM, one key near each edge of a small square display window and each key accessing a different option (Figure 1). Suppose that any option can be assigned to any key. And suppose the menu hierarchy is three levels deep, with four options in each display (only two levels are displayed in Figure 1). Given this configuration, at the bottom level of the

hierarchy there are 16 menus each with 4 options, or a total of 64 different terminal options. Then there are over 1 quadrillion possible arrangements of the options in each display (4! arrangements in each display, so $24^{1+4+16}$ arrangements overall).

The link from theory to practice through design is now easily made. Clearly, it is not possible to evaluate all of the different arrangements (designs) experimentally. This is where mathematical models have a critical role, in engineering in general and, more specifically, in human factors engineering (Byrne and Gray, 2003). They can be used to predict performance for each different configuration of an interface and, in this case, for each different arrangement of the menu options. By itself, this may be all that is required. One can simply iterate through all possibilities and identify the one or ones that optimize performance. However, when the number of different configurations gets too large or is infinite, it is necessary either to derive the optimal solution analytically or to use methods that can approximate it. This is where knowledge of optimization techniques becomes critical and why in this chapter some attention is given to such techniques.

Formally, we can treat optimization as finding the maximum (or minimum) of an objective function: for

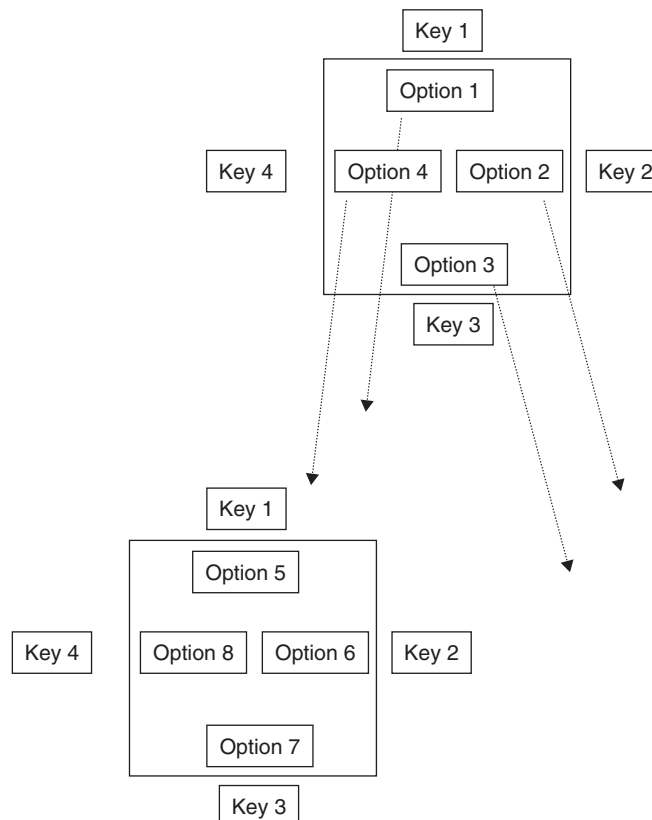

**Figure 1**  ATM arrangement of keys and options.

example, a weighted sum of $n$ key variables:

$$F(x) = \sum_{i=1}^{n} c_i x_i \qquad (1)$$

where the variables are $x_i$ and the weights on each variable are $c_i$. Of course, more complex and more general objective functions beyond the simple linear sum of equation (1) are possible. Generally, it is not possible to choose arbitrary values of the variables $x_i$, as these are constrained. In the ATM menu design example, we must choose arrangements that include one and only one placement of each of the four keys. In general, there will be a set of constraints, for example,

$$\sum_{i=1}^{n} a_i x_i \leq b_j \qquad (1 \leq j \leq m) \qquad (2)$$

where each of $m$ linear combinations of the variables $x_i$ and weights $a_i$ must be less than some constant $b_j$. Such optimization problems have been studied extensively in operations research, and solution procedures have been developed for many classes of problems: for example, linear programming (as above) or integer programming, where the $x_i$ values are constrained to integers. Not all mathematical models are optimization models, but many can be used in this way.

Although we focus on the use of mathematical models to optimize performance, we do not do so exclusively, for such models have a broader practical utility than simply the optimal design of an interface. First, the parameters of such models can indicate something about a quantity such as the relative speed of latent processes, a quantity that would be important if, say, one group has been exposed to a toxin and another group has not been so exposed (Smith and Langolf, 1981) or if, say, younger and older adults are being compared performing a particular task (Salthouse and Somberg, 1982). Second, models also have an important role to play before implementing an interface and incurring all the expenses that go along with such an implementation. Specifically, they can be used to estimate whether the interface will perform as desired (Gray et al., 1993). Third, models have still another, perhaps surprising role to play. They can identify situations where the intuitively most obvious course of action leads to paradoxical results (Meyer and Bitan, 2002). Fourth, because a mathematical model makes explicit the variables and parameters considered, the discipline of mathematical modeling also forces users to make explicit these variables and relationships, thus providing a solid foundation for the testing, extension, or perhaps ultimate rejection of the model. Somewhat paradoxically, there is an art to mathematical modeling, and that art is to abstract from the complex, real system of humans and devices those aspects most necessary for an accurate, yet economical prediction of performance. Of course, models have a theoretical purpose as well and we will make that clear as we go forward. Specifically, they are useful not only because they can provide testable predictions of complex theories (e.g., Sternberg, 1975;

Fific et al., 2010) but also because one can determine in certain cases whether models that appear on the surface as different indeed are different (Townsend, 1972).

The selection of examples below is necessarily limited by space, but also by a desire to give readers enough background material to understand how mathematical models, together with appropriate optimization techniques, can have a radical impact on design. An attempt has been made to be as broad as possible within the confines, giving to readers some sense of models currently used in design of interfaces as diverse as workstations, variable message signs, menu hierarchies, intelligent tutors, and warnings, among others.

Finally, we should end the introduction with a disclaimer. We recognize that some of the most creative design lies outside the scope of the procedures considered in this chapter. For example, consider the design of menu hierarchies. Recent efforts to improve performance include the compression of speech (Sharit et al., 2003) and, with cell phones and other technologies with very small display windows, the presentation of a portion of the hierarchy rather than just the current command (Tang, 2001). These more qualitative changes often bring about much larger changes than can be realized through the modeling and optimization techniques described below.

## 2  GENERAL MATHEMATICAL MODELS

We begin with some general tools that can be brought to bear on the design of an optimal interface. Perhaps the class of tools used most frequently by engineering psychologists are networks representing the processes involved in the performance of a task. Once the arrangement of the processes is understood, quantitative tools exist to estimate the response time. However, these tools often need to be augmented. For example, the output of an encoding process might not be perfect, changing from one trial to the next even though the objective stimulus did not change. The output of a decision process might change based on the payoff matrix; or the time to execute a response might change as a function of the number of possible responses. Tools to handle these and other more complex variations on behavior are discussed below.

### 2.1  Task Analysis and Activity Network Models

One can describe human performance in a task by starting with a general model of the human operator, identifying the components of the model critical for the task, and then using the model so constrained to predict performance. Introductions to the main general models for this purpose are discussed in Anderson (1993) and Byrne and Anderson (1998) for Adaptive Control of Thought–Rational (ACT-R), Liu et al. (2006) for Queuing Network–Model Human Processor (QN-MHP), Meyer and Kieras (1997a, b) for Executive-Process/Interactive Control (EPIC), and Newell (1990) for State Operator and Result (SOAR). It is often more direct to start by modeling the cognitive, perceptual, and motor activities in the specific task that the operator is performing. This approach is congruous with the state of

knowledge in experimental psychology. A psychologist may study memory, but the actual experiments will be conducted on a task such as recognition of an object. At this time, much knowledge in experimental psychology is organized as knowledge about the latent activities required to perform specific tasks such as searching a display or drawing a figure. A component of interest, such as perception, is emphasized, but the smallest unit of study is the task. This organizational scheme may be a temporary phase, or, if tasks turn out to be natural fundamental units, it may be permanent. In any case, most contemporary models are not for the entire human system, nor are they for isolated components. Most models are for a component within a task, even if presented in the literature as a model for the component alone. The implication is that if a model does not yet exist for performance in a new situation, it is unlikely that one can be made simply by snapping together existing models of components. A new model will usually need to be developed for the components in their new context.

### 2.1.1   Activity Networks

For context, the modeler needs a functioning model for the entire task. The handiest model for a task is often an activity network (e.g., Elmaghraby, 1977; Pritsker, 1979). An activity network indicates the arrangement of activities in the task, some following one upon another and some going on concurrently (see Figure 2). Each vertex $v_i$ in the network represents an activity $a_j$, and an arrow from one vertex to another indicates the order in which the activities must be performed. A path from a vertex $v_1$ to a vertex $v_2$, going along arrows in the proper directions, indicates that the activity represented at vertex $v_1$ precedes the activity represented at vertex $v_2$. Two activities $a$ and $b$ are called *sequential* if either $a$ precedes $b$ or $b$ precedes $a$. For example, in Figure 2 the activity "call begins," represented at vertex $v_1$, precedes the activity "system response," represented at vertex $v_2$. Two activities are called *concurrent* if and only if they are not sequential. For example, "system response" and "listen to beep" are concurrent. (Note that two activities are called concurrent if they could in principle be carried

out simultaneously, even if it happens that one of them is finished before the other starts.)

The duration of the task depends on the durations of the individual activities. Suppose all activities in the network must be completed for the task to be completed (there are other possibilities, of course). An activity network of this form is called a *critical-path network*. The task is completed when and only when all the activities on the longest path through the network are completed. The longest path through the network is the *critical path*, and the duration of the task is the sum of the durations of all the activities on the critical path. For example, in Figure 2 activity durations are listed immediately below the activity inside the vertex (assuming here these durations are constant). The durations of activities along the top path sum to 8; durations of activities along the bottom path sum to 11. Thus, the task duration is 11. If the durations of the activities are constants, then to reduce the task completion time, one must identify the activities on the critical path and minimize their durations. Shortening the duration of an activity not on the critical path has no effect.

***Application: Workstation Design***  When new workstations were designed for operators in a New York telephone company, the hope was that with faster displays and fewer keystrokes the time per call would drop. But, before the new workstations were installed, an attempt was made to determine whether this would actually be the case. Gray et al. (1993) modeled the way the new workstations would be used, extrapolating from videotapes of operators using the old workstations. The modelers used a technique called CPM-GOMS (John and Newell, 1989; John, 1990) to construct networks for the activities in phone calls. (CPM stands for both Cognitive Perceptual Motor and Critical Path Method. GOMS stands for Goals, Operators, Methods and Selection Rules.) The technique is an extension of the GOMS technique for task analysis in terms of goals, operators, methods, and selection rules (Card et al., 1983). The modeling predicted that the time per call would actually increase, and an increase was indeed found in later data from the new workstations.

What the modeling revealed was that activities that were performed more quickly with the new workstations would not shorten by much the overall time to complete the task, because the quicker activities would be going on concurrently with other slow activities. On the other hand, despite the need for fewer keystrokes with the new workstations, some new keystrokes would occur when there were no concurrent slow activities, so the time for the new keystrokes increased the call completion time. Here is an example where a model can be used not only to predict whether an interface will perform as desired but also why, if such is not the case, the performance will be less than desired. Given the right lead time, this in turn can suggest how to redesign the interface so that performance improves before it is implemented.

### 2.1.2   OP Diagrams

It was assumed above when discussing activity networks that the durations of the processes were constant. In practice, durations of activities are random variables, so

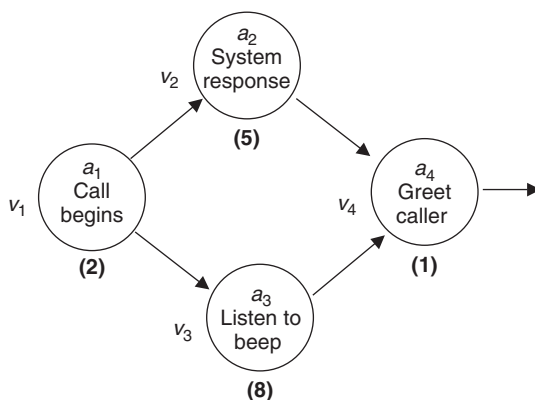

**Figure 2**   Activity network.

one is interested in the probability an activity is on the critical path (i.e., its *criticality*). With random activity durations, calculating the mean and variance of the task completion time is usually intractable, so simulations are carried out with programs such as MATLAB or programs especially designed for human factors, such as MICROSAINT (Laughery, 1985) and the recently developed SANLab (Patton and Grey, 2010). When durations have exponential or gamma distributions, exact formulas can be found with an OP (order-of-processing) diagram (Fisher and Goldstein, 1983). For example, if we let $T_i$ be the duration of activity $a_i$, then for the activity network in Figure 2 the expected value of the completion time is $E[\max\{T_1 + T_2 + T_4, T_1 + T_3 + T_4\}]$. This expectation can be computed easily if the foregoing conditions are met and the task is represented in an OP diagram, a discussion to which we now turn.

Figure 3 shows the beginning part of an OP diagram for a driver reading an electronic variable message sign that presents words one at a time. Each individual word is displayed, perceptually encoded, and comprehended. At any given time, a certain subset of activities will be executing; for example, the comprehension of the first word might go on simultaneously with the displaying of the second word. Such a set of activities executing simultaneously defines a state, and each possible state is represented by a vertex in the OP diagram. In the OP diagram in Figure 3, $w_1$ denotes the display of the first word, $e_1$ its encoding, $c_1$ its comprehension, and so on. In the state represented by the first vertex (labeled $s_1$), the first word is displayed ($w_1$) and the driver is encoding it ($e_1$). It is assumed that the durations of these activities are continuous random variables. Thus, the probability that two activities finish at the same time is zero, so such an event does not need to be represented in the OP diagram. In this case, one of these activities will finish first (not both), and when it does, the state is exited. The driver may finish encoding the first word before its display ends. In that case, in the next state ($s_2$) the first word is still being displayed, and the driver is comprehending it. The transition from the first state to this next state is indicated by an arrow labeled with the activity whose completion leads to this next state, in this case $e1$. The other way to exit the first state is for the display of the first word to finish before the driver has encoded it. The OP diagram indicates that in this case the driver does not complete the encoding of the

first word ($e_1$ appears in parentheses on the arc exiting from the state) and fails at reading the sign.

Every critical-path network can be converted to an OP diagram. In addition, situations such as two activities that must go on one at a time, but in any order, can be represented in an OP diagram but not in a critical-path network. After an OP diagram has been constructed, it can be used to calculate quantities such as the mean and variance of the task completion time and the probabilities of the task completing in various ways, such as success or failure at reading a variable message sign (Fisher and Goldstein, 1983; Goldstein and Fisher, 1991, 1992). In this case, if we let $T_i$ be the duration of activity $a_i$, the expected time to complete the task is no longer the expectation of the maximum of the path durations in the OP diagram. Instead, it is now a probability mixture of conditional expectations, where each conditional expectation is the time on average it takes to complete all activities along a path in the OP diagram. For example, if the top path through the OP diagram were taken, and it consisted of only those states listed ($s_1, s_2, s_3, s_5$), we would want to compute the following conditional expectation: $E[T_1 + T_2 + T_3 + T_5|$ path $(s_1, s_2, s_3, s_5)]$. We would need to weight this by the probability that path $(s_1, s_2, s_3, s_5)$ is taken and then do the same thing for all other paths in the OP diagram. Equations for the calculations may be found in Fisher and Goldstein (1983).

### 2.1.3 Identifying Activity Durations

We assumed above that durations of activities are known if calculations or simulations are needed. Durations are ideally found by observation, as in Gray et al. (1993). Durations of certain common activities are available in the literature (see references in Schweickert et al., 2003). Another source is expert opinion. However, it is often difficult for an expert to produce an accurate estimate of the duration of an activity. Schweickert et al. (2003) proposed that it may be more natural for an expert to produce a rank ordering of the differences in durations between pairs of activities. For example, in a telephone operator's task, an expert may judge that the difference in durations between greeting a customer and pressing the enter key is less than the difference in durations between entering a credit card number and listening to a beep. When the judgments are entered into a multidimensional scaling program

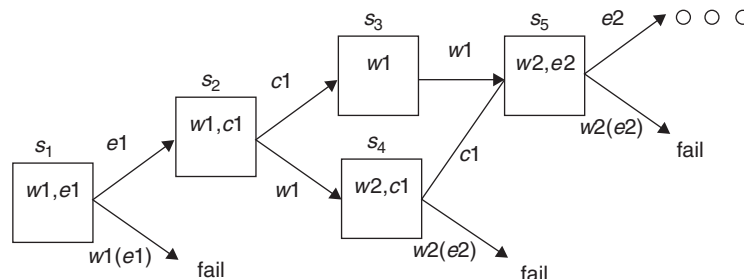

**Figure 3**  OP diagram.

(e.g., Shepard, 1962; Kruskal 1964), scale values for activity durations are produced. If the actual mean and variance of the duration of at least one activity are known for calibration, the scale values can be converted to estimates of mean activity durations. The estimates are only approximations. But Schweickert et al. (2003) found that they can lead to excellent predictions of the criticality and the product of criticality and duration for individual activities in simulations. (Activity durations were assumed to have gamma distributions.)

### 2.1.4  Identifying the Arrangement of Activities

We also assumed above that the arrangement of the activities is known. The activity arrangement in a task is ordinarily found by observation, discussion with operators, and inference. Sometimes an activity network has not been constructed, but a task analysis has been carried out, and the resulting diagram can readily be converted to an activity network (Schweickert et al., 2003; see also Anderson, 1993). In many information-processing tasks, activities are unobservable mental processes such as perceiving and deciding. An analyst may be able to infer their existence or ask about the operator's knowledge of them. Another approach is based on experimentation using the technique of task network inference. With the technique, the activity arrangement is obtained by manipulating experimental factors, such as the number of elements in a display, with the intention of using each factor to influence selectively the duration of a single activity, such as a visual search. The effects of the factors on task completion time provide the information needed to construct a critical-path network or to show that no such network is possible for the factors used (Dzhafarov et al., 2004; Schweickert, 1978; Schweickert and Townsend, 1989; Schweickert et al., 1992; Schweickert, Fisher and Sung, in press). The key idea is that when two activities are influenced selectively, patterns in task completion times differ depending on whether the pair of activities is sequential or concurrent. With this information for pairs of activities, a network can be constructed. After an activity network for the task has been constructed, simulations or calculations can be used to model effects of changes such as aging (Fisher and Glaser, 1996) or equipment modification.

***Application: Variable Message Signs***  Above, using an OP diagram to model a driver reading a variable message sign was discussed (Figure 3). The OP diagram can be used to predict the probability that a driver reads each of the words in the message and therefore understands the signs. In practice, it is often possible to present the message one, two, or three times in the legibility zone and even to vary the duration of each page in a multiple-page message (a message so long that it cannot be presented in its entirety on a single page of a variable message sign). It is by no means clear exactly how long each page should be displayed to maximize the probability that drivers understand the variable message sign when the message is displayed one or more times in the legibility zone. Recent research indicates that displaying the message more than once

increases the likelihood that drivers will understand the message (Dutta et al., 2005). The next step is to use an OP diagram to find the page durations that maximize the probability that drivers understand the message. In this case one would need to add an additional process to the OP diagram, which reflects the time that drivers have to read the message. This will be a function of the driver's speed and the distance from the sign at which the message on the sign first becomes legible. For any given setting of the parameters, one can easily compute the probability that the words on both pages are understood. The optimal page durations can then be estimated by iterating through the space of possible page durations.

## 2.2  Signal Detection Theory

Task analysis is a powerful methodology for understanding what a person does (task description) and interpreting how a person performs (task analysis). A basic distinction in task analysis is often made between resource-limited and data-limited tasks (Norman and Bobrow, 1975). In a *resource-limited task*, such as the ATM menu tasks noted earlier, performance improves as more resources (time in this case) are devoted to the task. If we try to rush the sequence of button pushes, errors are more likely. All of the tasks that were described in Section 2.1 were resource limited. In contrast, *data-limited tasks* do not show increased performance with more resources. These tasks are limited by the quality of the incoming data, so that no matter how many processing resources are employed, the performance (e.g., detecting or recognizing a signal) does not improve. An example of a data-limited task would be trying to hear an important news broadcast on a radio at the limit of reception. If the signal-to-noise ratio is too low, trying to analyze more intensely what was heard will hardly make the signal more recognizable. These data-limited tasks have often been modeled by signal detection theory (Green and Swets, 1966), a discussion to which we now turn.

In a signal detection task, accuracy is the dependent variable. A subject must decide whether or not a weak signal is present. When a signal is presented, it produces neural activation, but the same signal does not always produce the same amount of activation. To make matters worse, an amount of activation usually produced by a signal can sometimes be produced in the absence of a signal by background noise from the environment (or from the nervous system itself). Error-free performance is not possible under these circumstances. According to signal detection theory (SDT), the best that one can do is set a particular amount of activation, call it $x_c$, as a criterion. If the amount of activation present exceeds the criterion, one decides that a signal is present; otherwise, one decides that noise alone was present. The result is a $2 \times 2$ classification of events:

1. If a signal is present and the observer says that a signal is present, the event is called a *hit*.
2. If a signal is present and the observer says that a signal is not present, the event is called a *miss*.

3. If a signal is not present and the observer says that a signal was present, the event is called a *false alarm*.

4. If a signal is not present and the observer says that a signal is not present, the event is called a *correct rejection*.

In the prototypical version of signal detection theory, the activation produced by a signal is normally distributed with mean $\mu_s$ and the activation produced by noise alone is normally distributed with mean $\mu_n$. The variance of the two distributions is assumed to be the same, $\sigma^2$. The more intense the signal, the greater the mean activation produced by it. The greater the difference between the mean of the signal distribution and that of the noise distribution, the more sensitive the observer will be. A measure of sensitivity is $d'$:

$$d' = \frac{\mu_s - \mu_n}{\sigma}$$

The means and variances of the activation distributions, and hence $d'$, are assumed to be influenced by characteristics of the signal and noise but to be beyond the control of the observer.

What is under control of the observer is the location of the criterion. The location of the criterion is frequently specified, not by the value of $x_c$, but by the ratio of the density functions of the signal, $f_s(x_c)$, and noise, $f_n(x_c)$, distributions evaluated at the criterion $x_c$. This ratio is often called the *response bias*. A measure of the response bias is $\beta$, defined as

$$\beta = \frac{f_s(x_c)}{f_n(x_c)}$$

To estimate $d'$ and $\beta$ from data, one ordinarily assumes that the signal and noise distributions are normal, with equal variance, so these quantities are said to be *parametric*.

Signal detection theory is a good example of a mathematical model that can be used as an optimization model, directly influencing practice. The two parameters, $d'$ and $\beta$, describe the actual performance of the task when the distributions of signal and noise are given. But we can go further and use mathematical optimization techniques to find where a person *should* place the criterion (optimum $\beta$) rather than just where a person *does* place it. To do this, we develop an objective function: for example, the long-term expected payoff over many trials. To optimize performance, the observer should adjust the criterion, taking the probability of a signal into account as well as the costs and benefits of the various correct responses and errors (see, e.g., Macmillan and Creelman, 1991). The constraint set is implicit in the model of signal and noise given above.

Specifically, if one can assign values to hits ($V_H$), misses ($V_M$), correct rejections ($V_{CR}$), and false alarms ($V_{FA}$), and if one knows the probability of a signal, $p(s)$ and, by extension, the probability of noise, $p(n)$, the criterion $x_c$ which maximizes the expected gain can easily be found by knowing the optimal $\beta$ where

$$\beta_{op} = \frac{p(n)}{p(s)} \frac{V_{CR} + V_{FA}}{V_H + V_M} \tag{3}$$

Note that this optimum is independent of the actual distributions of signal and noise.

Above, we talked about signal detection theory outside the context of activity networks and more general OP diagrams. We now want to show how one can easily and immediately incorporate the elements of signal detection theory into the framework of OP diagrams. Suppose that a signal is presented and a response obtained. Then one might have only three processes: encoding, decision, and response. However, when a signal is presented, there are two different responses. Correspondingly, when noise is presented, there are two different responses. To model the task, one will need two different OP diagrams, one used when the signal is presented and one used when noise is presented. Consider just the case when the signal is presented. The state in which the decision process completes will now have two transitions associated with that completion, one indicating that the subject responds that the signal is present and one indicating that the subject responds that the signal is absent. The probabilities of these transitions are, respectively, the probability of a hit and the probability of a miss obtained from signal detection theory.

***Application: Inspection Tasks I*** An obvious application of signal detection theory is to data-limited tasks such as matching a paint color to a sample or listening to a car engine to detect a maladjusted tappet. These are inspection tasks and are considered in more detail in Sections 6.1–6.3.

## 2.3 Information Theory

Above, we described tasks in which one uses knowledge about the operation of the encoding and decision processes to assign values to the parameters in an OP diagram, thereby increasing the overall power of these diagrams. Here, we want to describe tasks in which one uses knowledge about the operation of the response selection processes, again to assign values to the parameters in an OP diagram. Specifically, we want to know how response times will vary as a function of the number of different responses that can be made in a given task. As an example, consider an in-vehicle collision-warning system. One could potentially warn drivers not only that a collision was going to occur but also where (in general) that collision was going to occur. As someone concerned with the design of such a system, one would like to know whether drivers will respond most quickly if they are warned that the collision will occur somewhere in front or somewhere behind the middle of the vehicle. Or, instead, should one warn the driver that the collision will occur in front, in back, to the left, or to the right? And, of course, more complex schemes are possible. To understand what needs to be done, some appreciation is needed for the role that information theory can play in this decision.

Generally speaking, one might assume that it is difficult, if not impossible, to decide on a common definition of information, let alone quantify that definition. Yet this is exactly what was done so elegantly by Shannon and Weaver (1949). Briefly, imagine two events, one very likely and one very unlikely. Suppose that the first event is: "The sun will rise tomorrow." The second event is: "The winning lottery number tomorrow will be 978654133." Most people would agree that there is much more information in the second message than in the first. So, let's take as a basic axiom the following: If the probability $p(x_i)$ of a message $x_i$ is greater than the probability $p(x_j)$ of a message $x_j$, the information $I(x_i)$ in message $x_i$ is less than the information $I(x_j)$ in message $x_j$. Rather surprisingly, together with a few other reasonable axioms, it follows necessarily that the information in a message can be written as follows:

$$I(x_i) = -\log p(x_i)$$

Assume that there are $n$ messages in a set $X$ of messages. Then one is frequently interested in the expected information in the message set, what is often called the *uncertainty*:

$$U(X) = E[I(X)] = \sum_{i=1}^{n} I(x_i) \cdot (x_i)$$
$$= \sum_{i=1}^{n} [-\log p(x_i)] \cdot p(x_i)$$

Now, taking this one step further, imagine that we have a set $S$ of $n$ stimuli and a set $R$ of $n$ responses. For the sake of simplicity, assume that $r_i$ is the correct response to stimulus $s_i$. Then we can ask how much information in the stimulus set is transmitted by the responses. In theory, anything between none of the information and all of the information could be transmitted. If a subject always gives the correct response, all of the information in the stimuli is transmitted by the responses. However, suppose that the probability that a subject gives response $r_i$ to stimulus $s_i$ is equal to chance ($1/n$) and, in fact, $p(r_j) = 1/n, j = 1, \ldots, n$. Then, none of the information in the stimuli is contained in the responses since the response that is made is entirely independent of the stimulus that is presented. A measure consistent with these intuitions, defined as the *information transmitted*, is easy to develop and is defined as follows:

$$T(S, R) = U(S) + U(R) - U(S, R)$$

where $U(S, R) = -\sum_{i=1}^{n} \sum_{j=1}^{n} p(s_i, r_j) \log p(s_i, r_j)$.

In light of these developments, Hick (1952) asked the following question: Would the response time in a task be related to the information transmitted? To answer this question, he ran an experiment in which the number $n$ of stimuli shown to participants varied across conditions. Each stimulus was associated with a unique response. The probability $p(s_i)$ that a particular stimulus could occur was simply set to $1/n$. He found a linear relation between the information transmitted and the response time:

$$RT(n) = a + bT_{n+1}(S, R) \qquad (4)$$

The interpretation of this relation is as follows. Suppose that the number $n$ of stimuli were a power of 2 ($n = 2^k, k$ a positive integer) and subjects always responded correctly. Then the information transmitted (assuming no errors) can be shown to be equal to $k$, which is the minimum number of binary decisions it takes to identify one of $n$ stimuli (again, $n = 2^k$). However, the reader will note that the information transmitted is indexed by $n + 1$, not $n$ as one might expect. Hick argued that the respondent making the decision might be choosing among $n + 1$ responses, $n$ of which were associated with a particular stimulus and one of which was associated with the absence of a stimulus. Hyman (1953) observed that the number of responses and information transmitted were well correlated. To determine whether it was the information, not the number of responses, which was controlling response time, he covaried the two and found that the ordering of the response times was consistent with the measure of the information transmitted, not the number of responses.

Predictions of response times from information theory are easily demonstrable in laboratory tasks with a relatively small number of alternatives, perhaps 16 or less (4 bits of information). However, they can be extended successfully to tasks with much higher levels of information per stimulus. For example, Bishu and Drury (1988) showed a good fit of information theory to complex surface wiring tasks in the communications industry, with information per stimulus up to 30 bits.

Finally, and as above with signal detection theory, we want to bring the discussion back to the more general framework of OP diagrams, if only briefly. In a task in which there are no errors (or few) and the number of stimuli in the message set varies across blocks of trials, a simple serial model can be used to represent the latent encoding, response selection, and response execution processes in an OP diagram or other network. The distribution of the duration of the response selection process is one of the parameters in the model. The mean of the distribution can be determined for each number $n$ of stimuli in the message set using information theory. From equation (1) it follows directly that this mean is equal to $bT_{n+1}(S, R)$. The sum of the means of the encoding and response execution processes is $a$.

### Application: In-Vehicle Collision-warning Systems

At the start of this section, brief mention was made of in-vehicle collision-warning systems. The utility of information theory for the design of such systems can now be made more clear. Suppose that participants are asked to indicate as quickly as possible from which direction an alarm has sounded. The first question is whether response times increase as the number of locations from which a warning can sound increases. In a recent experiment this number was varied between two and five (Wallace and Fisher, 1998). Response times

increased linearly as a function of the information transmitted, going up by almost 50% when the uncertainty in the stimulus set was largest. Of course, although times are longer with more alarm locations, subjects know better where to focus their attention when the location of the collision is delineated more clearly. Thus, although with few alarm locations drivers may quickly be able to determine that the collision is in front or in back of them, they will not know where more precisely to look. Additional time will be needed by the driver to find the object with which a collision is imminent. A complete model of the time that it takes a driver to locate the source of a collision will require not only a model of how quickly the driver can locate the general area of concern, but additionally, a model of how quickly within that general area of concern the driver can find the actual object that is creating the collision risk. There is every reason to believe that such a model can be constructed based on related models of visual search (e.g., Arani et al., 1984) and could be used to identify the number of warning locations that will minimize the time it takes drivers to respond appropriately to a threat.

***Application: Mail Sorting***   Mail sorting represents another instantiation of an information-theoretic model. The sorter needs the address of an envelope and sorts it into the correct slot from hundreds of slots in a mail route, each slot representing one address. Hoffmann et al. (1993) used information theory to predict mail-sorting times for Australian Post. In fact, such a model can be manipulated mathematically. Drury (1993) studied a mail-sorting system where part of the incoming mail stream was sorted into the correct order automatically. Ordered mail restricts the choices that are available [e.g., if the previous mail piece went into slot $i$ out of $n$, the information to be processed in the next piece would be a choice between $n - i$ alternatives]. This formed the basis of predicted savings in mail-sorting time from preordering of the mail.

## 2.4   Other Tools

We have described just several of many different tools that might be used to model the latent cognitive processes that govern the performance of participants in both laboratory and field settings. Many of these other tools, including associative networks (Anderson and Bower, 1973), connectionist networks (Rumelhart and McClelland, 1986), and shortest route networks, have their equivalent as OP diagrams and have been discussed elsewhere (Rouse, 1980). Other more general models, ACT-R (Anderson, 1983; Byrne and Anderson, 1998), queuing networks (Liu, 1996; Liu et al., 2006), SOAR (Newell, 1990), and EPIC (Meyer and Kieras, 1997a, b), about which we spoke earlier, can also easily be incorporated in the OP network framework.

## 3   VISUAL AND MEMORY SEARCH

The range of applications of task analyses and activity networks to human factors problems requiring cognition is too large to even begin to catalog, let alone

cover in some detail. However, we feel there is one area that stands centrally in human factors, has an extensive history of mathematical modeling (Townsend and Ashby, 1983), and continues to be crucial, namely search and scanning processes (Wolfe, 2007). Almost every one of us is involved daily in one form of search or another, not the least of which is the search for a particular option on an ATM or PC, or the search through voice mail. Below, models of visual and memory search are discussed and applications of these models are detailed.

### 3.1   Visual Search

The visual search through a display can be as simple as the scanning of an array of symbols presented to a person seated in front of a computer or as complex as the scanning of traffic visible to a driver who may be looking for a particular license plate number in a sea of cars. At the heart of all models of visual scanning are four latent cognitive processes: an encoding $e$ of the information to which attention is being paid; a comparison $c$ of the encoded information with the target; a decision to end the search since the target is present and respond $p$ that such is the case; or a decision to end the search since no target is present and respond $a$ that such is the case.

In theory, there are at least four different ways that one might scan a visual display for a target, the most obvious being a serial scan that terminates when the target is identified (*serial*, *self-terminating*). If there were multiple targets, the scan could not terminate until all stimuli in the display had been identified (*serial*, *exhaustive*). In some cases, users might scan the display in parallel, either stopping when the target was identified (*parallel*, *self-terminating*) or continuing until all stimuli had been scanned (*parallel*, *exhaustive*). It is straightforward to represent the architecture for each of the models and predict the response time when the durations of the latent processes are constant. However, it becomes more difficult to represent the architecture and predict the moments of the response time distributions when the durations of the latent processes are random variables, especially as constraints are added, say, to the number of decision processes in a parallel model that can be ongoing simultaneously.

To give the reader a sense for how the modeling is undertaken, a simple derivation will be made of the expected time that it takes a person to find a target when the search is a serial, self-terminating one and the display consists of an array of symbols (say, letters). Let $E_i$ represent the time to encode the $i$th symbol scanned in the display, whatever it is. Let $C_i$ represent the time to compare the $i$th symbol scanned with the target. The subscript $i$ will be dropped here because it is assumed that the distributions of these times are identical. Let $Y$ represent the time to respond that the target is present and $A$ represent the time to respond that a target is absent. Let $F$ be an indicator random variable that is set to $i$ if the target is identified as the $i$th symbol scanned in the search. Finally, let $P(F = i)$ be the probability that the target is in the $i$th location. Then the expected time, $E[T(\text{present})]$, to find a target when there are $n$

symbols can be written as the weighted sum of the time on average, $E[T(\text{present})| F = i]$, that it takes to find the target in each of the $i$ different positions:

$$E[T(\text{present})] = \sum_{i=1}^{n} E[T(\text{present})|F = i]P(F = i)$$

If the target is in the $i$th position, there are $i$ encoding operations and $i$ comparisons plus one decision to respond that the target is present. Let $e$, $c$, $y$, and $a$ represent, respectively, the expected encoding, comparison, target present, and target absent process durations (these symbols also are used to label the processes; the meaning will always be clear from the context). Assuming that the target is equally likely to be in any one of the $n$ positions [i.e., $P(F = i) = 1/n$], we find

$$\begin{aligned} E[T(\text{present})] &= \sum_{i=1}^{n} \frac{ie + ic + y}{n} \\ &= \frac{(n+1)(e+c)}{2} + y \end{aligned} \qquad (5)$$

The expected time to scan the display when the target is absent is simply $E[T(\text{absent})] = n(e + c) + a$. We can rewrite the expected time to scan the display when the target is present and absent as a linear function of the number of items in the display, as indicated by

$$\begin{aligned} E[T(\text{present})] &= y + \frac{e+c}{2} + \frac{(e+c)n}{2} \\ E[T(\text{absent})] &= a + (e+c)n \end{aligned} \qquad (6)$$

Note that the slope, $(e + c)/2$, of the linear function relating the expected target present response time to the number of stimuli in the display is half the size of the slope, $e + c$, relating the expected target absent response time to the number of stimuli in the display. This is just one of many examples where a mathematical model makes predictions that can easily be tested with actual data. Also note that as long as the assumption that the target is equally likely to be in any one of the $n$ positions on each scan is valid, it matters not in what order or orders the stimuli are scanned.

***Applications: Menu Hierarchies*** In the introduction to this chapter, we explained the role that mathematical models and optimization techniques can play in the design process by referring to the construction of the optimal menu hierarchy for an ATM. We now continue this discussion, specifying here and in detail the exact quantitative procedures that one can use to design the optimal menu hierarchy, not for an ATM, but for a PC. Users today interact with menu hierarchies constantly, whether on their cell phones, at their ATMs, or on their computers at home and at work. Regardless of the technology, it is still the case that the underlying structure of the menu hierarchy has a large impact on the time it takes users to access information at the terminal

nodes. It has been shown that, given some very simple assumptions, one can identify the structure of a particular hierarchy that minimizes the average time it takes unfamiliar users to access the information in that hierarchy (modeling the search behavior of familiar users requires a different set of assumptions). There are two cases. In the first case, the number of menus at each level in the hierarchy is equal to twice the number in the superordinate level, and the number of options in each menu is identical across all menus (Lee and MacGregor, 1985). In the second case, there are no constraints on the initial structure of the hierarchy (Fisher et al., 1990). It is the second case that we consider here.

Suppose that users scan serially through the options in a menu, stopping when they identify the option that leads them to the appropriate next level. Then, it is easy enough to derive expressions for how long on average it will take users to identify a terminal option. What is not so obvious is what alternative structures one should consider. For example, take the menu in Figure 4a. Call this the *seed hierarchy*. It is the menu that a design team might produce, one that is most detailed. Five menus are labeled, beginning at the top, M(1,1), and so on. There are two options in each of the five menus. For example, in menu M(2,1) there are two options, options 3 and 4. There are three *terminal menus*, M(3,1), M(3,2), and M(2,2), and six *terminal options* (7, 8, 9, 10, 5, and 6) in these menus. Ideally, one would like to examine the complete space of semantically well-defined hierarchies that can lead to the retrieval of information from the six terminal options. However, there is currently no way automatically of generating all such semantically well-defined hierarchies. Still, it is possible to identify a large subset of the semantically well-defined hierarchies. Specifically, suppose that a *nested hierarchy* is defined as one that is formed from the seed hierarchy by replacing one or more options in a menu with all of the terminal options that come beneath it. Examples include the nested hierarchies in Figures 4b and c. There are six nested hierarchies that can be formed from the one seed hierarchy. In a slightly more complex example, assume that there are 64 terminal options, 2 options in the top-level menu, 2 options in each of the second-level menus, and so on, down to the 64 terminal options in each of the 32 sixth-level menus. Then it can easily be shown that there are over 1 million different nested hierarchies, each semantically well defined. Experimentally, it would be impossible to search this space exhaustively. However, a recursive algorithm can easily be implemented which identifies the hierarchy that minimizes the expected terminal option access time (Fisher et al., 1990). It is an example of the application of dynamic programming, one of the optimization techniques to which reference was made earlier.

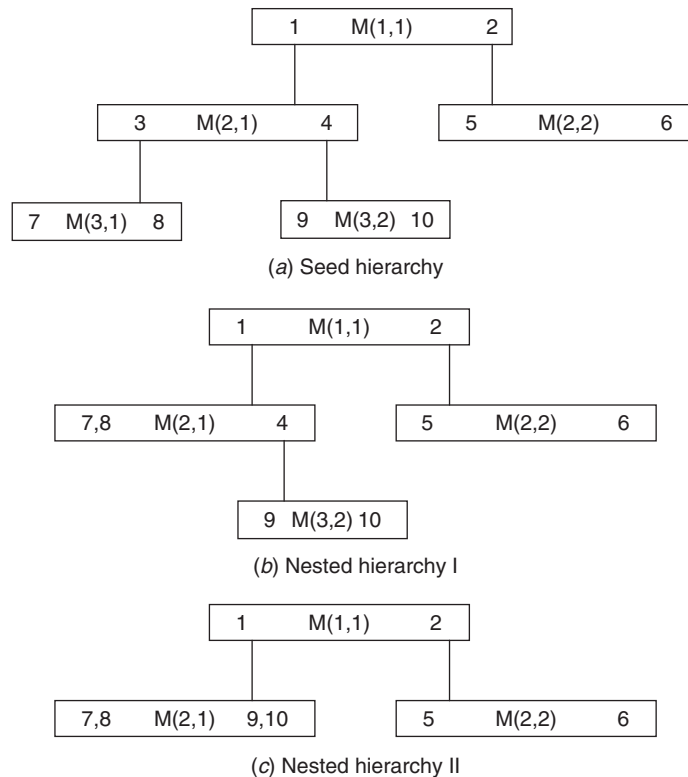
Very briefly, the time on average that it takes to find a terminal option from a nonterminal menu can be written recursively as the time on average that it takes to find the option in the current menu that leads to the terminal option plus a probability mixture of the time on average it takes to find the terminal option from each of the menus that can be reached from the current menu.


**Figure 4** Menu hierarchy.

This recursive formula is then implemented in computer code. Each menu in the hierarchy is represented on the computer as a node in a linked list, with the link from each option in a menu pointing to the menu which can be reached from that option. To search the entire space of nested hierarchies, one compares the time on average it takes to reach a terminal option from the current menu in the seed hierarchy with the time on average that it takes to reach a terminal option when all terminal options are nested in the current menu. If the time on average it takes to reach the terminal option from the current menu with the nested terminal options is shorter than the time on average that it takes to reach the terminal option with the options left unnested, one can replace the seed hierarchy with the nested hierarchy so constructed. In this way, the search space is reduced dramatically. Here is an example where optimization techniques, not just mathematical models, play a critical role in the design process.

### 3.2 Memory Search

In a memory search task, a participant is given a list of stimuli to memorize (say, four digits). The number of digits in the memory set is referred to as the *memory set size*. After memorizing the digits, the experimental trial begins. A probe digit is then displayed. The participant must indicate whether the probe is in the memory

set. Response time is graphed as a function of the memory set size. The best fitting lines relating the response times to memory set size for the case where the target is and is not present are often roughly parallel. The serial, self-terminating model cannot easily explain such parallelism, as can easily be seen from equation (6), if, among other things, the assumption that the distributions of the process durations associated with each item in the memory set do not depend on the identity of the item is generalized across memory sets of different sizes. However, a serial, exhaustive model can easily explain the parallelism (Sternberg, 1966, 1975; Townsend, 1972). Note that in memory search, unlike visual search, only the probe digit needs to be encoded since all of the items in the memory set have already been encoded. Thus, the formula for memory search will include only one encoding.

This might be seen as the rather tidy end to the puzzle of how it is that items in memory are scanned. However, the resolution depends on a number of critical assumptions, one of which, as we just stated, is that the distributions of the first and second comparison times in the serial, self-terminating model are identical. To see that this assumption is required, we need to refer to OP diagrams again and show that a parallel exhaustive model can mimic a serial, self-terminating one. The parallel exhaustive model is represented in Figure 5. To begin, imagine that there are two items in the memory
**Figure 5** OP diagram: memory search.

set and one target on the screen that matches one of the items in the memory set. Then the target is first encoded (state $s_1$ in Figure 5). If the search were a parallel exhaustive one, the two items in the memory set could be compared in parallel with the target ($s_2$). In this example, let $c_i$ represent the comparison time of the $i$th memory set item with the target. If $c_1$ finished before $c_2$, execution of $c_2$ would continue by itself ($s_3$), and finally, the participant would respond ($s_5$). Alternatively, if $c_2$ finished before $c_1$, execution of $c_1$ would continue by itself ($s_4$) and again the participant would respond ($s_5$). Note that because the search is exhaustive, both items in the memory set need to be compared before the response is executed. The rather surprising finding here (Townsend, 1972) is that the expected response time with this parallel, exhaustive model can mimic the expected response time with a serial, self-terminating model. To see this, imagine a serial, self-terminating model where the first comparison is relatively fast (the system is not fatigued) and the second is relatively slow. In particular, the distribution of the first comparison time in the serial, self-terminating model is equal to the distribution of the time spent in state $s_2$ and the distribution of the comparison time of the second (first) stimulus in memory with the target when it is processed last is equal to the distribution of the time spent in state $s_3(s_4)$. Finally, imagine that in the serial, self-terminating model the probability that the comparison of the target with the second item in memory occurs after the comparison of the target with the first item in memory is equal to this same probability in the parallel, exhaustive model (i.e., the probability of the path represented by the transition from $s_2$ to $s_3$). Then the expected response times of the parallel, exhaustive and serial, self-terminating models will be identical. Fortunately, more detailed tests exist which can resolve the mimicking (Schweickert, 1978; Townsend and Wenger, 2004). This example very nicely points out the importance of quantifying models wherever possible, thereby reducing needless testing or exploration of alternatives that turn out not to be identifiably different.

***Application: Toxicology*** One of the more elucidating applications of memory search models was developed by Smith and Langolf (1981). They asked a simple question: Could low levels of mercury exposure produce effects on the speed of processing in people who were otherwise asymptomatic? To test this hypothesis,

they had chlor-alkali workers who had been exposed to different levels of mercury perform a simple memory search task, estimating for each person the comparison time (among other quantities). They then regressed the estimated comparison time for each person on the corresponding level of exposure of that person to mercury. There were significant effects of the mercury level on comparison times. From a practical standpoint, the most heavily exposed workers had an increase of 100% in their scanning times, suggesting a serious reduction in short-term memory capacity (Baddeley, 1992). Interestingly, this model developed for purely theoretical purposes has become some 30 years later a useful tool for uncovering neurobehavioral toxicity (Fiedler et al., 1996).

## 4 VIGILANCE

When signals occur rarely, a common finding is that observers tend to miss more signals after some time on task. This is called a *vigilance decrement*. Often, there is a decrease in false alarms as well; that is, there is a decline in the total number of reports of a signal, correct or incorrect [see Davies and Parasuraman (1982) and See et al. (1995) for reviews]. It is natural to use signal detection theory to determine whether, as time goes by, observers become less sensitive to signals, or less prone to say "signal," or both. Results are complicated, but as a rough guide, Parasuraman and Davies (1977) found that sensitivity (measured, e.g., by $d'$) tends to decline when one stimulus occurs at a time (so identification relies on memory) and stimuli occur relatively frequently. The criterion (measured, e.g., by $x_c$ or $\beta$) tends to increase when stimuli are presented simultaneously (in a same or different task) or stimuli occur rarely.

As described earlier, one reason that signal detection theory is useful is that it divides the observer's processing into encoding and decision and provides separate measures characterizing each, $d'$ and $\beta$. Variables such as the probability of a signal are predicted, and often found in data, to significantly change the value of the decision parameter $\beta$, which represents the observer's choice of where to put the criterion, but not to significantly change the value of the encoding parameter $d'$, which represents the observer's sensitivity to the signal. However, it is readily acknowledged that the assumptions underlying the calculation and interpretation of $d'$ and $\beta$ are not met exactly.

To investigate alternatives, See et al. (1997) compared the performance in vigilance tasks of two measures of sensitivity and five measures of response bias, with an emphasis on the latter. [For the formulas, see See et al. (1997).] The two measures of sensitivity were the parametric $d'$, which was discussed above, and a widely used nonparametric analog, $A'$. The authors report that the two measures were functionally equivalent. They were highly correlated over subjects, each declined with time on task, and neither was influenced by signal probability or payoff scheme, factors thought to influence the response bias rather than the sensitivity. Thus, $d'$ seemed to function as expected.

However, such was not the case for response bias. For response bias, two parametric measures $\beta$ and $c$, and three nonparametric measures, $B'$, $B'_H$, and $B''_D$, were compared. The authors report that $\beta$ did not perform well; in particular, it was the least sensitive measure to signal probability and payoff scheme. The best performing measure was $c$ (Ingham, 1970),

$$c = \frac{x_c - (\mu_s + \mu_c)/2}{\sigma}$$

(The measure $c$ is the $z$ score for the criterion, $x_c$, but calculated with respect to a mean halfway between the means of the signal and noise distributions.) Of the nonparametric measures, the best performing was $B''_D$ (Donaldson, 1992),

$$B''_D = \frac{(1 - H)(1 - F) - HF}{(1 - H)(1 - F) + HF}$$

where $H$ is the probability of a hit and $F$ is the probability of a false alarm. Both $c$ and $B''_D$ were sensitive to signal probability and payoff scheme, both indicated a predicted change in bias over time, and both functioned well even when performance was at chance level. The data of See et al. (1997) satisfied a test for normal distributions with equal variance, and it would be useful to know whether their conclusions hold in other situations.

Balakrishnan (1998a,b) has argued that violations of assumptions underlying use of parameters $d'$ and $\beta$ could be causing misleading interpretations of data, but these pass unnoticed because of the apparent robustness of the measures under signal probability or payoff manipulations. Signal detection theory assumes that the distributions of activation produced by a signal or by noise are not influenced by the probability of a signal. This may be true for the distribution of a single sampled amount of neural activity, such as when signals are rare. But neural activation may be extended over locations and over time when signals are frequent. In this case, the observer may sample several amounts of activation. The probability distribution of a sample depends on the sample size. Hence, a change in the amount of activation sampled would be a change in encoding produced by a variable (the probability of a signal) thought to influence only the decision. (Note that if several samples are taken and the results combined to produce a better decision, we have moved from a data-limited to a resource-limited task. How the data are combined determines how the discriminability changes with the number of samples, or more generally with the time over which samples are taken. This would be another example of a speed–accuracy trade-off.) Whether this change is registered as a change in $d'$ or $\beta$ or both would depend on the forms of the underlying distributions and the way the size of the sample of observations is determined. To avoid such problems, Balakrishnan (1998a) proposed that distribution-free measures of response bias be used, and he developed new measures based on confidence ratings. Analysts using signal detection theory often ask observers to give a number indicating their confidence that a particular stimulus was a signal or noise. For example, response 1 would indicate very low confidence that the stimulus was a signal, and response 8 would indicate very high confidence that the stimulus was a signal. Note that with this procedure the analyst does not know what the observer would actually say if asked whether the stimulus was signal or noise. Balakrishnan proposed modifying the procedure slightly, so the observer produces a judgment about signal or noise together with a confidence rating that the judgment is correct. For example, response 1 would indicate a judgment of noise with very high confidence, and response 5 would indicate a judgment of noise with very low confidence. Similarly, response 6 would indicate a judgment of signal with very low confidence, and response 10 would indicate a judgment of signal with very high confidence.

The modified procedure leads to Balakrishnan's (1998a) distribution-free measures of response bias. An overall measure of bias is $\Omega$, the total of the amount of bias at each rating having a bias (not all ratings have a bias). For example, suppose that the rating 5 stands for "with low confidence, the stimulus is noise" and the rating 6 stands for "with low confidence, the stimulus is signal." For simplicity, suppose that the probability of signal equals the probability of noise equals $\frac{1}{2}$. Suppose that when 5 is used, three-fourths of the time it is used for noise and one-fourth of the time it is used for signal. Then there is no bias at rating 5. It is intended to indicate noise, and it usually does. It contributes nothing to $\Omega$. But suppose that when 5 is used, one-fourth of the time it is used for noise and three-fourths of the time it is used for signal. Then there is a bias at rating 5. It contributes to $\Omega$. Again, $\Omega$ is summed over only those ratings that have bias.

The amount of bias at rating 5, when it has a bias, is the total proportion of trials for which the rating 5 was used. Suppose that there were 200 noise trials and 200 signal trials, 400 total. Suppose that rating 5 was used 6 times for noise stimuli and 30 times for signal stimuli. The amount of bias contributed by rating 5 is $36/400 = 0.09$. An overall measure of bias is $\Omega$, the total of the amount of bias at each rating having a bias.

Using the measure of bias $\Omega$ in a vigilance task, Balakrishnan (1998b) found no evidence of bias in the decision rule for either relatively frequent or relatively rare signals (i.e., values of $\Omega$ were close to zero for probability of a signal 0.5 and 0.1). On the other hand, there was evidence for increased sensitivity for more frequent signals, indicated by increased $A'$. In other words, signal frequency appears to influence the encoding rather than the decision, the opposite of the usual signal detection theory interpretation. The performance measures themselves do not indicate how the processing was done, but Balakrishnan points out that the results are consistent with models in which the subject samples repeatedly from the stimulus, rather than just once. For rare signals the hypothesis of equal variances for signal and noise distributions can be rejected for the data of Balakrishnan (1998b). Instead, the variance is large for rare signals. For a critique of the

approach of Balakrishnan, see Mueller and Weidemann (2008).

***Application: Inspection Tasks II*** In any particular application, the payoffs are maximized when the criterion is set as indicated in equation (3) provided that the assumptions of signal detection theory are met. If the assumptions are met, then to improve performance, one would train observers to locate their criteria appropriately. However, if, contrary to assumption, signal frequency influences encoding by changing the size of the sample the observer takes from the stimulus, then to improve performance, training would emphasize taking time for adequate observation of the stimuli.

## 5 INSPECTION

Whether unaided manual or partially or fully automated, test and inspection tasks abound. The most obvious examples are from manufacturing quality control with products ranging in complexity from apples to Apple computers. Other examples come from checkout procedures in spacecraft, from aircraft structural inspection, from airport security, and even from inspection of restaurants for compliance with hygiene regulations. What these inspection examples have in common is that their input is an item whose state is unknown (apple, restaurant) and their output is the same item whose state has been determined. Unfortunately, not all state determinations are perfect: there are inspection errors, as noted in Section 2.2. In the current section, our interest is in mathematical models of inspection and their use in performance optimization. For a chapter length treatment of test and inspection, see Drury (2001).

As with any modeling activity the starting point should be a task analysis (see Section 2.1). Many detailed task analyses of inspection have been performed, resulting in a generic function-level model (e.g., Drury, 2001): initiate, present, search, decision, and response. Task analyses of specific inspection tasks go much deeper than this to provide insights and best practices (e.g., Drury, 1999). Here, however, we restrict ourselves to what are usually seen as the most difficult functions: search and decision. These are often the functions having the lowest reliability (Drury et al., 1997) and taking the greatest time to complete. Each has several useful mathematical models (e.g., visual search theory, Section 3.1) and opportunities for optimization making them appropriate instances for the current chapter. In addition, the models can be combined to give a more integrated view of the entire inspection task and can be used where parts of the task are automated. Both of these extensions are considered after models of search and decision are given individually in the context of inspection tasks.

### 5.1 Visual and Memory Search: Alternative Model

The visual search networks in Section 3.1 were developed to model rapid search processes, where each distracter is compared with the target (or target set) until a match is found. In contrast, inspection tasks often involve large and complex objects (e.g., circuit boards or aircraft internal structures) when the search process takes place much more slowly (many seconds or even minutes) and there are no distracters as such, just other elements that may or may not have a defect (e.g., an IC chip placed backward or a crack in aircraft structure). Here a model of search as a sequence of eye fixations appears more appropriate. Such models have existed for many years and are based on the following facts:

1. Visual information is available only when the eye is stationary or tracking a moving object. These fixations typically take between 0.2 and 1.0 s and the rapid saccadic movements between fixations preclude visual information intake.

2. In a single fixation, the probability of detecting a target falls off with the angle between the target and the optic axis. This means that a target is detectable only (with a given probability) in an area around the optic axis known as the *visual lobe*. Note that the visual lobe is not the fovea: Lobe size depends on target–background contrast and can range from subfoveal size for very difficult targets to almost the entire visual field of view for extremely easy targets.

A major preoccupation of visual search modelers has been how successive fixations are chosen from the visual field to perform the search task. The general consensus is that the fixation sequence arises partly from top-down factors (e.g., a predetermined search sequence based on the inspector's experience) and partly from bottom-up factors (e.g., a potential target at the periphery of vision, leading the next saccade to fixate that point). Models of this type are available (e.g., Wolfe, 1994).

If we treat the bottom-up information as essentially an "end game" to confirm a target, the top-down aspect has typically been modeled as either a random process or a systematic process (Morawski et al., 1980). A random process is characterized as having no memory for previous fixations, while a systematic process assumes perfect memory. In fact, a more general model of partial memory was devised by Arani et al. (1984), with the random and systematic models as special cases. They showed that memory has to be almost perfect to invalidate a random model, collaborating many studies that have fitted both models to the data and found adequate fits for the random model.

The random model assumes that each fixation $i$ is chosen randomly from a set of possible fixations (i.e., sampling with replacement). From this model it is easy to derive the cumulative search time distribution [i.e., the probability $P(t)$ that the target will be located at or before time $t$] as

$$P(t) = 1 - e^{-\lambda t}$$

Here, the parameter $\lambda$ is a constant incorporating lobe size and fixation duration information. In fact, both the mean and the standard deviation of this exponential
**Figure 6**  Cumulative probability distribution of a random model.

distribution are equal to $1/\lambda$. If the model is valid (and it typically is), a useful deduction from the model is that the time to detect a target will be extremely variable. A typical cumulative probability distribution of a random model is shown in Figure 6.

Note that the process has diminishing returns in that the expected gain from continued search decreases. This is the basis for an optimization model of stopping time in search. The model was developed first in Tsao et al. (1979) and developed much more fully in Chi and Drury (1998). If the value of detecting a target is $v$, the probability of an item having a target is $p$, and the cost of a unit of inspection time is $k$, we can find the three outcomes of a search task with the probability and value of each: (1) the target is present and found, (2) the target is present and not found, and (3) the target is not present. No false alarm is logically possible for a search task: Either the target is found or it is not. That is not to say that false alarms do not occur occasionally in searches, rather that the stopping models assume that the search terminates with a target detection or a failure to detect. If we multiply probability by value and sum over all outcomes, we have the expected value of the search task. This gives, after simplification,

$$\text{value expected} = -kt + vp(1 - e^{-\lambda t})$$

Setting the first derivative with respect to $t$ at zero to maximize expected value gives

$$k = vp\lambda e^{-\lambda t_{\text{opt}}} \qquad t_{\text{opt}} = \frac{1}{\lambda} \ln \frac{\lambda vp}{k}$$

Note that $t_{\text{opt}}$ increases when $p$ is high, $v$ is high, and $k$ is low. Thus, a longer time should be spent inspecting each area where (1) there is a greater prior probability of a defect, (2) there is a greater value to finding a defect, and (3) there is a lower cost of the inspection.

This describes a possible optimum behavior in a search task where a single target can occur. It has been verified by Drury and Chi (1995) as a reasonable model of actual inspection behavior. For a slightly different model, where the operator covers the search field in overlapping fixations, an equivalent optimization model was devised by Bavejo et al. (1996). That model described human field-of-view movements rather than the (untested) eye movements very well.

Extensions have been made to search models to cover multiple instances of a target (Drury and Hong, 2000) and multiple instances of multiple target types (Hong and Drury, 2002). Our optimization model of search can also be applied to multiple targets of the same or different types. Hong (2002) derived and validated such a model against human search time data with good results.

### 5.2  Decision Model: SDT Revisited

After completing the search function, the inspector will now have either (1) not found a target, in which case the item is by definition good, or (2) have found one (or even more than one) target that needs to be assessed for acceptance or rejection against a standard. The decision process (2) thus arises only when a potential target (an *indication* in nondestructive inspection terminology) has been found. At this point, any model that has two states of the item (defect, no defect) and two decision outcomes (accept, reject) is appropriate. SDT (Section 2.2) certainly meets this criterion and has a long history of application to inspection tasks. For example, Drury and Addison (1973) found that increased feedback in a glass inspection task raised the discriminability $d'$, and the benefit persisted over many months of measurement. In the 1970s and 1980s it became quite fashionable to apply SDT to inspection: for example, the studies reported in the book by Drury and Fox (1975). Legitimate warnings were raised about the use of a parametric form of SDT: for example, the assumption of normal distributions of equal variance (Megaw, 1979).

Optimization aspects of the SDT model, for example, the choice of optimum criterion $\beta_{\text{opt}}$, are directly testable. In noninspection decision tasks, the general finding is that $\beta_{\text{opt}}$ does not change as rapidly as it should with changes in the cost−value structure or changes in the a

priori probability of a defect. This has become known as the *sluggish beta* phenomenon. It arises if the decision maker does not take all of the available information into account in reaching a decision (i.e., the human as a degraded optimizer). This really calls into question whether any model of the human as a maximizer of expected value has any validity and eventually led to much more general models of the human as a satisficer rather than an optimizer, most famously the model of Newell and Simon (1972). However, if we treat the human as a degraded optimizer in the decision aspects of an inspection task (Chi and Drury, 2001), reasonable agreement with performance data is found. The warning is raised, however, that people may not be optimizers in the mathematically strict sense in inspection decisions, perhaps because they do not deal well with low-probability events (e.g., finding a bomb in an airline passenger's bag) or large costs (e.g., the tragedy of losing an airline to terrorism).

### 5.3 Reintegration of Search and Decision

Inspection tasks typically include both search and decision components. For example, Drury (2002) showed that a single unified model (essentially the generic functions, initiate, present, search, decision, and response, listed above) described all of the various airport security inspection processes. Some processes have no search (e.g., listening to a car engine for a loose tappet), whereas some have no decision (e.g., inspection of jet engine hubs for cracks where any crack must cause rejection). These are, however, the exception. The integration of models such as visual search and SDT involves issues beyond each individual model.

An early integration example was by Drury (1973), who collected many studies of the "speed effect" in inspection [i.e., the speed–accuracy trade-off (SATO)]. With visual search following a random cumulative model [e.g., equation (5)] and SDT providing the ultimate levels of type 1 and type 2 errors when search is complete, the SATO model shows the probability of a hit increasing over time with diminishing returns to reach some ultimate value less than 1.0. The probability of a false alarm for this model starts at zero for very short inspection times and gradually increases with inspection time, leveling at a different value. This model fitted much of the available SATO data and was interpreted as evidence for a search-plus-decision model. Later, Chi and Drury (2001) tested optimization aspects of this model against human performance in a task of inspecting circuit boards, again finding good agreement.

The second use of an integrated model is in diagnosis of inspection error. At its simplest the search-plus-decision model shows that search alone cannot produce false alarms. Hence, if there is only a search process, false alarms are logically excluded, and in practice will be extremely rare, as was shown to be the case by Drury and Forsman (1996). Where both search and decision occur, it is possible to separate the errors from the two functions with some additional effort. In a task of inspecting jet engine bearings, Drury and Sinclair (1983) used the fact that search was visual whereas decision was tactile to differentiate between search errors and decision errors. They found that search performance was poor but consistent across inspectors, whereas decision performance varied widely among inspectors. Their analysis led to the development of a successful training–retraining program for these inspectors (Drury and Kleiner, 1990). In another study of aircraft structural inspection, Drury et al. (1997) were able to use videotape analysis to separate the two functions, with findings very similar to those of Drury and Sinclair.

Finally, an integration of the two models has implications for analysis of the results of all inspection tasks. When SDT was first used for vigilance tasks, search was not recognized. However, many of the misses in inspection arise from the search process, not from a bias toward acceptance in the decision process. Hence, interpreting overall inspection results in terms of SDT is erroneous unless no search is involved. This is what Wiener (1975) called *jumping off the d-prime end*, and it is a legitimate criticism of early inspection modeling work (e.g., Drury and Addison, 1973). Unfortunately, this misinterpretation still happens. Again, the moral is that there is nothing as valuable as a good model or as misleading as an inappropriate model.

***Application: Automated Inspection*** If we can model the human inspector with reasonable success, how can we extend this modeling to situations where human and automation perform inspection tasks jointly? There are now excellent automated alternatives to some aspects of inspection; see, for example, the detailed review in Drury (2000). How can we incorporate human and automation models into overall inspection models to derive appropriate levels of automation (cf. Parasuraman et al., 2000)? Part of the problem is that most papers on automated inspection denigrate human roles, emphasize the wonders of algorithms, and often provide data only on probability of detection, ignoring false alarms.

The most obvious first step to explain the integration of human and automated inspection is to compare their relative merits directly. Drury and Sinclair (1983) examined an automated system for jet engine bearing inspection using the same measures of performance as were used for human inspectors, in this case ROC curves. Their conclusion was that neither human nor automation was particularly effective, leading to recommendations to improve the automated system and to the subsequent human training program (Drury and Kleiner, 1990).

A more comprehensive step was taken by Hou et al. (1993), who examined search and decision separately for human and automation. They use an SDT measure of discriminability (*A*) as well as inspection speed to compare human and algorithmic alternatives for each function. Their conclusion was that both purely automated systems, as well as the unaided manual system, were inferior to hybrid human–algorithm systems for circuit board inspection. We may be able to compare different human and automation hybrids by direct measurement, but true a priori allocation of function will come only when we can predict from models of the alternatives which hybrid systems to build and test.

## 6 DUAL TASKS

We have been describing tasks in which a person makes just one response in a given situation, that response depending on the stimulus ensemble presented to the person. However, the real world sometimes provides much more challenging situations. For example, suppose that a sign tells a driver to change lanes and then a car cuts in front. The responses are to turn and to brake. Typically, the time to respond to the second stimulus is greater than it would be if it had been presented alone. This and many other findings can be explained by a model of *dual-task* performance originally proposed by Davis (1957) and studied extensively since (e.g., McCann and Johnston, 1992; Pashler, 1998).

The model is in Figure 7. Stimulus $s_1$ is presented, followed after a brief interval by stimulus $s_2$, with required responses $r_1$ and $r_2$, respectively. Each stimulus requires perceptual processing, denoted $a_1$ or $a_2$ as appropriate, cognitive processing, denoted $b_1$ or $b_2$, and motor preparation processing, denoted $c_1$ or $c_2$. The interval between the stimuli is denoted SOA (stimulus-onset asynchrony). Perceptual and motor processing of either stimulus can go on concurrently with any other processing. But cognitive processing (response selection) for the two stimuli is sequential, so process $b_1$ must be completed before process $b_2$ can start. The delay in responding to the second stimulus is due to $b_2$ waiting for $b_1$ to finish.

Clearly from the bar chart in Figure 7 the processes can be represented as activities in a critical-path network. Knowledge of the activity arrangement can be obtained by selectively influencing activities (Schweickert, 1978; Schweickert, Fisher and Sung, in press) using the method of task network inference discussed earlier. Analysis of selective influence for this particular model is sometimes called *locus-of-slack logic* (e.g., McCann and Johnston, 1992). Much is known about where factors such as stimulus quality, display size, arithmetic difficulty, and so on, have their effects. For example, in a dual task by Johnston and McCann (2006), the first stimulus was a tone to be judged as higher or lower than a reference tone. The second stimulus was a trapezoid representing a runway. Its angle was to be judged as higher or lower than that of a reference trapezoid presented shortly earlier (corresponding to a judgment about approach to the "runway"). If the tone judgment was difficult, the time to respond to the trapezoid increased. Data indicated that tone judgment and trapezoid judgment were at locations $b_1$ and $b_2$, respectively, in the model. For reviews and critiques
of the model, see Pashler (1998), Logan (2002), and Townsend and Wenger (2004). The model assumes only one response selection process goes on at a time, and it is worth considering why. The two major models of response selection are accumulators and random walks. With each, a stimulus is presumed to transmit information over time. Incoming information is classified as favoring one of the possible responses. In an accumulator, information favoring a response increases the activation of that response. In a random walk, information favoring a response increases the net activation of that response and decreases the net activation of every other response. In both models, for each response a criterion has been set. As soon as the activation for some response reaches its criterion, that response is made.

For a given stimulus, every possible response is made with some probability and there is a probability that no response is made. The behavioral data consist of those probabilities, together with the probability distributions of the response times. It is helpful to realize that an accumulator model can always be constructed to account perfectly for the behavioral data (Dzhafarov, 1993). Hence, more import than goodness of fit is whether experimental factors can be explained coherently. On the whole, results are as one would expect; for example, stimulus quality ordinarily influences the rate at which activation increases and payoffs ordinarily influence criterion values. For a review, see Luce (1986).

A single neuron begins firing when the algebraic sum of the excitation and inhibition reaching it exceeds a threshold, so neural resources needed for an accumulator or a random walk in itself seem small. But with either an accumulator or a random walk, the system must be set by (1) selecting possible responses, (2) forming temporary associations between anticipated incoming bits of information and the responses they favor for the situation, and (3) setting the values of the response criteria. The resources for assembling and maintaining the settings may be considerable. Although evidence is indirect, there is growing opinion that the settings constrain only one decision to be made at a time

Many have considered whether two response selection processes can go on concurrently, at least sometimes. In the EPIC model (Meyer and Kieras, 1997a,b) a person has the option of executing two response selection processes concurrently and without interference. Most models allowing concurrent response selection assume that it is slower when concurrent (e.g., Navon and Miller, 2002; Tombu and Jolicoeur, 2003).

### Application: Scheduling Stimulus Presentations

For designing displays, one useful finding is that a delay in the onset of a second stimulus need not delay the response to the second stimulus or might only delay it by a small amount (e.g., Smith, 1969). In other words, the perceptual processing of the second stimulus may not be on the critical path to the second response and so may have slack. It is also useful to note that there is evidence that humans are able to control the order of the cognitive processes; that is, they can control whether $b_1$ is executed before $b_2$ or vice versa (Ehrenstein et al., 1997).

**Figure 7** Dual-processing network.

There is a relevant finding from scheduling theory. Suppose an activity is faster when executed alone than when executed concurrently with another activity, and the goal is to minimize the average of the times at which each task is finished with respect to the same time-zero starting point. The optimal schedule is usually to allocate all the capacity to one activity and then allocate it all to the other activity (i.e., to schedule the activities sequentially rather than concurrently) (Conway et al., 1967). To see this, suppose that activities *a* and *b* each take one unit of time if executed alone and two units of time if executed concurrently. Suppose that they are both ready to start at time zero. The average of their completion times with respect to a time-zero starting point is 1.5 if they are sequential and 2 if they are concurrent. In other words, humans may schedule response selection processes sequentially not because they must but because it is optimal.

If there is a choice as to when to display stimuli, having the second stimulus appear early would seem to do no harm and may be helpful. There are two potential problems with such a procedure. First, as soon as a stimulus is presented, irrelevant information from it may be sent to processes for the other stimulus (crosstalk) (see, e.g., Hommel, 1998). This may lead to increased response times and errors. Second, presenting the stimuli close together in time may lead to parallel processing, which can be more inefficient if, as noted above, the goal is to minimize the average completion time of two processes measured from the same starting point.

## 7 PSYCHOMOTOR PROCESSES

As noted above, processing time in a task can roughly be categorized as perceptual, cognitive, and motor, and the largest of these is often motor time. The study of movement is interdisciplinary, but as with sensation, the physics of the system is an integral part of the modeling. For an introduction to models, see Jagacinski and Flach (2003), and for a discussion of controversies, see *Controversies in Neuroscience, I: Movement Control* (Editors, 1992).

One of the simplest models to lead to a reasonable approximation of human movement is the mass, spring, and damper in Figure 8 [see Crossman and Goodeve (1963) for an early presentation]. A force $F(t)$ is applied over time by an agonist muscle to a limb of mass $m$. A restoring force is produced by an antagonist muscle represented by a spring. (The agonist could be represented by a spring as well.) Another force is damping due, say, to friction from sliding across a mouse pad or to an internal source such as the antagonist muscle itself or a joint. (The damper is illustrated as a piston in a cylinder filled with oil.) We consider a horizontal movement rather than a rotation through an angle; an analysis of a rotation would not be very different.

Let the position of the limb at time $t$ be $x$, with position zero at time zero. By Hooke's law, the spring produces a force proportional to its displacement from its equilibrium position, $q$. The direction of the force

**Figure 8** Mass, spring, and damper.

depends on whether the spring is stretched or contracted. The direction is opposite to the direction of the spring's displacement from its equilibrium position, so the force due to the spring is $-k(x - q)$. Note that if the agonist is represented by a spring-producing force $-k_1(x - q_1)$ and the antagonist is represented by a spring-producing force $-k_2(x - q_2)$, the sum of the two forces is $-(k_1 + k_2)[x - (k_1 q_1 + k_2 q_2)/(k_1 + k_2)]$. That is, the model with two springs can be replaced by an equivalent model with a single spring. The force due to the damper is proportional to the velocity but in direction opposite to it, that is, $-bd\,x(t)/dt$. By Newton's second law, the sum of all the forces equals the mass times the acceleration. That is,

$$m\frac{d^2x}{dt^2} = F(t) - k(x - q) - \frac{bdx}{dt} \qquad (7)$$

where $F(t)$ is the force applied by the agonist muscle and $-k(x - q)$ is the force applied by the antagonist muscle. Most movements are more complicated, and the model would include components such as gravity and multiple joints.

A model of motion is useful not only for describing the motion but also for considering how the motion is controlled. For optimal control (i.e., producing an input that maximizes some objective function), general principles are found, for example, in Kirk (1970) and Hogan (1988). For biological systems, two main ways of controlling a movement have been proposed. Suppose that the goal is to produce a position $A$ of the limb. The first way is for the system to estimate and then apply the force $F(t)$ needed to produce position $A$. The second way is not ordinarily available in a physical system, where the characteristics of the spring and damper are fixed. But in a biological system the stiffness

and other features of the muscles can be changed. Hence, to produce movement, the equilibrium position of the spring can be set directly to that needed to produce the limb position goal (Feldman, 1966). With both methods, later corrections can be made based on feedback, although these are more often considered with the first method.

To be useful, a model must produce known findings about human movement. One of the main results is Fitts's law. Suppose that a person moves a limb to a target of width $W$ centered at a distance $A$ away from the starting position. The time to make the movement is well approximated by

$$MT = c + d \log_2 \frac{2A}{W} \tag{8}$$

where $c$ and $d$ are free parameters (Fitts, 1954). The quantity $\log_2(2A/W)$ is called the *index of difficulty*. The relation was first fit to data for people moving a stylus back and forth continually between two targets, each of width $W$, with the centers of the targets separated by distance $A$. But it fits well for many other situations, for example, for moving a finger to a calculator button or a mouse pointer to a target (Card et al., 1983).

The simple mass, spring, and damper model leads to Fitts's law approximately when a force is applied to the limb (Langolf et al., 1976; for review, see Jagacinski and Flach, 2003). We illustrate the method of presetting the equilibrium position by giving a similar derivation leading to Fitts's law as an approximation for short movement times. Suppose the goal is to move the limb from starting position zero to position $A$. With this method of control, the force $F(t)$ in equation (7) is zero. Then the solution to equation (7) is (e.g., Resnick and Halliday, 1963)

$$x - q = Ce^{-bt/2m} \cos(\omega' t + \delta)$$

where $\omega' = \sqrt{k/m - (b/2m)^2}$, and $C$ and $\delta$ are parameters depending on the initial conditions. It is straightforward to check that this is a solution by taking first and second derivatives. When the motion is bounded, all solutions have this form for the underdamped case (when $b$ is small). In that case, the movement is a damped oscillation. Through trigonometric identities, the solution can be expressed in various equivalent ways.

Suppose that at time zero the initial position $x$ is zero and the initial velocity $dx/dt$ is zero. Then it is straightforward to see that $C = -q/\cos \delta$, $\delta$ is the angle whose tangent is $-b/2m\omega'$, and $\cos \delta = \sqrt{1 - b^2/4mk}$.

To set the limb position goal to $A$, set the equilibrium position $q$ to $A$. With these parameters, the position $x$ of the limb at time $t$ is

$$x = A - Ae^{-bt/2m} \frac{\cos(\omega' t + \delta)}{\cos \delta}$$

According to the model, the limb will oscillate, passing back and forth over the target position $A$ and

stopping at it at time infinity. (Oscillations in a movement can often be viewed when moving a mouse pointer to a target on a computer screen.) We are interested in the time at which the limb moves into the target interval and does not leave it. As an approximation, let us say that this happens when the envelope of the oscillations is within the target interval. Consider the lower boundary of the envelope (the result is the same if we consider the upper boundary). It reaches the target interval when

$$A - \frac{W}{2} = A - \frac{Ae - bt/2m}{\cos \delta}$$

Then

$$\frac{W}{2} = \frac{Ae - bt/2m}{\cos \delta}$$

$$\ln \frac{W}{2A} = -\frac{bt}{2m} + \ln(\cos \delta)$$

$$t = \frac{2m}{b} \ln \frac{2A}{W} + \frac{2m}{b} \ln(\cos \delta)$$

The log can be changed from base $e$ to base 2 by multiplying by $\ln 2$, and the result is in the form of Fitts's law.

We mention one more regularity for checking a working model. In the task for which Fitts's law applies, a person is given a target's center position and width and produces a movement time. In a slightly different task, a person is given a target position $A$ and a movement time goal $MT$ and produces a movement to a position. The standard deviation of the movement positions produced, $W_e$, is well approximated by Schmidt's law,

$$W_e = \frac{cMT}{A}$$

where $c$ is a free parameter (Schmidt et al., 1979). The two tasks are similar, as are the two laws, and a model leading to each as a special case has been proposed by Meyer et al. (1990).

The basic mass, spring, and damper model described above fails to predict some aspects of movement accurately (see, e.g., Langolf et al., 1976; Jagacinski et al., 1980), so there are many variations of the basic model. Controlling a movement with a single brief initial step function force predicts movements more asymmetrical than are found in data, and better fits are produced by assuming an initial accelerating force and a final decelerating force (the bang-bang model; see Jagacinski and Flach, 2003). The equilibrium point hypothesis has trouble explaining fast movements. De Lussanet et al. (2002) propose as an improvement controlling the movement by moving the equilibrium point to its goal position at a constant velocity rather than in a jump. Some evidence that the equilibrium point moves is provided in an experiment by Bizzi et al. (1992).

It is difficult to differentiate between the hypothesized methods of control (i.e., control by directly producing forces and control by setting the equilibrium
**Figure 9**  Relation between speed and path width.

point). One difficulty is that when changes in the system are observed, it is difficult to establish that they occurred for the purpose of control. Naturally, for a complicated system, different methods of control are probably used in different situations, as proposed by Schmidt and McGown (1980).

Fitts's law describes terminal aiming tasks, where the path to the target is unimportant but hitting the target at the terminal point of the aiming task is vital. This task is self-paced, and in fact, Fitts's law describes a speed–accuracy trade-off. A rather different form of self-paced movement is a path control task where the operator must move along a path without exceeding lateral boundaries. Examples are walking along a narrow corridor, driving along a narrow road, or even sewing along a seam of fixed width. An early study of line drawing along fixed-width paths (Drury, 1971) derived a model based on the operator as an intermittently acting servomechanism. At any instant, the operator finds himself or herself at some point across the allowed width and must choose how to make an open-loop movement during the next sampling interval. Drury et al. (1987) and Montazer et al. (1989) modeled this task as one of choosing a direction (angle $\theta$ to centerline) and a distance ($R$ in direction $\theta$) for the next movement. They assumed that the objective function was to maximize the distance traveled along the path ($R \cos \theta$) while minimizing the probability of going outside the path boundaries. The constraint set was derived from models of the buildup of lateral error in blind movements (e.g., Beggs and Howarth, 1970). The optimization model gave the same formulation as Drury's original (1971) model, namely

$$\text{speed} = \text{constant} \times \text{path width}$$

The model was derived and validated for movements on straight and circular courses. For very large widths, the speed is limited by other factors, such as a speed limit on a highway, so the linear relationship will eventually flatten out at high widths. Figure 9 shows speed–width relationships found by a number of authors for many different vehicles, including unpublished data on a personal "scooter" with side-by-side wheels. As in other examples, the optimization model provides a good description of performance.

***Application: Manual Assembly***  Many workers perform manual assembly tasks when their hands are located above their shoulders or far out from the sides of their body. Although this is not the preferred location (Konz, 1967), it is still a situation common in the workforce (Wiker et al., 1989). Some such tasks resemble a repetitive Fitts's tapping task. In fact, it has been estimated that anywhere between 40 and 80% of the cycle times in typical manual assembly tasks are due to the move and positioning elements required to perform the task (Arberg, 1963). To study such elements by themselves, Wiker et al. asked subjects to move a tool back and forth, repeatedly, between two holes. The tool was shaped like a small hand drill and contained a stylus that the subject had to position in the center of the hole. In this task it was possible to adjust, among other things, the movement amplitude (the distance between the two holes, let this be labeled $A$), direction (horizontal or vertical), target hole diameter ($2W$), positioning tolerance (the distance $T$ between the outer perimeter of a pin being placed in the center of a round hole and the edge of the hole), task duration, tool mass ($m$, in kilograms), duty cycle (number of repetitions per second, $N$), and hand elevation (height of arm above shoulder height, $E$). Wiker et al. (1989)

found that there was a lawful relation between these factors and the movement and positioning time (MT) [an elaboration of Fitts's law first proposed by Hoffman (1981; cited in Chung, 1983)]:

$$MT(ms)$$
$$= 106 + (68 + 0.015E + 0.00034E \times m \times N)\text{IDM}$$
$$+ (24 + 0.001E \times N)\text{IDP} \qquad (9)$$

where the index of move, IDM, and index of position, IDP, are defined as follows:

$$\text{IDM} = \log_2 \frac{A}{2W} \qquad \text{IDP} = \log_2 \frac{2W}{T}$$

(The relation between equations (9) and (8) is immediately apparent given the definition of IDM, which was referred to above in a different context as the index of difficulty.)

As an example of the changes in the movement and positioning times observed as a function of changes in the independent variables, Wiker et al. (1989) find that the move and positioning times increased, respectively, by 15.3 and 26.5% when the arm went from $15°$ below shoulder height to $60°$ above shoulder height. The equation above is particularly useful if, say, one wants to identify the optimal elevation, assuming that workers of many different heights will be performing the job.

## 8  TRAINING, EDUCATION, AND INSTRUCTIONAL SYSTEMS

Training continues to be of central importance in human factors in both the private and public sectors. However, quantitative models that could be used in training, and more broadly in education, have remained elusive for the most part. This is changing radically. Below we discuss some of the very earliest work and then segue to a discussion of some more current research.

### 8.1  Paired-Associate Models

Much was done in the 1950s and 1960s with paired-associate learning (Estes, 1959; Bush and Mosteller, 1951). In that work, and in much that followed (Bower, 1961), an attempt was made to predict the rate at which the associations between stimuli and responses were learned. In a typical paradigm, participants would be given a stimulus, say a letter, and be asked to produce the correct response, say a particular digit. A number of factors were varied, including the total number of stimuli in the list, the time between repetitions of the same stimulus, and the time between the last trial and an evaluation of performance.

In the simplest case, the one we describe here, the stimulus–response pair is assumed to be in one of two states, either learned ($C$, or conditioned) or not learned ($\overline{C}$, not conditioned). Let $c$ be the probability that it is learned on any one trial. Let $g$ be the probability $P(\text{correct})$ that the participant guesses the correct answer, assuming that the stimulus–response association is not learned; assume that this probability is 1 if the association is learned. Then the model can be presented formally as a two-state Markov chain where:

| State on Trial $n$ | State on Trial $n + 1$ | | Response when in state | $P(\text{correct})$ |
|---|---|---|---|---|
| | $C$ | $\overline{C}$ | | |
| $C$ | 1 | 0 | $C$ | 1 |
| $\overline{C}$ | $c$ | $1 - c$ | $\overline{C}$ | $g$ |

It can easily be shown that the probability that a participant responds correctly after $n$ trials is equal to

$$P(\text{correct}) = 1 - (1 - g)(1 - c)^n$$

Now, suppose that one wanted to maximize the joint probability that each of the stimuli had been learned after $n$ training trials, where $n$ is greater than the number of paired associates. Then Karush and Dear (1966) have derived the optimal training strategy. It is so simple that it can easily be described in a sentence or two. One must first train exactly once all stimulus–response pairs. One then needs to keep track of an index for each stimulus–response pair: That index is set to the zero if the response on the preceding trial was incorrect; it is set to the number of successive correct responses if the response on the preceding trial was correct. One then selects to train on the next trial the stimulus with the smallest such index. Unfortunately, simple two-state models cannot explain some of the results. In fact, Katsikopoulos and Fisher (2001) have shown that if one is going to explain several of the most critical results, one will need two Markov chains, one applied on each trial in which an association is trained and one applied on each trial in which an association is not trained. Moreover, the chains will need, at a minimum, four states. This has made the analytic derivation of the optimal global training strategy all but impossible. Instead, optimization is performed over a relatively small horizon or simulations are used to approximate the best training schedule.

***Application: Morse Code***   The applications of the work in paired-associate learning are relatively few but still potentially significant. In the military, some soldiers continue to be trained in the use of Morse code as a backup. The associations between the stimuli, "dots" and "dashes," and the responses, letters and digits, must be learned. The training takes a very long time, so the military was interested in learning whether something could be done to reduce the training time (Fisher and Townsend, 1993). For an application such as this, the assumptions required to identify the optimal order in which to train the stimuli as set forth by Karush and Dear (1966) are reasonably well satisfied, and so their method can be applied with very little additional cost (since the training was already being done on a computer and the stimuli and responses recorded). Other applications might well include the learning of simple multiplication

facts (the multiplicands are the stimulus and the product is the response) or the vocabulary in a foreign language (the foreign word is the stimulus and the English word equivalent is the response).

## 8.2 Complex Skill Acquisition

A more complex model of learning is needed than the paired-associate model described above if one is going to explain the majority of learning that goes on in the classroom and elsewhere. Anderson (1983) has developed just such a model, one that is widely used and constantly under development, its most recent version being referred to as ACT-R (Anderson et al., 2004). Very briefly, the process starts with a task analysis, often using the GOMS procedures mentioned above (Card et al., 1983). Once a task is decomposed into increasingly better defined goals, a working model is built from two general types of knowledge: declarative and procedural knowledge.

*Declarative knowledge* is based on the instructions that the participant receives when performing a task and on the task analysis. These are stored in a semantic network. For example, a student will learn that the sum of three angles in a triangle must equal $180°$. *Procedural knowledge* is stored as production rules, rules that take actions consistent with the declarative component, including retrieving information from memory, focusing attention on a certain area of the display, pressing a key in response to a stimulus, and so on. For example, the three rules in Table 1, described in more detail in Taatgen and Lee (2003), are used to add three numbers (see rules 1, 2, and 3). There are various hard constraints on both the general form that productions can take and the execution of those productions. Most relevant here

are two such constraints. First, only one item at a time can be retrieved from declarative memory. Second, the production rules must fire in sequence.

From the standpoint of learning, the question that must be addressed is how participants over time become faster when performing complex tasks. In general terms, skill acquisition has been broken down into three stages: the cognitive, associative, and autonomous stages (Fitts, 1964). The answer within the framework of ACT-R has varied over time. Most recently, Taatgen and Anderson (2002) have suggested that with enough use, two rules that occur one after one another can be combined in such a way that the retrieval request from declarative memory in the first rule is no longer assumed to be necessary. Thus, only one production rule is necessary, a rule consisting of the IF part of the first rule and the THEN part of the second rule. An example is given in Table 1 in rule 1&2. A relatively time-consuming step has now been saved, in particular the retrieval from declarative memory of the sum of the first two numbers. This is identified by them as *production compilation* and is consistent with their results in several different experiments.

### Application: Training Air Traffic Controllers

Taatgen and Lee (2003) used ACT-R to model the improvement in performance over time of participants (college undergraduates) asked to perform the Kanfer–Ackerman air traffic controller task (Ackerman, 1988; Ackerman and Kanfer, 1994). The task is a complex one and can be decomposed hierarchically into the unit task level (e.g., land a plane on the runway), the functional level (e.g., find a runway to land), and the keystroke level (e.g., press a particular key). Taatgen and Lee identified the declarative knowledge and task-independent procedural rules needed to perform each task at each level. In addition, they identified formally under what conditions declarative knowledge and task-independent production rules could be combined into task-specific production rules through the mechanism that was identified above as production compilation. Using values for parameters obtained outside the Kanfer–Ackerman air traffic controller task, they predicted for each of the first 10 trials how performance at the unit task level, functional level, and keystroke level would vary. They found that qualitatively their model fits the results very nicely. This is an example where the mathematical model could be used to limit the selection of interfaces to examine more completely, perhaps in an experiment, assuming that too large a number were available initially to evaluate fully.

## 9 WARNINGS

A warning device can be characterized in terms of signal detection theory. Consider a smoke alarm that goes off when the concentration of certain particles in the air exceeds a critical value. The critical value corresponds to the response bias. The standardized difference between the mean concentration of particles when there is a fire and when there is not corresponds to

**Table 1 Production Rules and Compilation**

| Rule 1 | IF | the goal is to add three numbers, $n_1, n_2,$ and $n_3,$ |
|---|---|---|
| | THEN | send a retrieval request to declarative memory for the sum $s_{1+2} = n_1 + n_2$ of the first two numbers. |
| Rule 2 | IF | the goal is to add three numbers AND the sum $s_{1+2}$ of the first two numbers is retrieved, |
| | THEN | send a retrieval request to declarative memory for the sum of (a) the first two numbers, $s_{1+2}$, and (b) the third number $n_3$; label this last sum $s_{1+2+3}$. |
| Rule 3 | IF | the goal is to add three numbers AND the sum $s_{1+2+3}$ of the first three numbers is retrieved, |
| | THEN | the answer is the retrieved sum, $s_{1+2+3}$. |
| Rule 1&2 | IF | the goal is to add the two numbers 3 and 5 together with a third number, $n_3$, |
| | THEN | send a request to declarative memory for the sum of 8 and $n_3$. |

the sensitivity of the device. In most environments the operator is not in a position to change the frequency of hits (there is a fire and the warning device indicates such), misses, false alarms (there is no fire and the warning device indicates that there is such), and correct rejections of the device itself. However, in some environments the operator can, and probably will, actually want to alter the frequency of false alarms (without tinkering with the warning system mechanics).

For example, consider nurses working in an intensive care unit (ICU). Such nurses will want to reduce the number of times that the warning sounds. This will reduce the number of times that a true emergency is present, given that the warning sounded, as well as the number of times that no emergency is present, given that the warning sounded. Meyer and Bitan (2002) realized that this will in turn reduce the information in the warning. At the extreme, if the operator is always able to take actions that prevent the warning from sounding in a true emergency, only false alarms will be generated. It is known that the operator's response time is influenced by the frequency of false alarms produced by the warning system; most important in this context, response time decreases when the frequency of false alarms increases (Getty et al., 1995). This raises the question of whether a warning device is more valuable or less valuable for better operators (i.e., operators who have reduced the number of times that an emergency situation occurs).

Because the answer depends on the combined effect of several quantities, this question would be difficult to answer without a model. Using signal detection theory, Meyer and Bitan (2002) calculated the predictive value of warnings as a function of the probability of a system failure. The positive predictive value is the probability that there actually is a failure given that the device produces an alarm. Let $F$ denote an actual failure of the system and $f$ denote that an alarm is given. Then the positive predictive value, PPV, is $P(F|f) =$ hits/(hits + false alarms). Analogously, the negative predictive value, NPV, is the probability the system is normal given that the device does not produce an alarm. Let $N$ denote the normal state of the system, and let $n$ denote that no warning is given. Then the negative predictive value is $P(N|n)$. It is clear from the information in Table 2 that the positive predictive value decreases as the operator reduces the number of instances of system failure from 100 (left side) to 10 (right side). The negative predictive value can easily be shown to increase here.

Given the data in the table, Meyer and Bitan (2002) asked how one might index the overall effect on the operator of changes in these two indices, the positive and negative predictive values, that were heading in opposite directions. They suggested several ways that one might combine this information, one of which is to use information theory and, in particular, to compute the information transmitted by the warning system, something we have already discussed above. Meyer and Bitan (2002) considered three hypothetical warning devices with different values of $d'$ and $\beta = 1$ (i.e., neutral bias). For each, they found that the negative predictive value increased slightly as the probability of actual failure decreased from 0.200 to 0.001. However, the positive predictive value decreased and was considerably lower at the low end of this range than at the high end, and so was the information transmitted. In short, the diagnostic value of an alarm is worse for better operators.

***Application: Intensive Care Units***   The conclusion above was borne out in an experiment on a simulated intensive care nurse's workstation, with an imperfect device warning that a patient needed attention (Meyer and Bitan, 2002). Performance of participants improved over time in the experiment. But the positive predictive value of an alarm decreased and the negative predictive value increased in such a way that the information transmitted by the alarm decreased as they became better operators. Unfortunately, the behavioral implications of these findings are not immediately clear. On the one hand, it is known that as the informative value of a warning goes down, operators are less likely to take action. On the other hand, it is clearly beneficial to reduce the number of situations in which a warning is required. Here is a situation where a mathematical model of a system has uncovered a problem that would probably not have been recognized. However, by itself it cannot be used to solve the problem. More information is needed about the performance of operators in such complex situations.

## 10   SUMMARY

We set out to show the broad range of uses to which mathematical models can be put in the design of the interface between the human user and the environment. Most centrally, we set out to show that such models not only can be used to design an interface, but can actually be used to optimize the interface. We gave several such examples, including (1) the design of optimal menu hierarchies, (2) the design of optimal inspection schedules, and (3) the design of optimal training sequences. Of course, as we made clear throughout the chapter, mathematical models have a broader use

**Table 2  Positive Predictive Value**

| Device's Response | System State | | Device's Response | System State | |
|---|---|---|---|---|---|
| | *F* | *N* | | *F* | *N* |
| *f* | 90 | 10 | *f* | 9 | 10 |
| *n* | 10 | 90 | *n* | 1 | 90 |
| | $PPV = \dfrac{90}{90 + 10} = 0.9$ | | | $PPV = \dfrac{9}{9 + 10} = 0.47$ | |

than simply optimizing the interface. We gave several examples of other uses as well, including (1) the prediction of performance with a particular interface to determine whether it will function as desired and therefore should be considered for implementation, (2) the identification of the effects of neurotoxic agents on the speed of latent processes, and (3) the determination of whether two apparently different models actually make different predictions.

We are hopeful that mathematical modeling will continue to play an important and increasing role in the design of the interface. There are several indications that such will be the case, including a recent special issue of *Human Factors* devoted entirely to mathematical models as well as the formation several years ago within the Human Factors and Ergonomics Society of a technical group whose interests focus on modeling. And, of course, we hope that this chapter will motivate others in the research community to think more broadly about how they too might apply one or more of the many modeling techniques described herein to the design of an interface.

# CHAPTER 34

# HUMAN SUPERVISORY CONTROL

**Thomas B. Sheridan**
**Massachusetts Institute of Technology**
**Cambridge, Massachusetts**

## 1 DEFINITIONS OF HUMAN SUPERVISORY CONTROL

Human supervisory control is construct, formally something constructed by the mind: a theoretical entity, a working hypothesis or concept pertaining to a relatonaship between a human and a machine or physical system. It is not by itself a normative or predictive model, though it is descriptive of relationships between system elements where both human and computer actively interact. The word "human" is added because the term "supervisory control" is sometimes used by control engineers to describe software agents that aid in system measurement.

This chapter is not a comprehensive or even-handed review of the literature in human–robot interaction, monitoring, diagnosis of failures, human error, mental workload, or other closely related topics. Sheridan (1992, 2002), Sarter and Amalberti (2000), Degani (2004), and Sheridan and Parasuraman (2006) cover these aspects more fully.

The term human supervisory control is derived from the close analogy between the characteristics of a human supervisor's interaction with subordinate human staff members and a person's interaction with "intelligent" automated subsystems. A supervisor of people gives directives that are understood and translated into detailed actions by staff members. In turn, staff members aggregate and transform detailed information about process results into summary form for the supervisor. The degree of intelligence of staff members determines the supervisor's willingness to delegate. Automated subsystems permit the same sort of interaction to occur between a human supervisor and the process (Ferrell and Sheridan, 2010). Supervisory control behavior is interpreted to apply broadly to include vehicle control (aircraft and spacecraft, ships, highway and undersea vehicles), continuous process control (oil, chemicals, power generation), robots and discrete tasks (manufacturing, space, undersea, mining), and medical and other human–machine systems.

In a strictest definition, the term human supervisory control (or just supervisory control as often used in the present context) indicates that one or more human operators are setting initial conditions for intermittently adjusting and receiving information from a computer that itself closes an inner control loop through electromechanical sensors, effectors, and the task environment. In a broader sense, supervisory control means interaction with a computer to transform data or to produce control actions. Figure 1 compares supervisory control with direct manual control (Figure 1a) and full automatic control (Figure 1e). Figures 1c and 1d characterize supervisory control in the strict formal sense; Figure 1b characterizes supervisory control in the latter (broader) sense.

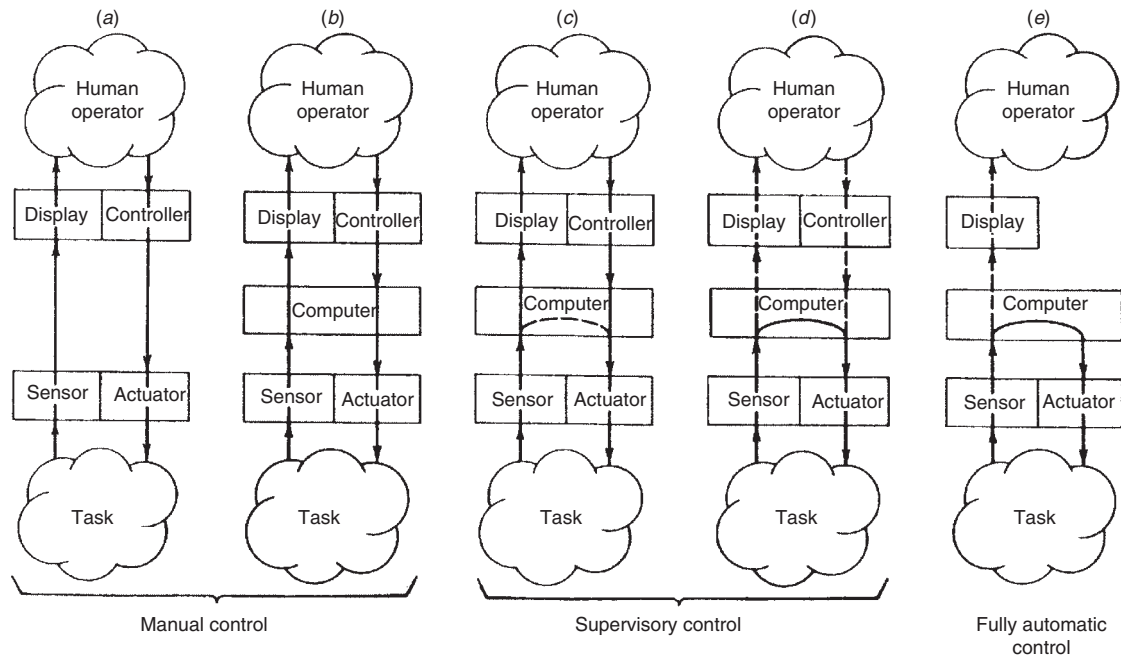
The essential difference between these two characterizations of supervisory control is that in the first and stricter definition the computer can act on new information independent of and with only blanket authorization and adjustment from the supervisor; that is, the computer implements discrete sets of instructions by itself,


**Figure 1** Supervisory control as related to direct manual control and full automation.

closing the loop through the environment. In the second definition the computer's detailed implementations are open loop; that is, feedback from the task has no effect on computer control of the task except through the human operator. The two situations may appear similar to the supervisor, since he or she always sees and acts through the computer (analogous to a staff) and therefore may not know whether it is acting open loop or closed loop in its fine behavior. In either case the computer may function principally on the efferent or motor side to implement the supervisor's commands (e.g., do some part of the task entirely and leave other parts to the human or provide some control compensation to ease the task for the human). Alternatively, the computer may function principally on the display side (e.g., to integrate and interpret incoming information from below or to give advice to the supervisor as to what to do next, as with an "expert system"). Or it may work on both the efferent and afferent sides.

## 2 SOME HISTORY

The 1940s saw human factors engineering come into being to ensure that soldiers could operate machines in World War II. In the 1950s human factors emerged as a professional field, first in essentially empirical "knobs and dials" form, concentrating on the human–machine interface, accompanied by ergonomics, which focused on the physical properties of the workplace. This was

supported over the next decade by the theoretical underpinnings of human–machine systems theory and modeling (Sheridan and Ferrell, 1974). Such theories included control, information, signal detection, and decision theories originally developed for application to physical systems but now applied explicitly to the human operator. As contrasted with human factors engineering at the interface, human–machine systems analysis considers characteristics of the entire causal "loop" of decision, communication, control, and feedback—through the operator's physical environment and back again to the human.

From the late 1950s the computer began to intervene in the causal loop: electronic compensation and stability augmentation for control of aircraft and similar systems, electronic filtering of signal patterns in noise, and electronic generation of simple displays. It was obvious that if vehicular or industrial systems were equipped with sensors that could be read by computers and, by motors that could be driven by computers, then, even though the overall system was still very much human controlled, control loops between those sensors and motors could be closed automatically. Thus, the chemical plant operator was relieved of keeping the tank at a given level or the temperature at a reference; he or she needed only to set in that desired level or temperature signal from time to time. So, too, after the autopilot was developed for the aircraft, the human pilot needed only to set in the desired altitude to heading; an automatic system would strive to achieve this reference, with the pilot monitoring to ensure that the aircraft did in fact go where desired.

The automatic building elevator, of course, has been in place for many years and is certainly one of the first implementations of supervisory control. Recently, developers of new systems for word processing and handling of business information (i.e., without the need to control any mechanical processes) have begun thinking along supervisory control lines.

The full generality of the idea of supervisory control came to the author and his colleagues (Sheridan, 1960; Ferrell and Sheridan, 1967) as part of research on how people on Earth might control vehicles on the moon through round-trip communication time delays (imposed by the speed of light). Under such constraint, remote control of lunar roving vehicles or manipulators was shown to be possible only by performing in "move-and-wait" fashion. This means that the operator can commit only to a small incremental movement open loop, that is, without feedback (which actually is as large a movement as is reasonable without risking collision or other error), then stopping and waiting one delay period for feedback to "catch up," then repeating the process in steps until the task is completed.

Experimental attempts to drive or manipulate continuously this way only produced instability, as simple control theory predicts (i.e., where loop gains exceed unity at a frequency such that the loop time delay is one half-cycle, instead of errors being nulled out, they are only reinforced). Performing remote manipulation with delayed force feedback was later shown by Ferrell (1967) to be essentially impossible since forces at unexpected times act as significant disturbances to produce instability. At least the visual feedback can be ignored by the operator.

It was shown that if, instead of the human operator remaining within the control loop, he or she communicates a goal state relative to the remote environment, and if the remote system incorporates the capability to measure proximity to this goal state, the achievement of this goal state can be turned over to the remote subordinate control system for implementation. In this case there is no delay in the control loop implementing the task, and thus there is no instability.

There necessarily remains, of course, a delay in the supervisory loop. This delay in the supervisor's confirmation of desired results is acceptable as long as (1) the subgoal is a sufficiently large "bite" of the task, (2) the unpredictable aspects of the remote environment are not changing too rapidly (i.e., disturbance bandwidth is low), and (3) the subordinate automatic system is trustworthy.

Under these conditions and as computers gradually become more capable both in hardware and software (and as "machine intelligence" finally makes its real if modest appearance), it is evident that telemetry transmission delay is in no way a prerequisite to the usefulness of supervisory control. The incremental goal specified by the human operator need not be simply a new steady-state reference for a servomechanism (as in resetting a thermostat) in one or even several dimensions (e.g., resetting both temperature and humidity or commanding a manipulator endpoint to move to a new position, including three translations and three rotations

relative to its initial position). Each new goal statement can be the specification of an entire trajectory of movements (as the performance of a dance or a symphony) together with programmed branching conditions (what to do in case of a fall or other unexpected event).

In other words, the incremental goal statement can be a program of instructions in the full sense of a computer program which make the human supervisor an intermittent real-time computer programmer, acting relative to the subordinate computer much the same as a teacher or parent or boss behaves relative to a student or a child or subordinate worker. The size and complexity of each new program are necessarily a function of how much the computer can (be trusted to) cope with in one bite, which in turn depends on the computer's own sophistication (knowledge base) and the complexity (uncertainty) of the task.

## 3   EXAMPLES OF HUMAN SUPERVISORY CONTROL IN CURRENT TECHNOLOGICAL SYSTEMS

While supervisory control first evolved in delayed feedback situations such as controlling robots on the moon from Earth, it has grown to encompass a wide variety of other systems and for different reasons that have mostly to do with what humans do best (setting goals) and what computers do best (routine execution of conrol actions based on sensed feedback).

Supervisory control is now found in various forms in many industrial, military, medical, and other contexts. However, this form of human interaction with technology is still relatively little recognized or understood in a formal way by system designers who want to take maximum advantage of automation yet want to benefit from the intelligence of the human agent.

Aircraft autopilots are now "layered," meaning that the pilot can select among various forms and levels of control. At the lowest level the pilot can set in a new heading or rate of climb. Or he or she can program a sequence of heading changes at various waypoints or a sequence of climb rates initiated at various altitudes or program the inertial guidance system to take the aircraft to a given runway at a distant city. Given the existence of certain ground-based equipment, the pilot can program an automatic landing on a given runway, and so on. The pilot not only can set commands for different control models but also can also modify different modes of display: how information is presented. Sheridan (2002) reviews how such automation is creeping into the aircraft flight deck. Sarter and Amalberti (2000) describe the modern flight management system in some detail.

Efforts now underway by governments in both the United States and Europe are major technological upgrades of the air traffic control systems. In the United States it is called NextGen (for NextGeneration Air Transportation System), and in the European Community it is called Single European Sky, or SESAR. The two efforts are being coordinated, and in both cases involve the introduction of much new automation and

**Table 1 Some NextGen Flight Operations Using Supervisory Control**

Negotiating four-dimensional (4D) (three in space, one in time) flight trajectories shortly before pushback

Dealing with off-nominal aircraft on the airport surface

Controller/pilot use of digital data communication (Datalink)

Traffic flow manager use of new capacity/flow/weather models

Aircraft operation conflict and resolution responsibilities

Responding to aircraft deviation from their assigned 4D trajectories

Weather conflict and decision to reroute around weather patterns

Effecting a new ''best equipped–best served'' policy

Dynamic reconfiguration of en route or terminal airspace

Merging and spacing in terminal airspace

Setting up for continuous curved rather than step-down descent

Pairing for descent to parallel runways

supervisory control, for example in the flight operations listed in Table 1 (Sheridan, 2010).

The unmanned aeronautical vehicle (UAV) is now subsuming an ever greater role in military operations and soon will do the same in domestic airspace to monitor national borders, inspect crops, and possibly eventually carry freight. UAVs are typically flown by setting successive waypoints in 3D space, a supervisory function.

Supervisory control of a simpler sort is now evident in the cruise control system of current automobiles and trucks and is being upgraded in the form of "advanced" or "intelligent" cruise control, wherein a radar detector controls speed to maintain a safe distance behind a leading vehicle.

In modern hospital operating rooms, intensive care units, and ordinary patient wards there are numerous supervisory control systems at work. The modern anesthesiology workstation is a good example. Drugs in liquid or gaseous form are pumped into the patient at rates programmed by the anesthesiologist and by sensors monitoring patient respiration heart rate and other variables.

Modern chemical and nuclear plants can be programmed to perform heating, mixing, and various other processes according to a time line and including various sensor-based conditions for shutting down or otherwise aborting the operation. Nandi and Ruhe (2002) describe the use of supervisory control in sintering furnaces. Seiji et al. (2001) provide an extensive review of modern supervisory control in nuclear power plants.

Robots of all kinds are being developed: for industrial manufacturing (e.g., for both inspection and assembly of products on assembly lines); for space (e.g., planetary rovers); for undersea applications (e.g., in the British Petroleum oil spill and oceanographic research); for security applications (e.g., inspecting threatening packages in airports and other public places);

military applications (e.g., detonating improvised explosive devices); home cleaning applications (e.g., cleaning swimming pools, vacuuming carpets); offices (e.g., delivering mail); and hospitals (e.g., for minimally invasive surgery). Most of these robots have mobility capability; some have arms for manipulation. Almost all embody supervisory control, at least in primitive form.

Many of the examples cited above characterize the first or stricter definition of supervisory control previously given (Figures 1c and d), where the computer, once programmed, makes use of its own artificial sensors to ensure completion of the tasks assigned. Many familiar systems, such as automatic washing machines, dryers, dishwashers, or stoves, once programmed, perform their operations open loop; that is, there is no measurement or knowledge of results. If the task can be performed in such open-loop fashion, and if the human supervisor can anticipate the task conditions and is good at selecting the right open-loop program, there is no reason not to employ this approach. To the human supervisor, whether the lower level implementation is open or closed loop is often opaque and/or of no concern; the only concern is whether the goal is achieved satisfactorily. For example, a programmable microwave oven without the temperature sensor in place operates open loop, whereas the same oven with the temperature sensor operates closed loop. To the human supervisor or programmer, they look the same.

A very important aspect of supervisory control is the ability of the computer to "package" information for visual display to the human supervisor, including data from many sources; from the past, present, or even predicted future; and presented in words, graphs, symbols, pictures, or some combination. Ubiquitous examples of such integrated displays are so-called *decision support tools* in aircraft and air traffic control, chemical and power plants, and various other industrial or military settings too numerous to review here. General interest in supervisory displays became evident in the mid-1970s (Edwards and Lees, 1981; Sheridan and Johannsen, 1976; Wiener and Curry, 1980; Sheridan and Hennessy, 1984).

## 4 SUPERVISORY ROLES AND HIERARCHY

The human supervisor's roles are (1) planning offline what task to do and how to do it; (2) teaching (or programming) the computer what was planned; (3) monitoring the automatic action online to make sure that all is going as planned and to detect failures; (4) intervening, which means the supervisor takes over control after the desired goal state has been reached satisfactorily or interrupts the automatic control in emergencies to specify a new goal state and reprogram a new procedure; and (5) learning from experience so as to do better in the future. These are usually time-sequential steps in task performance.

We may view these steps as being within three nested loops, as shown in Figure 2. The innermost loop, monitoring, closes on itself; that is, evidence of something interesting or completion of one part of the cycle of

| SUPERVISORY STEP | ASSOCIATED MENTAL MODEL | ASSOCIATED COMPUTER AID |
|---|---|---|
| 1. PLAN | | |
| a) Understand controlled process | Physical variables: transfer relations | Physical process training aid |
| b) Satisfice objectives | Aspirations: preferences and indifferences | Satisficing aid |
| c) Set general strategy | General operating procedures and guidelines | Procedures training and optimization aid |
| 2. TEACH | | |
| a) Decide and test control actions | Decision options: state-procedure-action implications; expected results of control actions | Procedures library; action decision aid (in-situ simulation) |
| b) Decide, test, and communicate commands | Command language (symbols, syntax, semantics) | Aid for editing commands |
| 3. MONITOR AUTOMATION | | |
| a) Acquire, calibrate, and combine measures of process state | State information sources and their relevance | Aid for calibration and combination of measures |
| b) Estimate process state from current measure and past control actions | Expected results of past actions | Estimation aid |
| c) Evaluate process state: detect and diagnose failure or halt | Likely modes and causes of failure or halt | Detection and diagnosis aid for failure or halt |
| 4. INTERVENE | | |
| a) If failure: execute planned abort | Criteria and options for abort | Abort execution aid |
| b) If error benign: act to rectify | Criteria for error and options to rectify | Error rectification aid |
| c) If normal end of task: complete | Options and criteria for task completion | Normal completion execution aid |
| 5. LEARN | | |
| a) Record immediate events | Immediate memory of salient events | Immediate record and memory jogger |
| b) Analyze cumulative experience; update model | Cumulative memory of salient events | Cumulative record and analysis |

**Figure 2**  Functional and temporal nesting of supervisory roles.

the monitoring strategy leads to more investigation and monitoring. We might include minor online tuning of the process as part of monitoring. The middle loop closes from intervening back to teaching; that is, human intervention usually leads to programming of a new goal state in the process. The outer loop closes from learning back to planning; intelligent planning for the next subtask is usually not possible without learning from the last one.

The three supervisory loops operate at different time scales relative to one another. Revisions in fine-scale monitoring behavior take place at brief intervals. New programs are generated at somewhat longer intervals. Revisions in significant task planning occur only at still longer intervals. These differences in time scale further justify Figure 2.

More and more a multiplicity of computers are used in a supervisory control system, as shown in Figure 3. One typically large computer is in the control room to generate displays and interpret commands. This can be called a human-interactive computer (HIC), part of a human-interactive system (HIS). It in turn forwards that command to various microprocessors that actually close individual control loops through their own associated sensors and effectors. The latter can be called task-interactive computers (TICs), each part of its own task-interactive system (TIS).

The HIC is conceived to be a large enough computer to communicate in a human-friendly way using near-natural language, good graphics, and so on. This includes being able to accept and interpret commands and to give the supervisor useful feedback. The HIC should be able to recognize patterns in data sent up to it from below and decide on appropriate algorithms for response, which it sends down as instructions. Eventually, the HIC should be able to run "what would happen if . . ." simulations and be able to give useful advice from a knowledge base, that is, include an expert system.

The HIC, located near the supervisor in a control room or cockpit, may communicate across a barrier of time or space with a multiplicity of TICs, which probably are microprocessors distributed throughout the plant or vehicle. The latter are usually coupled intimately with artificial sensors and actuators in order to deal in low-level language and to close relatively tight control loops with objects and events in the physical world.

The human supervisor can be expected to communicate with the HIC intermittently in information "chunks" (alphanumeric sentences, icons, etc.) while the task communicates with the TIC continuously in computer language at the highest possible bit rates. The availability of these computer aids means that the human supervisor, while retraining the knowledge-based behavior function, is likely to download some of the rule-based programs and almost all of the skill-based programs into the HIC. The HIC, in turn, should download a few of the rule-based programs, and most of the skill-based programs, to the appropriate TICs.

Figure 4 presents the functions of Figure 2 in the form of a flowchart. Each supervisory function is shown above, and the (usually multiple) automated subsystems of the TIC are shown below. Normally, for any given task, the planning and learning roles are performed offline relative to the online human-mediated and automatic operations of the other parts of system and therefore are shown at the top with light lines connecting them to the rest of the system. Teaching precedes monitoring on the first cycle but thereafter follows monitoring and intervening (as necessary) within the intermediate loop. The inner loop monitoring role is carried out within the "estimate state" and "allocate attention" boxes.

Allocation of functions between the human and the machine need not be fixed. There have been numerous papers discussing the potential for dynamic allocation—where the allocation changes as a function of the flow of demands and the workload of the two entities (see, e.g., Sheridan, 1997). In the sections that follow the various supervisory roles are discussed in more detail, bringing

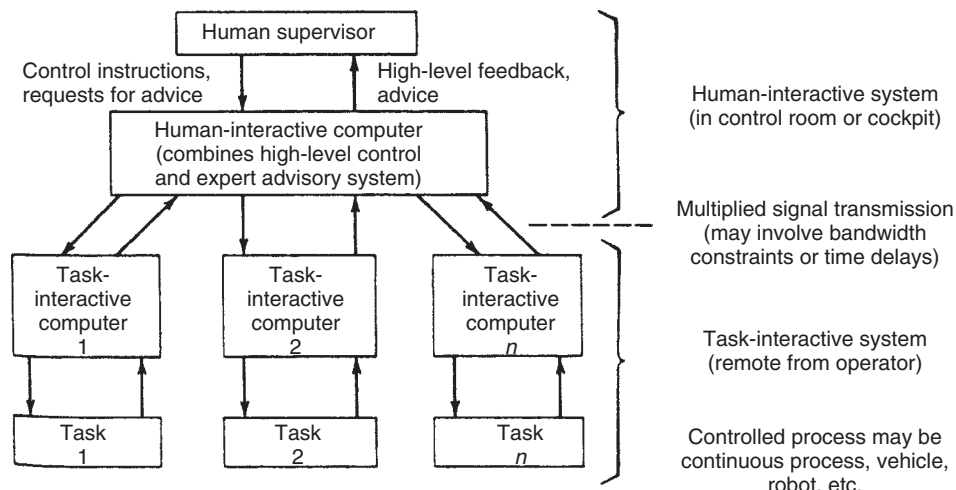

**Figure 3** Hierarchical nature of supervisory control.
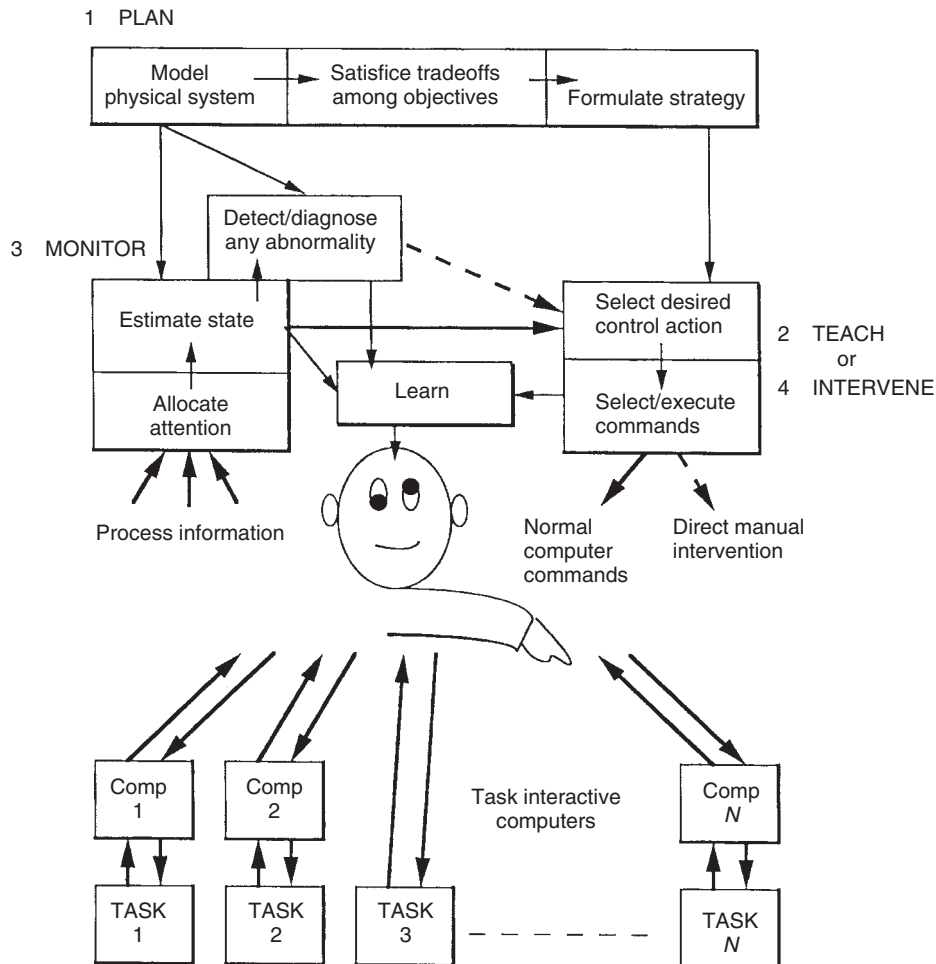

**Figure 4**  Flowchart of supervisor functions (including both mental models and decision aids). (From Sheridan, 1992.)

in examples of research problems and prototype systems to aid the supervisor in these roles.

## 5  SUPERVISORY LEVELS AND STAGES

Supervisory control may involve varying degrees of computer aiding in acquiring information and executing control, as in Table 2). This "level of automation" idea, originally presented in Sheridan and Verplank (1978) with 10 rather than 8 levels, has been picked up and used by others in various ways. Parasuraman et al. (2000) added the idea that the successive stages of information acquisition, information analysis, action decision, and action implementation are usually automated to different degrees. The best degree of automation is seldom the same at the various stages.

Figure 5 is an example of how, in the writer's opinion, the Federal Aviation Administrations's NextGen

**Table 2  Scale of Degrees of Automation**

1. The computer offers no assistance; the human must do it all.

2. The computer suggests alternative ways to do the task.

3. The computer selects one way to do the task and

4. Executes that suggestion if the human approves or

5. Allows the human a restricted time to veto before automatic execution or

6. Executes the suggestion automatically, then necessarily informs the human, or

7. Executes the suggestion automatically, then informs the human only if asked.

8. The computer selects the method, executes the task, and ignores the human.

project will automate operations at the four stages in the midterm and far term as compared to the current levels.

Experience with military systems calls attention to the appropriateness of various levels of automation (Cummings, 2005):

The Patriot missile system has a history of friendly fire incidents that can at least be partially attributed to a lack of understanding of human limitations in supervisory control. . . .

The Patriot missile has two modes: semiautomatic (management by consent, (level 4 above—an operator must approve a launch) and automatic (management by exception —the operator is given a period of time to veto the computer's decision (level 5 above). However, in practice the Patriot is typically left in the automatic mode and the friendly fire incidents are believed to be a result of problems in the automatic mode. There are known "ghosting" problems with the Patriot radar: because operations are in close proximity to other Patriot missile batteries, false targets will appear on a Patriot operator's screen. Under the automatic mode (management by exception), operators are given approximately 15 seconds to reject the computer's decision, which is insufficient to solve both false targeting problems as well as adequately address friend or foe concerns through any other means of communication. After the accident investigations, the US Army admitted that there is no standard for Patriot training, autonomous operations procedures (automatic mode) are not clear, and that operators commonly lose situational awareness of air tracks).

## 6 PLANNING AND LEARNING: COMPUTER REPRESENTATION OF RELEVANT KNOWLEDGE

The first and fifth supervisory roles described previously, planning and learning, may be considered together since they are similar activities in many ways. Essentially, in the planning role the supervisor asks "What would happen if . . . ?" questions of the accumulated knowledge base and considers what the implications are for hypothetical control decisions. In learning, the supervisor asks "What did happen?" questions of the database for the more recent subtasks and considers whether the initial assumptions and final control decisions were appropriate.

The designer of an automatic control system or manual control system must ask: "What variables do I wish to make do what, subject to what constraints and what criteria?" The planning role in supervisory control requires that the same kinds of questions be answered, because, in a sense, the supervisor is redesigning an automatic control system each time that he or she programs a new task and goal state. Absolute constraints

on time, tools, and other resources available need to be clear, as do the criteria of trade-off among time, dollars and resources spent, accuracy, and risk of failure.

Just as computer simulation figures into planning, it also figures into supervisory control—the difference being that such simulation may more likely be subjected to time stress in supervisory control. Simulation requires acquiring some idea of how the process (system to be controlled) works, that is, a set of equations relating the various controllable variables, the various uncontrollable but measurable variables (disturbances), and the degree of unpredictability (noise) on measured system response variables. This is a common representation of knowledge. Given measured inputs and outputs, there are well-established means to infer the equations if the processes are approximately linear and differentiable.

Once such a model is in place, the supervisor can posit hypothetical inputs and observe what the outputs would be. Also, one may use such a process model as an "observer" (in the sense of modern control theory). Namely, when control signals are put into both the model and actual processes and the model parameters are then trimmed to force certain model outputs to conform to corresponding actual process outputs that can be measured (Figure 6), other process outputs that are inconvenient to measure may be estimated ("observed") from the model. Just as this is a theoretical prerequisite to optimal automatic control of physical systems, so it is likely to be a useful practice to aid humans in supervisory control (Sheridan, 1984).

A different type of knowledge representation is that used by the artificial intelligence (AI) community. Here knowledge is usually couched in the form of if–then logical statements called production rules, semantic association networks, and similar forms. The input to a simulated program usually represents in cardinal numbers a hypothetical physical input to a simulated physical system. In contrast, the input to the AI knowledge base can be a question about relationships for given data or a question about data for given relationships. This can be in less restrictive ordinal form (e.g., networks of diadic relations) or in nominal form (e.g., lists).

Currently, there is great interest in how best to transfer expertise from the human brain (knowledge representation, mental model) into the corresponding representation or model within the computer, how best to transfer it back, and when to depend on each of those sources of information. This research on mental models has a lively life of its own (Falzon, 1982; Gentner and Stevens, 1983; Rouse and Morris, 1984; Sheridan, 1984; Moray, 1997) quite independent of supervisory control.

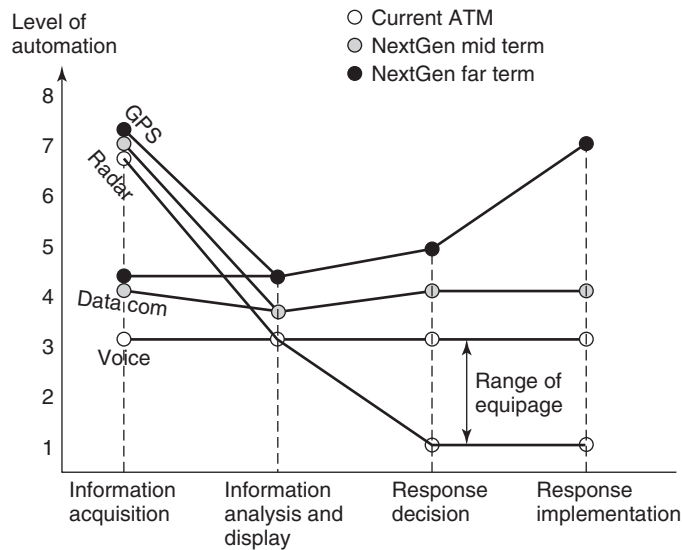
An important aspect of planning is visualization. The now rather sophisticated tool of computer simulation, when augmented by computer graphics, enables remarkable visualization possibilities. When further augmented by human interactive devices such as head-mounted visual and auditory displays and high-bandwidth force-reflecting haptics (mechanical arms), the operator can be made to feel present in a virtual world, as has been popularized by the oxymoron *virtual reality*. Of course, the idea of virtual reality is not new. The original idea


**Figure 5**  Estimated levels of automation of NextGen automation.

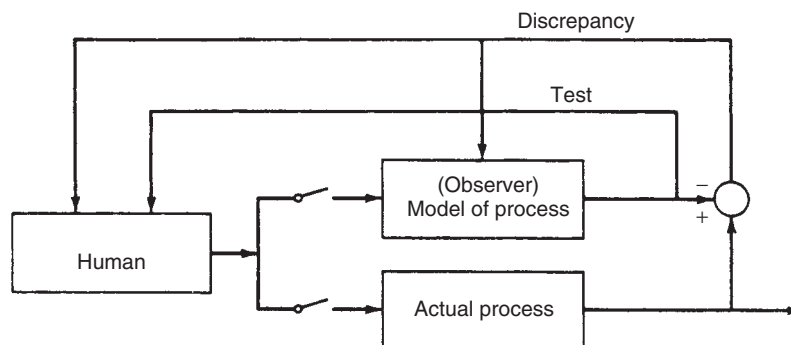

**Figure 6**  Use of computer-based observer as an aid to supervisor.

of Edwin Link's first flight simulators (developed early in the 1940s) was to make the pilot trainee feel as if he or she were flying a real aircraft. First they were instrument panels only, then a realistic out-the-window view was created by flying a servo-driven video camera over a scale model, and finally, computer graphics were used to create the out-the-window images. Now all commercial airlines and military services routinely train with computer display, full-instrument, moving-platform flight simulators. Similar technology has been applied to ship, automobile, and spacecraft control. The salient point for the present discussion is that the new simulation capabilities now permit visualization of alternative plans as well as better understanding of complex state information in situ, during monitoring. That same technology, of course, can be used to convey a sense of presence in an environment that is not simulated but is quite real and

merely remote—communicated via closed-circuit video with cameras slaved to the observer's head.

Supervisory aiding in planning of the moves of a telerobot is illustrated by the work of Park (1991). His computer graphic simulation let a supervisor try out moves of a telerobot arm before committing to the actual move. He assumed that for some obstacles the positions and orientation were already known and represented in a computer model. The user commanded each straight-line move to a subgoal point in three-dimensional space by designating a point on the floor or the lowest horizontal surface (such as a tabletop) by moving a cursor to that point (say, A in Figure 7a) and clicking, then lifting the cursor by an amount corresponding to the desired height of the subgoal point (say, A) above that floor point and observing on the graphic model a blue vertical line being generated from the floor point to the subgoal point in space. This process was repeated
**Figure 7** Park's display of computer aid for obstacle avoidance: (*a*) human specification of subgoal points on graphic model; (*b*) generation of virtual obstacles for a single viewing position (above) and a pair of viewing positions (below). (From Park, 1991.)

for successful subgoal points (say, B and C). Using the computer display, the user could view the resulting trajectory model from any desired perspective (although the "real" environment could be viewed only from the perspective provided by the video camera's location). Either of two collision avoidance algorithms could be invoked: a detection algorithm that indicated where on some object a collision occurred as the arm was moved from one point to another or an automatic avoidance algorithm that found (and drew on the computer screen) a minimum-length, no-collision trajectory from the starting point to the new subgoal point. Park's aiding scheme also allowed new observed objects to be added to the model by graphically "flying" them into geometric correspondence with the model display. Another aid was to generate virtual objects for any portion of the environment in the umbral region (not visible) after two video views (Figure 7b). In this case the virtual objects were treated in the same way in the model and in the collision avoidance algorithms as the visible objects. Experiments with this technique showed that it was easy to use and that it avoided collisions.

At the extreme of time desynchronization is recording an entire task on a simulator, then sending it to the telerobot for reproduction. This might be workable when one is confident that the simulation matches the reality of the telerobot and its environment or when small differences would not matter (e.g., in programming telerobots for entertainment). Doing this would certainly make it possible to edit the robot's maneuvers until one was satisfied before committing them to the actual operation. Machida et al. (1988) demonstrated such a technique by which commands from a master–slave manipulator could be edited much as one edits material on a video-tape recorder or a word processor. Once a continuous sequence of movements had been recorded, it could be played back either forward or in reverse at any time rate. It could be interrupted for overwrite or insert operations. Their experimental system also incorporated computer-based checks for mechanical interference between the robot arm and the environment.

A number of planning aids are manifest in modern air traffic control. Computers are used to show the expected arrival of aircraft at airports and the gaps between them. This helps the human controller to command minor changes in aircraft speed or flight path to smooth the flow. The center TRACON automation system (CTAS) assists in providing an optimal schedule and three-dimensional spacing. Other systems use radar data to project ahead and alert the controller to potential conflicts (violation of aircraft separation standards) (Wickens et al., 1997). NextGen promises a number of additional decision aiding displays, such as those listed in Table 1.

One aspect of supervisory control that is often not planned and is taken for granted (and where learning can be painful) is team coordination in distributed decision making. NextGen has thankfully recognized the problem and has established research efforts into what in that context is called "cooperative air traffic management." In the military operations context Cummings (2005) provides an example:

On April 14, 1994, two US Army Black Hawk helicopters were transporting U.S., French, British, and Turkish commanders, as well as Kurdish para-military personnel across this zone when two US F-15 fighters shot them down, killing all 26 on board. The Black Hawks had previously contacted and received permission from the AWACs to enter the no-fly zone. Yet despite this, AWACs confirmed that there should be no flights in the area when the F-15s misidentified the US helicopters as Iraqi Hind helicopters. The teamwork displayed in this situation was a significant contributing factor to the friendly fire incident, as the F-15s never learned from AWACs that a friendly mission was supposed to be in the area. It was later determined that the F-15 wingman backed up the other F-15's decision that the targets were Iraqi forces despite being unsure, which was yet another breakdown in communication. Each team member did not share information effectively, resulting in the distributed decision making of the AWACs and F-15s pilots to come to incorrect and fatal conclusions

## 7  TEACHING THE COMPUTER

Teaching or programming a task, including a goal state and a procedure for achieving it and including constraints and criteria, can be formidable or quite easy, depending on the command hardware and software. By command hardware is meant the way in which human response (hand, foot, or voice) is converted to physical signals to the computer. Command hardware can be either analogic or symbolic. Analogic means that there is a spatial or temporal isomorphism among human response, semantic meaning, and/or feedback display. For example, moving a control up rapidly to increase the magnitude of a variable quickly, which causes a display indicator to move up quickly, would be a proper analogic correspondence.

Symbolic command, by contrast, is accomplished by depressing one or a unique series of keys (as typing words on a typewriter) or uttering one or a series of sounds (as in speaking a sentence), each of which has a distinguishable meaning. For symbolic commands a particular series or concatenation of such responses has a different meaning from other concatenations. Spatial or temporal correspondence to the meaning or desired result is not a requisite. Sometimes analogic and symbolic can be combined: for example, where up–down keys are both labeled and positioned accordingly.

It is natural for people to intermix analogic and symbolic commands or even to use them simultaneously. Typical industrial robots are taught by a combination of grabbing hold and leading the endpoint of the manipulator around in space relative to the workpiece, at the same time using a switch box on a cable (a teach pendant) to key in codes for start, stop, speed, and so on, between various reference positions. This happens, for example, when a person talks and points at the same time or plays the piano and conducts a choir with his or her head or free hand.

In regard to teaching the computer, Ferris et al (2010) use the term *directability*, which they define as ability to direct efficiently and safely the activities of the automation. They point out that the interface must be designed to avoid what Norman 1986 has called the gulf of execution, "where an operator struggles with identifying and operating the proper controls and commands to translate an intended action into the machine's language." They point out that problems occur when, for example, different aircraft employ automation controls with similar shape, feel, and/or location that activate different systems or require different manipulations (Abbott et al., 1996). Such inconsistencies can leave pilots who transition between aircraft or airlines highly vulnerable to errors, especially when under stress.

Supervisory command systems have been developed for mechanical manipulators that utilize both analogic and symbolic interfaces with the supervisor and that enable teaching to be both rapid and available in terms of high-level language. Brooks (1979) developed such a system, which he called SUPERMAN, which allows the supervisor to use a master arm to identify objects and demonstrate elemental motions. He showed that even without time delay for certain commands, which refer to predefined location, supervisory control that included both teaching and execution took less time and had fewer errors than manual control.

Yoerger (1982) developed a more extensive and robust supervisory command system that enables a variety of arm–hand motions to be demonstrated, defined, called on, and combined under other commands. In one set of experiments, Yoerger compared three different procedures for teaching a robot arm to perform a continuous seam weld along a complex curved workpiece. The end effector (welding tool) had to be kept 1 in. away and retain an orientation perpendicular to the curved surface to be welded and move at constant speed. Yoerger tested his subjects in three command (teaching) modes. The first mode was for the human teacher to move the master (with slave following in master–slave correspondence) relative to the workpiece in the desired trajectory. The computer would memorize the trajectory and then cause the slave end effector to repeat the trajectory exactly. The second mode was for the human teacher to move the master (and slave) to each of a series of positions, pressing a key to identify each. The human would then key in additional information specifying the parameters of a curve to be fit through these points and the speed at which it was to be executed, and the computer would then be called upon for execution. The third mode was to use the master–slave manipulator to contact and trace along the workpiece itself, to provide the computer with the knowledge of the location and orientation of the surfaces to be welded. Then, using the typewriter keyboard, the human teacher would specify the positions and orientations of the end effector relative to the workpiece. The computer could then execute the task instructions relative to the geometric references given.

Identifying the geometry of the workpiece analogically and then giving symbolic instructions relative to it proved the constant winner. The reasons for this advantage apparently are the same as for Brooks's results

described previously, provided of course that the time spent in the teaching loop is sufficiently short.

There are many programming languages for industrial robots, but a lack of standardization of programming methods for robots poses challenges. For example, there are over 30 different manufacturers of industrial robots, so there are also 30 different robot programming languages required.

Some robot programming languages are essentially visual. The software system for the Lego Mindstorms NXT robots is worthy of mention. It is based on and written by Labview. The approach is to start with the program rather than the data. The program is constructed by dragging icons into the program area and adding or inserting them into a sequence. For each icon you then specify the parameters (data). For example, for the motor drive icon you specify which motors and by how much they move.

A *scripting language* is a high-level programming language that is used to control the software application and is interpreted in real time, or "translated on the fly," instead of being compiled in advance. A scripting language may be a general-purpose programming language or it may be limited to specific functions used to augment the running of an application or system program. Some scripting languages, such as RoboLogix, have data objects residing in registers, and the program flow represents the list of instructions, or instruction set, that is used to program the robot. The RoboLogix instruction set is shown in Figure 8.

Programming languages are generally designed for building data structures and algorithms from scratch, while scripting languages are intended more for connecting, or "gluing," components and instructions together. Consequently, the scripting language instruction set is usually a streamlined list of program commands that are used to simplify the programming process and provide rapid application development.

Teaching airplane autopilots is a good example of the teaching role in supervisory control. Modern airplanes can now adjust their throttle, pitch, and yaw damping characteristics automatically. They can take off and climb to altitude autonomously or fly to a given latitude and longitude and can maintain altitude and direction despite wind disturbances. They can approach and land automatically in zero-visibility conditions. To do these tasks, airplanes make use of artificial sensors, motors, and computers programmed in supervisory fashion by pilots and ground controllers. In this sense airplanes are telerobots in the hands of their pilot teachers. In the aviation world the supervising pilot is called a flight manager.

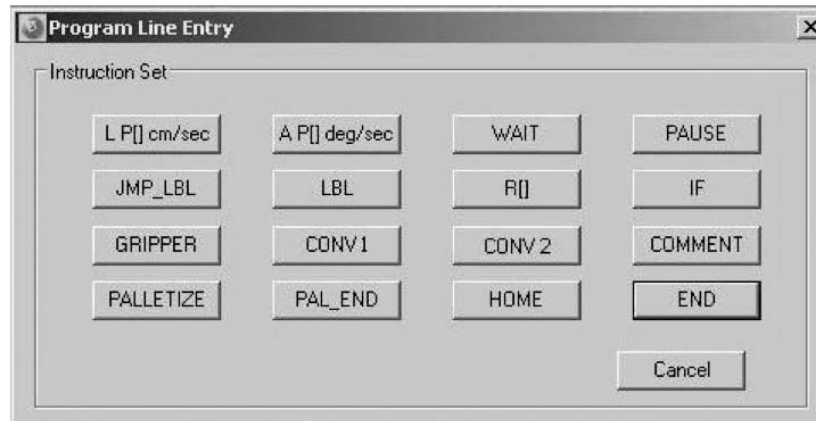
The flight management system (FMS) is the aircraft embodiment of the HIC discussed previously and currently is where the supervisory teaching is done. The typical FMS has a cathode ray tube (CRT) display and both generic and dedicated keysets. More than 1000 modules provide maps for terrain and navigational aids, procedures, and synoptic diagrams of various electrical and hydraulic subsystems. Proposed electronic maps show planned flight route, weather, and other navigational aids. When the pilot enters a certain flight


**Figure 8**   RoboLogix instruction set (from Wikipedia).

plan, the FMS can visualize the trajectory automatically and call attention to any waypoints that appear to be erroneous on the basis of a set of reasonable assumptions. Conflict probe displays call the ground controller's attention to incipient separation violations, while cockpit traffic displays do the same for the pilot.

The problem of authority is one of the most difficult (Boehm-Davis et al., 1983). Popular mythology is that the pilot is (or should be) in charge at all times. But when a human turns control over to an automatic system, it is the exception that she or he can do something else for a while (as in the case of setting one's alarm clock and going to sleep). It is also recognized that there are limited windows of opportunity for escaping from the automation (once you get on an elevator you can get off only at discrete floor levels). People are seldom inclined to "pull the plug" unless they receive clear signals indicating that such action must be taken and unless circumstances make it convenient for them to do so. Examples of some current debates follow:

1. Should there be certain states or a certain envelope of conditions for which the automation will simply seize control from the pilot?

2. Should the computer deviate from a programmed flight plan automatically if critical unanticipated circumstances arise?

3. If the pilot programs certain maneuvers ahead of time, should the aircraft execute these automatically at the designated time or location, or should the pilot be called upon to provide further concurrence or approval?

4. In the case of a subsystem abnormality, should the affected subsystem be reconfigured automatically, with after-the-fact display of what has failed and what has been done about it? Or should the automation wait to reconfigure until after the pilot has learned about the abnormality, perhaps been given some advice on the options, and had a chance to take initiative?

It is important to emphasize that simple and ideal command-and-feedback patterns are not to be expected as systems get more complex. In interactions between a human supervisor and his or her subordinates, or a teacher and the students, it can be expected that the teaching process will not be a one-way communication. Some feedback will be necessary to indicate whether the message is understood or to convey a request for clarification on some aspect of the instructions. Further, when the subordinate or student does finally act on the instruction, the supervisor may not understand from the immediate feedback what the subordinate has done and may ask for further details. This is illustrated in Figure 9 by the light arrows, where the bold arrows characterize the conventional direction of information in feedback control.

Teaching a computer for supervisory control actually goes beyond what can be thought of as providing if–then–else instructions for mechanical actions (as with a robot or vehicle), usually called the *control law*. It also includes setting or changing parameters of how properties of the system (states) are measured, how such information is displayed, how the interaction of the system with its environment is modeled or simulated for planning future actions, as well as properties of the control interface. These many options for system parameter change are illustrated in Figure 10.

## 8   MONITORING OF DISPLAYS AND DETECTION OF FAILURES

The human supervisor monitors the automated execution of the task to ensure proper control (Parasuraman, 1987). This includes intermittent adjustment or trimming if the process performance remains within satisfactory limits. It also includes detection of if and when it goes outside limits and the ability to diagnose failures or other abnormalities. The subject of failure detection in human–machine systems has received considerable attention (Rasmussen and Rouse, 1981). Moray (1986) regards such failure detection and diagnosis as the most

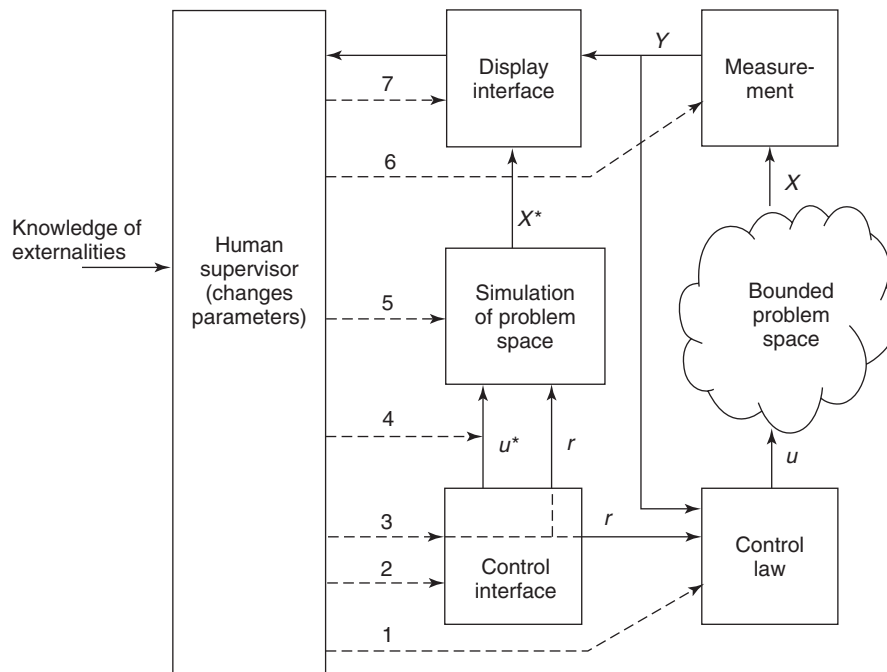

**Figure 10**  Set of options for changing parameters in supervisory control.

important human supervisory role. I prefer the view that all five supervisory roles are essential and that no one can be placed above the others.

The supervisory controller tends to be removed from full and immediate knowledge about the controlled process. The physical processes that he or she must monitor tend to be large in number and distributed widely in space (e.g., around a ship or plant). The physical variables may not be immediately sensible by him or

her (e.g., steam flow and pressure) and may be computed from remote measurements on other variables. Sitting in the control room or cockpit, the supervisor is dependent on various artificial displays to give feedback of results as well as knowledge of new reference inputs or disturbances. These factors greatly affect how he or she detects and diagnoses abnormalities in the process, but whether removal from active participation in the control loop makes it harder (Ephrath and

Young, 1981) or easier (Curry and Ephrath, 1977) remains an open question. Gai and Curry (1978) and Wickens and Kessell (1979, 1981) have studied various psychophysical aspects of this problem.

Ferris et al. (2010) call attention to what they call *observability* (i.e., lack of adequate feedback about targets, actions, decision logic, or operational limits). The concept comports with the same term in control theory, which has to do with how well the internal states of a system can be inferred by knowledge of its external outputs:

> Low observability has been shown to lead to a lack or loss of mode awareness, that is, a lack of knowledge and understanding of the current and future automation configuration and behavior . . . One manifestation of reduced mode awareness are automation surprises, in which pilots detect a discrepancy between actual and expected or assumed automation behavior . . . often resulting from uncommanded or indirect (i.e., without an explicit instruction by the pilot) mode transitions.

These authors also discuss the serious problem of mode awareness and errors. Mode errors of *commission* occur when a pilot executes an action that is appropriate for the assumed but not the actual current mode of the system. Mode errors of *omission* take place when the pilot fails to take an action that would be required given the currently active automation configuration and behavior (Abbott et al., 1996).

Sarter et al. (2007) describe a study in which airline pilots participated in a full-mission 747-400 simulation that included a variety of challenging automation events. Using eye motion instrumentation, they found that pilots monitor basic flight parameters to a much greater extent than visual indications of the automation configuration. More specifically, pilots frequently fail to verify manual mode selections or notice automatic mode changes. In other cases, they do not process mode annunciations in sufficient depth to understand their implications for aircraft behavior.

In traditional control rooms and cockpits the tendency has been to provide the human supervisor with an individual and independent display of each variable and for a large fraction of these to provide a separate additional alarm display that lights up when the corresponding variable reaches or exceeds some value. Thus, modern aircraft may easily have over 1000 displays and modern chemical or power plants 5000 displays. In the writer's experience, in one nuclear plant training simulator, during the first minute of a "loss of coolant accident," 500 displays were shown to have changed in a significant way, with 800 more in the second minute.

Clearly, no human being can cope with so much information coming simultaneously from so many seemingly disconnected sources. Just as clearly, such signals in any real operating system actually are highly correlated. In real-life situations in which we move among people, animals, plants, or buildings, our eyes, ears, and other senses easily take in and comprehend vast amounts of information just as much as in the power plant. Our

genetic makeup and experience enable us to integrate the bits of information from different parts of the retina and from different senses from one instant to the next, presumably because the information is correlated. We say we "perceive patterns" but do not pretend to understand how. In any case the challenge is to design displays in technological systems to somehow integrate the information to enable the human operator to perceive patterns in time and space and across the senses. As with teaching (command), the forms of display may be either analogic (e.g., diagrams, plots) or symbolic (e.g., alphanumerics) or some combination.

In the nuclear power industry the safety parameter display system (SPDS) is now required of all plants in some form. The idea of the SPDS is to select a small number (e.g., 6–10) of variables that tell the most about plant safety status and to display them in integrated fashion such that by a glance the human operator can see whether something is abnormal and, if so, what and to what relative degree. Figure 11 shows an example of an SPDS. It gives the high-level or overview display (a single computer "page"). If the operator wishes more detailed information about one variable or subsystem, he or she can page down (select lower levels). These can be diagrams having lines or symbols that change color or flash to indicate changed status and alphanumeric to give quantitative or more detailed status. These can also be bar graphs or cross plots or integrated in other forms. One novel technique is the Chernoff face (Figure 11*c*), in which the shapes of eyes, ears, nose, and mouth differ systematically to indicate different values of variables, the idea being that facial patterns are easily perceived. Allegedly, the Nuclear Regulatory Commission, fearful that some enterprising designer might employ this technique before it was proven, formally forbade it as an acceptable SPDS.

As noted previously (Figure 3), an important potential of the HIC is for modeling the controlled process. Such a model may then be used to generate a display of observed state variables that cannot be seen or measured directly. Another use is to run the model in fast time to predict the future, given of course that the model is calibrated to reality at the beginning of each such predictive run. A third use, now being developed for application to remote control of manipulators and vehicles in space, helps the human operator cope with telemetry time delays (as shown in Figure 12, wherein video feedback is necessarily delayed by at least several seconds). By sending control signals to a computer model as a basis for superposing the corresponding graphic model on the video, the graphic model will "lead" the video picture and indicate what the video will do several seconds hence. This has been shown to speed up the execution of simple manipulation tasks by 70–80% (Noyes and Sheridan, 1984).

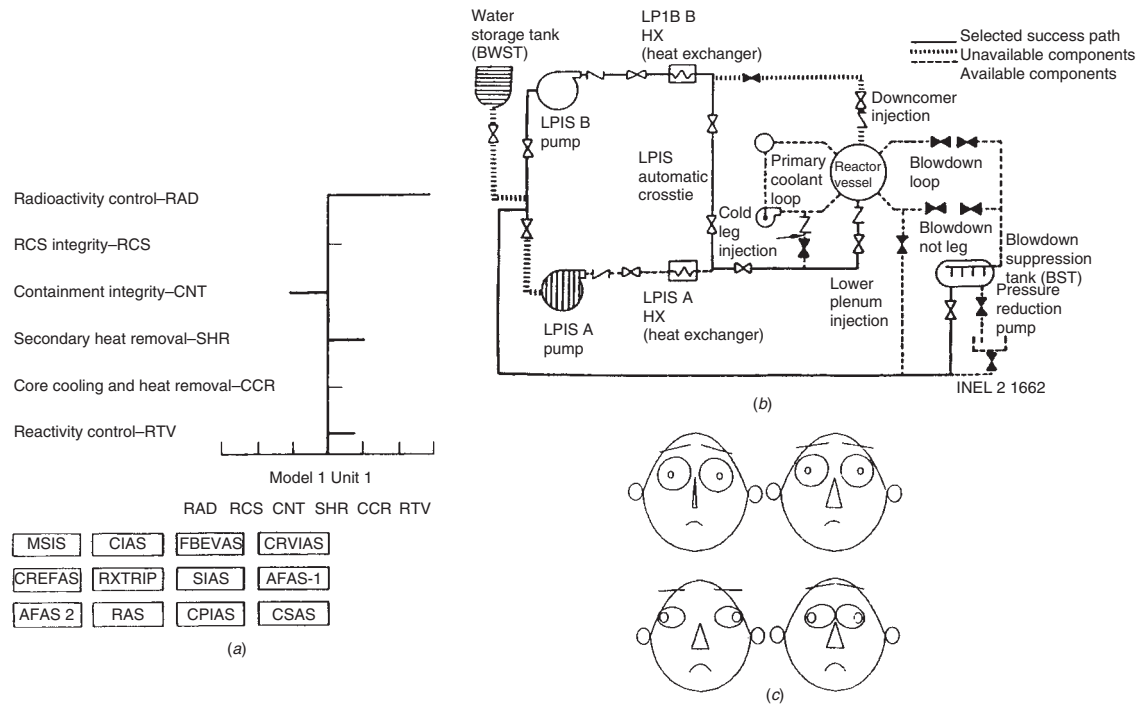
Advances in computer graphics, as driven by the computer game industry, film animation and special effects, and other simulations (virtual reality), have meant that computer displays are theoretically limitless in what they can display: dynamically at high resolution, in color, and on a head-mounted display if that is called for. The challenge for the display designer is then:


**Figure 11** Safety parameter display system for a nuclear power plant.

What will provide the most effective interaction with the human supervisor?

A final aspect of supervisory monitoring and display concerns format adaptivity—the ability to change the format and/or the logic of the displays as a function of the situation. Displays in aerospace and industrial systems now have fixed formats (e.g., the labels, scales, and ranges are designed into the display). Alarms have fixed set points. However, future computer-generated displays even for the same variables may be different at various mission stages or in various conditions. Thus, formats may differ for aircraft takeoff, landing, and on-route travel and be different for plant startup, full-capacity operation, and emergency shutdown. Some alarms have no meaning or may be expected to go off when certain equipment is being tested or taken out of service. In such a case adaptive formatted alarms may be suppressed or the set points changed automatically to correspond to the operating mode. Future displays and alarms could also be formatted or adjusted to the personal desires of the supervisor to provide any time scale, degree of resolution, and so on, necessary at the time. Ideally, some future displays could adapt based on a running model of how the human supervisor's perception was being enhanced.

A currently popular research challenge is to measure highway vehicle driver task workload and whether driver's use of the potential in-vehicle information distracters, such as cell phone, radio, navigation system, and so on, should be prohibited during busy demands of traffic (Boer, 2000; Llaneras, 2000; Lee et al., 2002). This would make the driver interfaces adaptive.

There are hazards, of course, in allowing emergency displays to be too flexible, to the point where they cause errors rather than preventing them. Mode errors, where the operator believes that he or she is operating in one mode but actually is operating in a different mode, can be dangerous. An example of where flexibility in monitoring displays went awry was in an aircraft accident that occurred in Europe several years ago. In this instance the pilot could ask to have either descent rate (thousands of feet per minute) or descent angle (degrees) presented, and depending on how the model control panel had been set, the number was indicated by two digits displayed at the same location. In this case the pilot forgot which mode he had requested (although that information was also displayed but at a different location). The result was a misreading and a tragic crash.

## 9 INTERVENING AND HUMAN RELIABILITY

Sarter and Woods (2000) and Wiener (1988) write about automation surprises, the tendency of automatic systems to catch the human supervisor off-guard such that the human thinks: What is the automation doing now? What will it do next? How did I get into this mode? Why did it do this? How do I stop the machine from doing this? Why won't it do what I want?

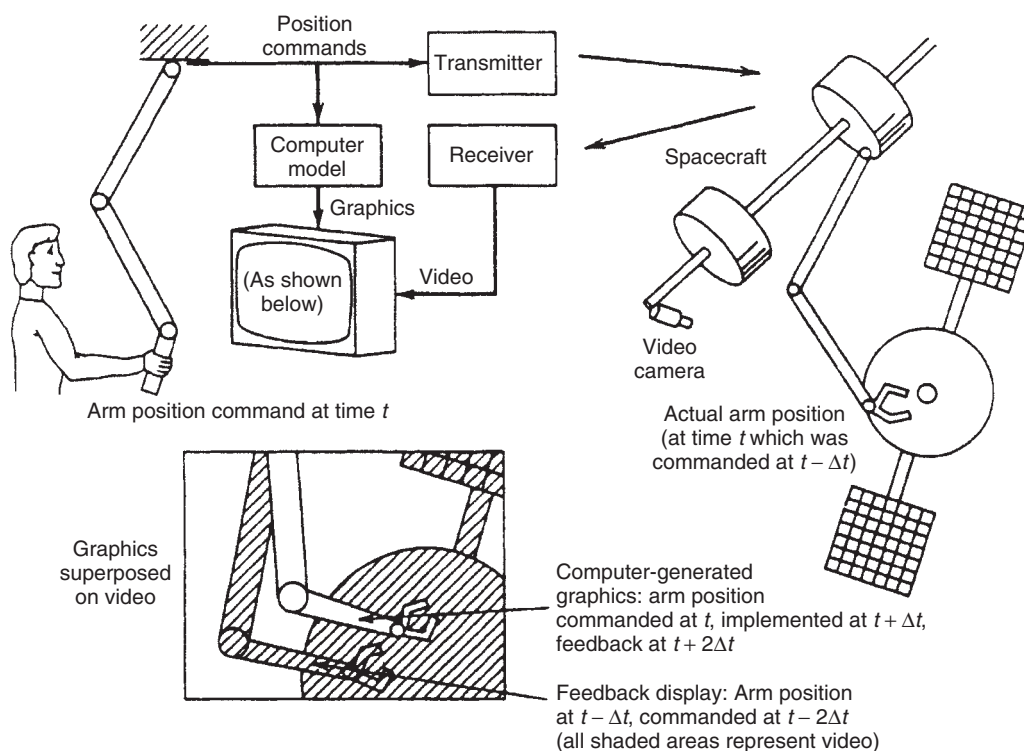
The challenge of surprise is a great one, and there are no easy answers. Computers do what they have been


**Figure 12**   Predictor display for delayed telemanipulator.

programmed to do, which is not always what the user intended. User education—toward better understanding of how the system works—is one remedy. Another is to provide error messages that are couched in a language understandable to the operator (not in the jargon of the computer programmer, a problem so familiar to all users of computers). Generally, the solution lies in some form of feedback—to lead the human in making a mild or radical intervention, as appropriate.

The supervisor decides to intervene when the computer has completed its task and must be retaught for the next task, when the computer has run into difficulty and requests of the supervisor a decision as to which way to go, or when the supervisor decides to stop automatic action because he or she judges that system performance is not satisfactory. Intervention is a problem that really has not received as much attention as teaching and monitoring. Yet systems are being planned in which the supervisory operator is expected to receive advice from a computer-based system about remote events and within seconds decide whether to accept the computer's advice (in which case the response is commanded automatically) or reject the advice and generate his or her own commands (in effect, intervene in an otherwise automatic chain of events).

It is at the intervention stage that human error most reveals itself. Errors in learning from past experience, planning, teaching, and monitoring will surely exist. Many of these are likely to be corrected as the supervisor

notes them "during the doing." It is after the automatic system is functioning and the supervisor is monitoring intermittently that those human errors make a difference and where it is therefore critical that the human supervisor intervene in time and take appropriate action when something goes wrong. Thus, the intervention stage is where human error is most manifest.

If human error is not caught by the supervisor, it is perpetuated slavishly by the computer, much as happened to the Sorcerer's Apprentice. For this reason supervisory control may be said to be especially sensitive to human error. Several factors affect the supervisor's decision to intervene and/or his or her success in doing so.

1. *Trade-Off between Collecting More Data and Taking Action in Time*. The more data collected from the more sources, the more reliable is the decision of what, if anything, is wrong and what to do about it. Weighed against this is that if the supervisor waits too long, the situation will probably get worse, and corrective action may be too late. Formally, the optimization of this decision is called the *optional stopping problem*.

2. *Risk Taking*. The supervisor may operate from either risk-averse criteria such as minimax (minimize the worst outcome that could happen) or more risk-neutral criteria such as expected value (maximize the subjectively expected gain).

Depending on the criterion, the design of a supervisory control system may be very different in complexity and cost.

3. *Mental Workload*. This problem is aggravated by supervisory control. When a supervisory control system is operating well in the automatic mode, the supervisor may have little concern. When there is a failure and sudden intervention is required, the mental workload may be considerably higher than in direct manual control, where in the latter case the operator is already participating actively in the control loop. In the former case the supervisor may have to undergo a sudden change from initial inattention, moving physically and mentally to acquire information and learn what is going on, then making a decision on how to cope. Quite likely this will be a rapid transient from very little to very high mental workload.

Although the subject of human error is currently of great interest, there is no consensus on either a taxonomy or a theory of causality of errors. One common error taxonomy relates to locus of behavior: sensory, memory, decision, or motor. Another useful distinction is between errors of omission and those of commission. A third is between slips (correct intentions that inadvertently are not executed) and mistakes (intentions that are executed but that lead to failure).

In supervisory control there are several problems of human error worth particular mention. One is the type of slip called capture. This occurs when the intended task requires a deviation from a well-rehearsed (behaviorally) and well-programmed (in the computer) procedure. Somehow habit, augmented by other cues from the computer, seems to capture behavior and drive it on to the next (unintended) step in the well-rehearsed and computer-reinforced routine.

A second supervisory error, important in both planning and failure diagnosis, results from the human tendency to seek confirmatory evidence for a single hypothesis currently being entertained (Gaines, 1976). It would be better if the supervisor could keep in mind a number of alternative hypotheses and let both positive and negative evidence contribute symmetrically in accordance with the theory of Bayesian updating (Sheridan and Ferrell (1974). Norman (1981), Reason and Mycielska (1982), Rasmussen (1982), and Rouse and Rouse (1983) provide reviews of human error research from their different perspectives.

Theoretically, anything that can be specified in an algorithm can be given over to the computer. However, the reason the human supervisor is present is to add novelty and creativity: precisely those ingredients that cannot be prespecified. This means, in effect, that the best or most correct human behavior cannot be prespecified and that variation from precise procedure must not always be viewed as errant noise. The human supervisor, by the nature of his or her function, must be allowed room by the system design for what may be called trial and error (Sheridan, 1983).

What training should the human supervisory controller receive to do a good job at detecting failures and intervening to avoid errors? As the supervisor's task becomes more cognitive, is the answer to provide training in theory and general principles? Curiously, the literature seems to provide a negative answer (Duncan, 1981). In fact, Moray (1986), in his review, concludes that there seems to be no case in the literature where training in the theory underlying a complex system has produced a dramatic change in fault detection or diagnosis. Rouse (1985) similarly concludes "that the evidence [e.g., Morris and Rouse (1985)] does not support a conclusion...that diagnosis of the unfamiliar requires theory and understanding of system principles." Apparently, frequent hands-on experience in a simulator (i.e., with simulated failures) is the best way to enable a supervisor to retain an accurate mental model of a process.

A final issue to be mentioned in conjunction with human reliability is that of trust. It comes in two forms: overtrust, also called automation bias, and under trust. Ferris et al. (2010) provide illustrations of both. An example of overtrust occurred in the fatal 1995 accident over Cali, Columbia, where pilots got confused over waypoint indications and were far off course but neverthess trusted the FMS to take care of them as they flew into a mountain. An example of untertrust was a survey of fighter pilots who opinied that UAVs could never replace human piloted aircraft in various search and other missions.

## 10 MODELING SUPERVISORY CONTROL

For 35 years various models of supervisory control have been proposed. Most of these have been models of particular aspects of supervisory control, not apparently claiming to model all or even very many aspects of it. The simplest model of supervisory control might be that of nested control loops (Figure 13), where one or more

**Figure 13** Nested control loops of aerospace vehicle.

inner loops are automatic and the outer one is manual. In aerospace vehicles the innermost of four nested loops is typically called "control," the next "guidance," and the next "navigation," each having a set point determined by the next outer loop. Hess and McNally (1997) have shown how conventional manual control models can be extended to such multiloop situations. The outer loop in this generic aerospace vehicle includes the human operator, who, given mission goals, programs in the destination. In driving a car the functions of navigation, guidance, and control are all done by a person and can be seen to correspond roughly to knowledge-based, skill-based, and rule-based behavior.

Figure 14 is a qualitative functional model of supervisory control, showing the various cause–effect loops or relationships among elements of the system and emphasizing the symmetry of the system as viewed from top and bottom (human, task) of the hierarchy.

Figure 15 extends Rasmussen's model of skill-based, rule-based, and knowledge-based behavior to show various interactions with computer aids having comparable levels of intelligence.

One problem the supervisor faces is allocating attention between different tasks, where each time that he or she switches tasks there is a time penalty in transfer, typically different for different tasks and possibly

1. Task is observed directly by human operator's own senses.

2. Task is observed indirectly through artificial sensors, computers, and displays. This TIS feedback interacts with that from within HIS and is filtered or modified.

3. Task is controlled within TIS automatic mode.

4. Task is affected by the process of being sensed.

5. Task affects actuators and in turn is affected.

6. Human operator directly affects task by manipulation.

7. Human operator affects task indirectly through a controls interface, HIS/TIS computers, and actuators. This controls interaction with that from within TIS and is filtered or modified.

8. Human operator gets feedback from within HIS, in editing a program, running a planning model, etc.

9. Human operator orients him or herself relative to control or adjusts control parameters.

10. Human operator orients him or herself relative to display or adjusts display parameters.

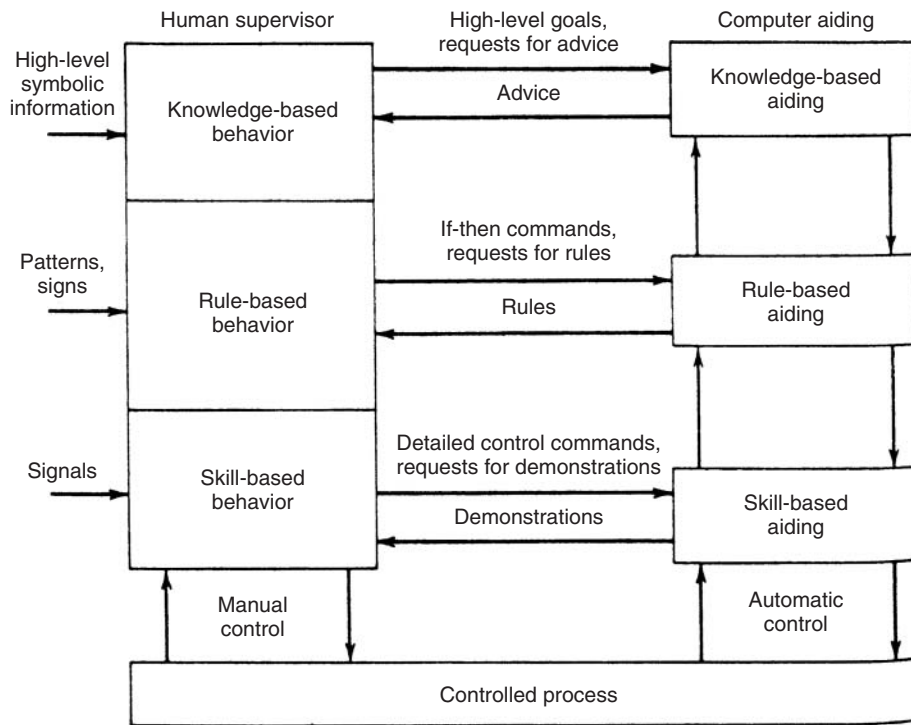
**Figure 14**　Multiloop model of supervisory control. (From Sheridan, 1984.)


**Figure 15** Supervisor interactions with computer decision aids at knowledge, rule, and skill levels.

involving uses of different software procedures, different equipment, and even bodily transportation of himself or herself to different locations. Given relative worths for time spent attending to various tasks, it has been shown (Sheridan, 1970) that dynamic programming enables the optimal allocation strategy to be established. Moray et al. (1982) applied this model to deciding whether human or computer should control various variables at each succeeding moment. For simpler experimental conditions, the model fit the experimental data (subjects acted like utility maximizers), but as task conditions became complex, apparently it did not. Wood and Sheridan (1982) did a similar study where supervisors could select among alternative automatic machines (differing in both rental cost and productivity) to do assigned tasks or do the tasks themselves. Results showed the supervisors to be suboptimal, paying too much attention to costs and too little to productivity, and in some cases using the automation when they could have done the tasks more efficiently manually. Govindaraj and Rouse (1981) modeled the supervisor's decisions to divert attention from a continuous task to perform or monitor a discrete task.

Rouse (1977) utilized a queueing theory approach to model whether from moment to moment a task should be assigned to a computer or to the operator. The allocation criterion was to minimize service time under cost constraints. Results suggested that human–computer "misunderstanding" of one another degraded efficiency more than limited computer speed. In a related flight simulation study, Chu and Rouse (1979) had a computer

perform those tasks that had waited in the queue beyond a certain time. Chu et al. (1980) extended this idea to have the computer learn the pilot's priorities and later make suggestions when the pilot was under stress.

Tulga and Sheridan (1980) and later Pattipatti et al. (1983) utilized a model of allocation of attention among multiple task demands, a task displayed on the computer screen to the subject as is represented in Figure 16. Instead of being stationary, these demands appear at random times (not being known until they appear), exist for given periods of time, then disappear at the end of that time with no more opportunity to gain anything by attending to them, While available, they take differing amounts of time to complete and have differing rewards for completion, which information may be available after they appear and before they are "worked on." The human decision maker in this task need not allocate attention in the same temporal order in which the task demands become known, nor in the same order in which their deadline will occur. Instead, he or she may attend first to that task which has the highest payoff or takes the least time and/or may plan ahead a few moves so as to maximize gains. The Tulga–Sheridan experimental results suggest that subjects approach optimal behavior, which, when heavily loaded (i.e., there are more opportunities than he or she can possibly cope with), simply amounts to selecting the task with highest payoff regardless of time to deadline. These subjects also reported that their sense of subjective workload was greatest when by arduous planning they could barely keep up with all
**Figure 16** Multitask computer display used in the Tulga–Sheridan experiment.

tasks presented. When still more tasks came at them and they had to select which they could do and which they had to off-load, subjective workload decreased.

Researchers and designers of supervisory control systems must cope with a number of questions. Among these are (1) how much autonomy is appropriate for the TIC, (2) how much the TIC and the HIC should tell the human supervisor, and (3) how responsibilities should be allocated among the TIC, HIC, and supervisor (Johannsen, 1981).

The famous Yogi Berra allegedly counseled: "Never make predictions, especially about the future!" Nevertheless, it is ethically mandatory that we predict as best we can. However, recent decades have seen a shift away from monolithic, computationally predictive models toward frameworks or categorizations of models, each of which may be quite simple—involving elementary control laws, a few heuristics, or pattern recognition rules. Thus, as knowledge and understanding of supervisory control have grown, along with its complexity, researchers have come to realize that they need not and cannot be held to comprehensive predictive models, desirable as they may be.

The most difficult, and it might even be said impossible, aspect of supervisory control to model is that of setting in goals, conditions, and values. Even though overall goals may be given to an actual system (or given in an experiment), how those are translated into subgoals and conditional statements remains elusive. The same is true for communicating values (criteria, coefficients of utility, etc.). Although this act of evaluation remains the sine qua non of why human participation in system control must remain, there is little prospect for mathematical modeling of this aspect in the near future.

## 11 POLICY ALTERNATIVES FOR HUMAN SUPERVISORY CONTROL

This section confronts the question of what policies might be adopted in dealing with the human–automation

interaction challenges that are unavoidable in the systems discussed here. Dilemmas will surely arise with regard to (a) when not to follow the recommendation of a decision support tool or when to bypass automation when either is believed to have failed or not be appropriate to the current situation and (b) how long to wait for automation to act before intervening manually.

The public will still demand both safety and efficiency and may continue to place stringent expectations on the human to provide both unless and until automation can prove itself sufficiently robust and reliable. New technology permits closer surveillance of human behavior. These facts could even exacerbate the pressures to maintain the "blame game" of punishing what may be seen as errant behavior, even though it is fully recognized that all human beings are inclined to err from time to time (Kohn et al., 2000). Institutional cultures change slowly, even given that large human–machine system developments such as NextGen have explicitly embodied efforts to work toward a "just culture" (Dekker, 2007) in dealing with human frailties. That puts a new emphasis on learning from mistakes rather than on meting out punishment.

It seems that five alternative policy approaches with regard to human operator roles and responsibilities can be distinguished (Sheridan, 2010). These are offered as contrasting approaches. Most likely some amalgam of these will be adopted by management in different system contexts.

1. *Maintain the typical status quo of full human operator responsibility.* Operators would undergo extensive training in decision support tools and automation so they could understand their use and limitations. Accordingly, they would be expected to use them wisely and continue to be responsible for safety and operations. The advantage of this approach

would be to minimize the need for policy and training changes in an evolving system. The disadvantage would be in leaving open dilemmas faced by the human operators as to what to do when automation seems to be inadequate to handle a situation or the controller is unsure of whether the automation will act before it is too late.

2. *Define explicit behavior thresholds and criteria to determine when controllers would be held responsible*. For example, in NextGen the automation will assume certain control functions previously performed by ground controllers communicating with pilots and vectoring aircraft, so controllers might be instructed not to bypass or override the automation unless and until certain explicit criteria (with respect to time, distance, etc.) are met. The ground controllers would be trained accordingly. The advantage of this approach would be that the controller would have very specific rules as to his or her responsibility. The disadvantage would be that defining such rules might be difficult to agree on and in any case seem to limit the controller's discretion. Further, the more detailed the rules are that the controller is asked to commit to memory, the more likely that some details will be forgotten or confused.

3. *Define and emphasize in both training and operation the ideal behavior and rationale to be used for each operation*. The advantage would be that with operators understanding and appreciating the basic operational concepts they could make best use of their professional expertise and experience. The disadvantage would be that there may not be uniformity in their response to events, particularly off-nominal events.

4. *Expect operators to "always do their best" in deciding when and how to employ automation or to bypass or override*. The (refined) record-keeping would determine whether they would be exonerated in any mishap. The advantage of this approach would be that the operator would be somewhat protected if the evidence showed he or she was really trying but the constraints of the situation were just too much to handle. The disadvantage would be that operators might be motivated toward laxity, hoping in any case to claim they were doing their best based on the evidence.

5. *Expect operators to "always do their best" but allow them to signal in real time when they feel they must intervene in an automated process*. Encourage them to announce when they have a decision dilemma or regard the situation as untenable. The advantage would be to add evidence to the record of what happened. The disadvantage would be the same as that under 4 above.

## 12 SOCIAL IMPLICATIONS AND THE FUTURE OF HUMAN SUPERVISORY CONTROL

One near certainty is that, as technology of computers, sensors, and displays improves, supervisory control will become more prevalent. This should occur in two ways: (1) a greater number of semiautomated tasks will be controlled by a single supervisor (a greater number of TICs will be connected to a single HIC) and (2) the sophistication of cognitive aids, including expert systems for planning, teaching, monitoring, failure detection, and learning, will increase and include more of what we now call knowledge-based behavior in the HIC.

The World Wide Web has enabled easy worldwide communication (for those properly equipped). One aspect of that communication that up to now has hardly become manifest is the ability to exercise remote control. A number of experimental demonstrations have been performed on controlling robots between continents, and in military operations UAVs are being controlled this way, but delayed feedback still poses a difficulty for continuous control, so supervisory control clearly has an advantage here. In the future we should see many more applications of moderate- and long-distance remote control.

Concurrently, understanding by the layperson (including those of both corporate and government bureaucracies) should come to understand the potential of supervisory control much better. At the present time the layperson tends to see automation as "all or none," where a system is controlled either manually or automatically, with nothing in between. In robotized factories the media tend to focus on the robots, with little mention of design, installation, programming, monitoring, fault detection and diagnosis, maintenance, and various learning functions that are performed by people. In the space program the same is true; options are seen to be either "automated," "astronaut in extravehicular activity (EVA)," or "astronaut or ground controlling telemanipulator" without much appreciation for the potential of supervisory control.

In considering the future of supervisory control relative to various degrees of automation and to the complexity or unpredictability of task situations to be dealt with, a representation such as Figure 17 comes to mind. The meaning of the four extremes of this rectangle are quite identifiable. Supervisory control may be considered to be a frontier (line) advancing gradually toward the upper right-hand corner.

For obvious reasons, the tendency has been to automate what is easiest and to leave the rest to the human. This has sometimes been called the technological imperative. From one perspective this dignifies the human contribution; from another it may lead to a hodge-podge of partial automation, making the remaining human tasks less coherent and more complex than need be, resulting in overall degradation of system performance (Bainbridge, 1983; Parsons, 1985)

"Human-centered automation" has become a popular phrase (Billings, 1991) and is often used in relation to human supervisory control. Therefore, to end this chapter, we might consider its alternative meanings. Below are 10 alternative meanings (stated in italics) that
**Figure 17** Combinations of human and computer control to achieve tasks at various levels of difficulty.

the author has gleaned from current literature. In every case the meaning must be qualified, as is done by the one or two sentences following each particular meaning of the phrase.

1.  *Allocate to the human the tasks best suited to the human, allocate to the automation the tasks best suited to it.* Yes, but for some tasks it really is easier to do them manually than to initialize the automation to do them. And at the other end of the spectrum are tasks that require so much skill or art or creativity that it simply is not possible to program a computer to do them.

2.  *Keep the human operator in the decision and control loop.* That is a good idea provided that the control tasks are of appropriate bandwidth, attentional demand, and so on.

3.  *Maintain the human operator as the final authority over the automation.* Realistically, this is not always the safest solution. It depends on the task context. In nuclear plants, for example, there are safety functions that cannot be entrusted to the human operator and cannot be overridden by him or her. Examples have been given previously in the case of aircraft automation.

4.  *Make the human operator's job easier, more enjoyable, or more satisfying through friendly automation.* That is fine if operator ease and enjoyment are the primary considerations and if ease and enjoyment necessarily correlate with operator responsibility and system performance, but often these conditions are not the case.

5.  *Empower the human operator to the greatest extent possible through automation.* Again one must remember that operator empowerment is not the same as system performance. Maybe the designer knows best. Don't encourage megalomaniacal operators.

6.  *Support trust by the human operator.* Trust of the automation by the operator is often a good thing, but not always. Too much trust is just as bad as not enough trust.

7.  *Give the operator computer-based information about everything that he or she should want to know.* We now have many examples of where too much information can overwhelm the operator to the point where performance breaks down and even when the operator originally wanted "all" the information.

8.  *Engineer the automation to reduce human error and keep response variability to the minimum.* This, unfortunately, is a simplistic view of human error. Taken literally it reduces the operator to an automaton, a robot. Modest levels of error and response variability enhance learning (Darwin's requisite variety).

9.  *Make the operator a supervisor of subordinate automatic control system(s).* Although this is a chapter on supervisory control, it must be noted that for some tasks direct manual control may be best.

10. *Achieve the best combination of human and automatic control, where best defined by explicit*

*system objectives.* Again, in some ideal case, where objectives can reliably be reduced to mathematics, this would be just fine. Unfortunately, automatic judgment of what is good and bad in a particular situation is seldom possible, even for a machine programmed with the best available algorithms or heuristics. Fortunately, judgment of what is good and bad in a particular situation is almost the essence of what it is to be human.

The bottom line is that proper use of automation depends upon context, which in turn depends upon designer and operator judgment.

I have written elsewhere about the long-term social implications of supervisory control (Sheridan, 1980; Sheridan et al., 1983). My concerns are reviewed here very briefly:

1. *Unemployment.* This is the factor most often considered. More supervisory control means more efficiency, less direct control, and fewer jobs.

2. *Desocialization.* Although cockpits and control rooms now require two- to three-person teams, the trend is toward fewer people per team, and eventually one person will be adequate in most installations. Thus, cognitive interaction with computers will replace that with other people. As supervisory control systems are interconnected, the computer will mediate more and more interpersonal contact.

3. *Remoteness from the Product.* Supervisory control removes people from hands-on interaction with the workpiece or other product. They become not only separated in space but also desynchronized in time. Their functions or actions no longer correspond to how the product itself is being handled or processed mechanically.

4. *Deskilling.* Skilled workers "promoted" to supervisory controller may resent the transition because of fear that when and if called on to take over and do the job manually they may not be able to. They also feel loss of professional identity built up over an entire working life.

5. *Intimidation by Higher Stakes.* Supervisory control will encourage larger aggregations of equipment, higher speeds, greater complexity, higher costs of capital, and probably greater economic risk if something goes wrong and the supervisor does not take the appropriate action.

6. *Discomfort in the Assumption of Power.* The human supervisor will be forced to assume more and more ultimate responsibilities. Depending on one's personality, this could lead to insensitivity to detail, anxiety about being up to the job requirements, or arrogance.

7. *Technological Illiteracy.* Supervisory controllers may lack the technological understanding of how the computer does what it does. They may come to resent this and resent the elite class who do understand.

8. *Mystification.* Human supervisors of computer-based systems could become mystified about the power of the computer, even seeing it as a kind of magic or "big brother" authority figure.

9. *Sense of Not Being Productive.* Although the efficiency and mechanical productivity of a new supervisory control system may far exceed that of an earlier manually controlled system that a given person has experienced, that person may come to feel no longer productive as a human being.

10. *Eventual Abandonment of Responsibility.* As a result of the factors described previously, supervisors may eventually feel that they are no longer responsible for what happens; the computers are.

These 10 potential negatives may be summarized with a single word: alienation. In short, if human supervisors of the new breed of computer-based systems are not given sufficient familiarization with and feedback from the task, sufficient sense of retaining their old skills, or ways of finding identity in new ones, they may well come to feel alienated. They must be trained to feel comfortable with their new responsibility, must come to understand what the computer does and not be mystified, and must realize that they are ultimately in charge of setting the goals and criteria by which the system operates. If these principles of human factors are incorporated into the design, selection, training, and management, supervisory control has a positive future.

## 13 CONCLUSIONS

Computer technology, both hard and soft, is driving the human operator to become a supervisor (planner, teacher, monitor, and learner) of automation and an intervener within the automated control loop for abnormal situations. A number of definitions, models, and problems have been discussed. There is little or no present consensus that any one of these models characterizes in a satisfactory way all or even very much of supervisory control with sufficient predictive capability to entrust to the designer of such systems. It seems that for the immediate future we are destined to run breathless behind the lead of technology, trying our best to catch up.

# CHAPTER 35

# HUMAN DIGITAL MODELING IN DESIGN

**Vincent G. Duffy**
**Purdue University**
**West Lafayette, Indiana**

## 1   DEFINITIONS AND FOUNDATIONS OF HUMAN DIGITAL MODELING

Human digital modeling can be considered a digital representation of the human inserted into a simulation or virtual environment to facilitate prediction of safety and/or performance (Duffy, 2009a; Demirel and Duffy, 2007a). These include some visualization as well as the math and/or science in the background (Duffy, 2009a; Demirel and Duffy, 2007b). Applications in this field demonstrate how to reduce the need for prototyping and incorporate ergonomics and human factors earlier in the design process (Duffy, 2010b; Applied Human Factors and Ergonomics International, 2012). Recent new model development and applications include aviation models, manufacturing and service industries, virtual ergonomic assessment, anthropometrics, automotive design, human shape design, Bayesian modeling, human behavior modeling, risk assessment modeling, and validation (Duffy, 2010b). These will be outlined in this chapter. In the consumer-driven marketplace, the time it takes to bring a new or modified product to market can support or hinder new product launch. Human digital modeling can improve time to market and increase safety and ultimately the profitability of the organization (Duffy, 2010b).

As was stated in the preface in a recent related book, the growing body of literature in human digital modeling makes it difficult for newcomers to identify the key elements quickly (Duffy, 2009b). This chapter is intended to summarize what is available as new developments in the field while incorporating the foundations that these recent developments were built upon. Within this emerging area, there exists opportunity for human factors and ergonomics practitioners and researchers to develop a common language for better communication with practicing engineers and product designers. At present, very few in the human factors and ergonomics community have the opportunity for formal coursework that incorporates digital human modeling. In addition, Chaffin notes that "we are graduating very few engineers (probably less than 10%) who even have a first course in human factors and ergonomics" (Chaffin, 2005) and encourages participation from the human factors and ergonomics community in this emerging area (Chaffin, 2002).

For a human factors community, the term *human digital modeling* may really make more sense than *digital human modeling*, which is why human digital modeling has really become a human factor and the title of this chapter has used the reverse order wording "human digital modeling" to draw the attention of human factors and ergonomics practitioners who may consider "digital human modeling" to be somehow not very accessible. The remainder of the chapter is intended to demonstrate that the field has carefully incorporated the foundations of human factors and ergonomics and provides a great set of tools for bringing human factors and ergonomics earlier into the design process and the potential for new ones to still be developed or incorporated into commercially available tools. However, as the field has developed under the terminology digital human modeling (DHM), that term will be used in this chapter when that referenced literature also used that DHM terminology.

For the practicing engineer, human digital modeling represents the opportunity to reduce the need for physical prototyping as it typically makes the analyses available through commercial computer-aided engineering (CAE) and product life-cycle management (PLM) software packages. It also provides opportunities for engineers to facilitate faster product development efforts and reduce time to market for new products. For the field to continue in development, there needs to be the continuing dialogue between engineers and human factors and ergonomics specialists. Where the engineers also have human factors and ergonomics expertise or where the human factors and ergonomics specialists are engineers, there is the opportunity for faster adoption of

these methods. For the methods previously developed in human digital modeling or DHM to have greater adoption, it will take the readers of this chapter to take it upon themselves to do so.

Since a very small percentage of engineers have been trained in human factors and ergonomics, and only a small percentage of human factors and ergonomics specialists have the opportunity to learn about DHM as a part of the course curriculum, the developers of the analysis tools are currently tasked with that effort of facilitating adoption within their client organizations. They may at times be viewed somewhat suspiciously because they typically come from organizations with commercial objectives or they may be ignored from a variation of the NIH (not-invented-here) syndrome. Actually, commercial software developers such as Siemens-Jack, CATIA-Delmia, and Ramsis have been great facilitators so far for this emerging area that has such great potential for impacting product design and consumer applications in a positive way. However, just as in medicine Dr. Jim Bagian tells about doctors who may not appreciate medical techniques that were not taught formally during their medical training (Williams and Bagian, 2010), so engineers appear to be falling into this potential pitfall by ignoring emerging capabilities of PLM packages that could support their efforts to bring consumer-friendly designs to the marketplace.

Some early DHM models that have been available for up to 35 years have not been rapidly assimilated into organizations where they could improve the ergonomic design of most of the hardware and software systems used today (Chaffin, 2009). The benefits of using related technologies have been well documented over the last decade in various books, papers, and conference presentations. In outlining the past and present in North America and Europe from a scientific perspective, Bubb and Fritzsche (2009) focuses on five different lines of development, including anthropometric models, models for production design, biomechanical models, anatomical models, and cognitive models. Sheridan (2009) extends the discussion on the cognitive side and considers a historical perspective on human performance modeling. Though this tradition developed professionally through a technical group within the Human Factors and Ergonomics Society beginning in 2004, Sheridan traces the development over 50 years focusing on models intended to predict the results of future measurements that have been popular and widely applicable.

Researchers in the United States and Sweden highlighted some organizational and technical conditions that may be inhibiting faster adoption, including lack of trained DHM personnel (Chaffin, 2009; Hanson et al., 2009). Some use cases, and some of the connecting points to the human factors and ergonomics methodologies are specifically outlined in this chapter (Brazier et al., 2003; Bubb and Fritzsche, 2009; Chaffin, 2009; Duffy, 2007b; Peacock and Karwowski, 1993). Recent advances in human digital modeling demonstrate that this emerging area is developing as an international effort with contributions recently from Belgium, Canada, China, France, Greece, Ireland, Italy, Japan, Germany, Hong Kong, Korea, Malaysia, The Netherlands, Poland, Singapore, Spain, Sweden, Taiwan, the United Kingdom, and the United States (Duffy, 2009b, 2009c, 2010a).

## 2 MODELING FUNDAMENTALS

For the purposes of understanding the current state of development in the field of human modeling, modeling fundamentals will be outlined in relation to stages of development, that is, first, second, and third generation. Within this outline, one may distinguish those different generations of models as follows. First-generation models tended to be more empirically or data driven and focused on the physical aspects of work or human–system design. Second-generation models have tended to be more computationally driven. Those first built into the commercially available CAE and PLM software would be considered first-generation models. As the need for advanced product assessment often included multiple objectives and multiple constraints, the proposed solutions developed in research were more mathematically based.

First-generation models tended to have more validation and data to support predictions. Second-generation models may have broader applicability due to the multiple objectives and constraints that they address. Challenges arise as to the validity and limits of such applications. These have also tended to be more focused on the physical aspects, capitalizing on existing models that could be considered mathematically for further development. As the sponsor of some of the early models referred to by Sheridan were the military, with concerns in aviation at the time, some second-generation models (outlined in Abdel-Malek and Arora, 2009; Marler et al., 2009; Yang, 2009) and shifting paradigms also came from the military. The Virtual Soldier Project, which drove this second-generation modeling perspective, initially focused on the physical aspects as the cognitive models that existed were not part of the commercially available tools or original scope. As the nature of the work is changing, the requirements for modeling the cognitive aspects have increased. As these become more well known and understood across disciplines outside of psychology and cognitive science, there is greater potential for their integration into the commercially available tools. Representative samples of each will be outlined in Sections 2.1 and 2.2.

### 2.1 Physical Aspects of Work

Commercially available first-generation DHM simulation and analysis tools are outlined in Table 1. These have enabled the analysis of tasks that required lifting, carrying, and lowering.

A typical computer manikin application is shown in Figure 1 for an assembly task. Figure 2 shows the field of vision and reach envelope used in modern applications of DHM.

Advanced first-generation models enable one to move beyond some limiting assumptions of the first-generation models and analysis tools and have tended to focus on verification and validation. These tend to not

**Table 1 Selected First-Generation Analysis Tools Available in Commercially Available DHM Simulation Tools**

| Performance Model | Data Source | Input Parameters |
| --- | --- | --- |
| National Institute of Occupational Safety and Health (NIOSH) lifting equation | Waters et al., 1993 | Posture and lift begin and end, object weight, hand coupling |
| Low-back injury risk assessment | Chaffin et al., 1999 | Joint torques, postures |
| Strength assessment | Ciriello and Snook, 1991 | Task description, hand coupling, gender |
| Fatigue analysis | Rohmert, 1973 | Joint torques, strength equations |
| Metabolic energy expenditure | Garg et al., 1978 | Task descriptions, gender, load description |
| Rapid upper limb assessment | McAtamney and Corlett, 1993 | Posture assessment, muscle use, force description |
| Ovako working posture | Karhu et al., 1977 | Posture assessment |
| Comfort | Variety of sources, including Dreyfuss, 1993; Porter and Gyi, 1998; Rebiffe, 1966 | Posture assessment |

*Source*: Adapted from Raschke et al. (2001).

**Figure 1** Typical computer manikin application (eM-Human Advanced/RAMSIS): analysis of a preliminary assembly position at the Volvo S60 Road Traffic Information (RTI) unit. (Modified from Sundin and Ortengren, 2006. Courtesy of Volvo Car Corporation/Wiley.)

yet be available in commercial CAE or PLM packages. For instance, Marras (2006) highlights the need to consider the dynamic aspects of task, where the static posture assumption is a limitation of the revised NIOSH lift equation. It is estimated that the potential risk to the lower back from lifting may be underestimated by as much as 40% by assuming a static posture (Feyen et al., 2000). Marras outlines options by considering use of a lumbar motion monitor to estimate the potential risk due to the dynamic aspects of the task. The lumbar motion monitor (Figure 3; Marras, 2006) and motion capture systems (Cappelli and Duffy, 2007; Tian et al., 2007) allow for the capture of velocities and accelerations and angular velocities and angular accelerations that can be used to determine the likelihood of high risk for a task. Additional information on the capabilities and limitations of motion capture systems and other instrumentation in support of dynamic digital human modeling can be found in Wang (2009) and Morr

et al. (2009). Wang describes the use of motion capture for discomfort evaluation and notes the challenges in capturing a measure of discomfort, as it is not a measure that can be considered directly the opposite of comfort. In their chapter on instrumentation, Morr et al. (2009) consider digital human models and validation-related matters when a human is a passenger in a vehicle, but not as part of the product interaction. This is the case in vehicle crash simulations.

Efforts to extend the use of existing models such as comfort analysis were undertaken in various studies including use of comfort angles in vehicles when designing an ATM for people with limited mobility. Figure 4 shows that old and new designs can be compared to validate the use of previous measures in circumstances other than those for which they were intended. Some methodologies established for verification and validation in first-generation and advanced first-generation DHM model development are outlined by Oudenhuijzen and
**Figure 2** Analysis functions. Top: field of vision, where lines represent the range of vision from close to peripheral. To the left: a reach envelope depicting points that can be reached by the right hand, where all equipment and details within the envelope can be reached comfortably without the need to "lean." (From Sundin and Ortengren, 2006. Courtesy of Delmia/Wiley.)

**Figure 3** Marras's lumbar motion monitor exoskeletal system enabling measures of the dynamic aspects of task. It captures information for calculation of the velocities and accelerations and angular velocities and angular accelerations that assist in predicting risk of lower back musculoskeletal injury (Marras, 2006).

colleagues (2009). Examples for the creation of three-dimensional (3D) libraries for aviation are also available (Oudenhuijzen et al., 2010). Their suggested methodologies are particularly relevant to the further development of advanced first-generation, data-driven models and second-generation, computationally driven models.

## 2.2 Assessment of Cognitive-Based Tasks

Cognitive modeling within the DHM community really represents the third generation of models. The cognitive aspects have been debated within the DHM community. The initial focus of DHM was on improving time to market by leveraging use of the CAE models considering predictions about risk to the lower back, for instance, to reduce the need for physical prototyping. As noted in Sundin and Ortengren (2006), some within the field believe that the cognitive models are underdeveloped. Yamaguchi and Proctor (2009) take exception and suggest that the cognitive models are simply not well known or well integrated into commercially available tools. They refer to some models such as Hick's law (Hick, 1952) that enable predictions of reaction time. This model is also noted by Sheridan in describing the history of human performance modeling. Referring back to Table 1, one can see that this and Shannon's model (Shannon, 1949) on communication in the presence of noise actually precede even the oldest of those initial analysis tools in commercially available DHM software packages. An additional representation of the cognitive aspects of task, independent of the quantitative aspects, is shown pictorially as Wickens's information-processing model in Figure 5 (Wickens et al., 2004; Wickens and Carswell, 2006).

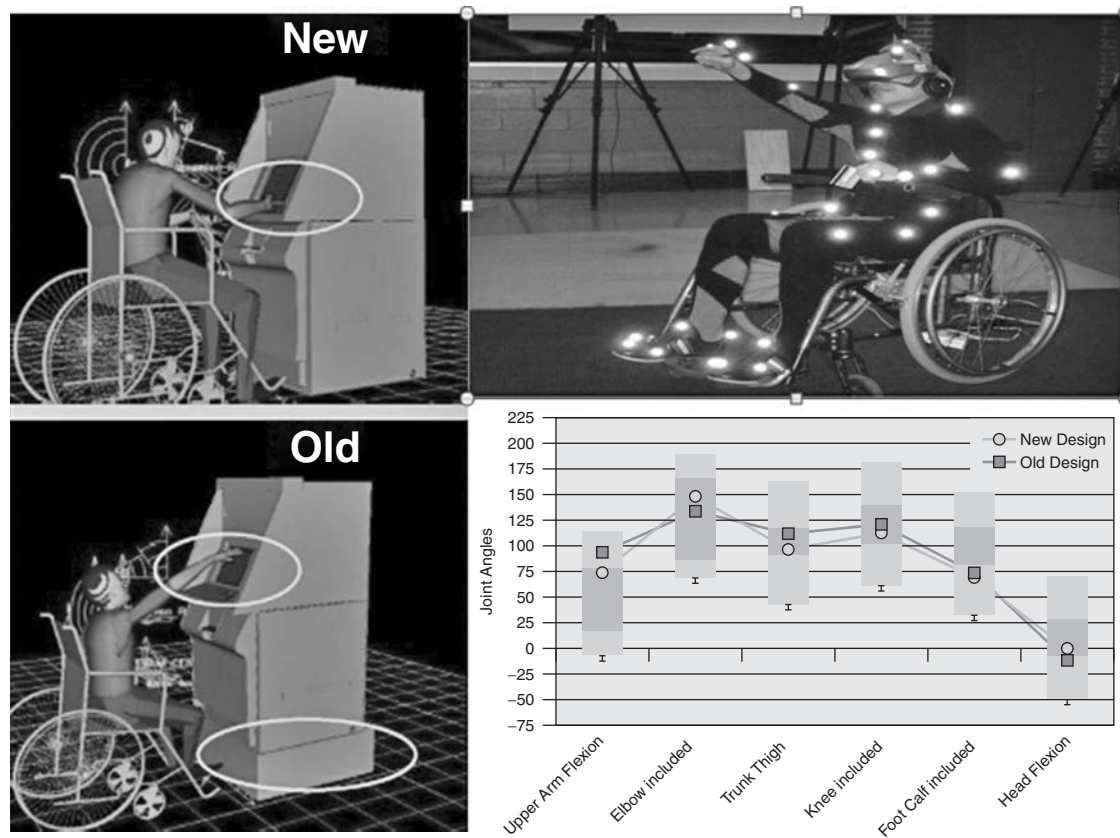
The difference in what is traditionally considered human performance modeling and digital human modeling comes back to the original definition given earlier. The digital human model has a visualization, whereas the human performance modeling community has not included that as an expectation in their model development efforts. So the two communities serve different purposes and continue to coexist without a great deal of overlap. The impact is related to Proctor's comment that


**Figure 4** A person with limited mobility with a head-mounted virtual reality display and reflective markers on a motion capture suit in the upper right. Motion capture, when integrated with computer-aided engineering designs to allow more realistic interaction with devices, can be used to help improve prediction of performance and safety for new designs. In this example, the old ATM design is 30 cm taller, as illustrated in the lower left. The new design, in the upper left, provides improved head flexion and upper arm flexion. Results given in the lower right are based on analysis tools originally developed for automobile design but showed similar outcomes with subjective measures of comfort. (Adapted from Li et al., 2006.)

the cognitive models are not as well known. The digital human modeling community focused on incorporating the visualizations, since the models incorporating the visualization with the math and/or science in the background have lent themselves well to communication that impacts decisions, as evidenced by the ergonomics practitioners at Ford Motor Company (Brazier et al., 2003; Stephens, 2006; Stephens and Jones, 2009).

Examples of cognitive models that incorporate the visualization aspect have been shown in considering various physiological measures such as facial skin temperature with visualizations that provide part of a multimodal measure of mental workload (Or and Duffy, 2007; Thomas et al., 2009). Others that have the cognitive models integrated with the visualization are highlighted by Gore, including MIDAS, the Man-Machine Integration Design and Analysis System (Gore, 2009). In the context of decisions about man–machine integration in the military Lockett and Archer (2009) and Meunier et al. (2009) outline clear examples where the

integration of cognitive and physical considerations in the modeling and visualization domain impact decisions about systems development. These, in most cases, were the predecessors to the Virtual Solider project intended to serve a broader set of product and systems design objectives than the previous examples reviewed by Lockett and Archer. The rationale for the computationally driven approach (previously described as second-generation models) is given by Abdel-Malek and Arora (2009) with consideration for limitations in empirically or data-driven model development (Abdel-Malek and Arora, 2009; Marler et al., 2009) and the synergies that are possible if the two approaches are considered in parallel.

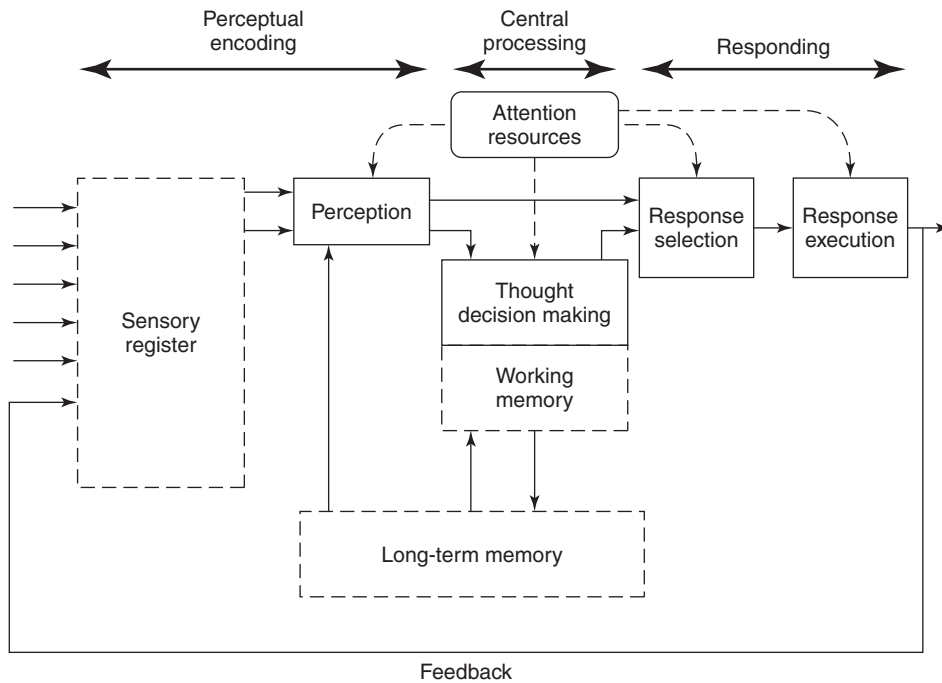
Where models like ACT-R (Adaptive Control of Thought–Rational; Anderson and Libiere, 1998) have been built upon for some integrated and hybrid models (Lockett and Archer, 2009), some have noted limitations of these models and architectures in their current form in terms of integration into the Virtual Soldier Project


**Figure 5** Wickens's information-processing model. (From Wickens et al., 2004; see also Wickens and Carswell, 2006.)

(Marler et al., 2009). Some driving-related models that consider both vehicle and driver control are based on the ACT-R concept (Salvucci, 2007). It is fortunate that, while noting the limitations for developing and applying driving-related models based on ACT-R, some researchers in Europe (Lenk and Mobus, 2010) are proposing alternatives such as a Bayesian approach (Lenk and Mobus, 2010; Mobus and Eilers, 2010).

## 3 METHODS OF EVALUATION AND ANALYSIS

Depending on the level of complexity of the human–system interaction requirements and the past expertise

developed in simulating the human performance and safety-related outcomes for that type of task, there may be various aspects of the physical world needed in testing that may represent elements of a physical prototype. These may be considered on a continuum (Duffy, 2007a); see Figure 6. This suggests that currently there are limitations in human digital models and in new devices that require hand controls, and in assembly in some cases there may be a need for physical prototyping either fully or partially.

With regard to interactive virtual design there has been discussion about when the actual boundaries of the virtual environment need to be represented physically (Szczerba et al., 2007; Stephens, 2006; Li et al.,

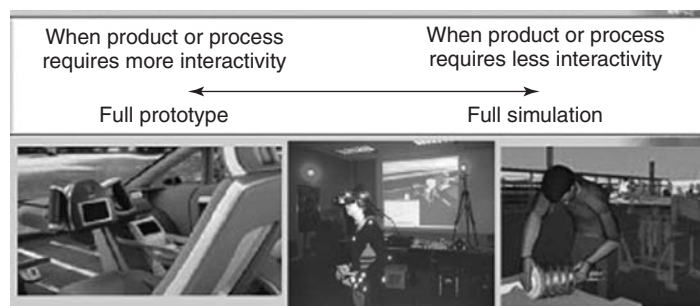

**Figure 6** Virtual prototyping capabilities and limitations: DHM in virtual design shown on a continuum. (Adapted Duffy, 2007a.)

2006). Demirel and Duffy (2009) demonstrate the potential benefits of incorporating force feedback in virtual interactive design assessments. LaFiandra (2009) outlines available methods, models, and technology related to lifting biomechanics. Types of models include the NIOSH lift equation, Snook tables, link segment models, electromyography (EMG) models, and recommendations regarding team lifting. Predicting maximum foot and hand force is highly desired not only for specifying the force limit of industrial workers but also for evaluating hand or foot control which requires a high demand of force (Wang et al., 2010).

Related software referred to by LaFiandra (2009) not previously discussed in Section 2.1 includes University of Michigan's 3D Static Strength Prediction Program (3DSSPP), AnyBody Technology (Denmark: Aalborg University), and Santos (Virtual Soldier Research, University of Iowa). 3DSSPP software predicts static strength requirements for tasks such as lifts, presses, pushes, and pulls considering postural data, force parameters, and anthropometry as input. Even for the controls requiring low force demand, maximum static strength can be used as an objective indicator for defining discomfort evaluation criteria (Wang et al., 2010). AnyBody provides the opportunity to model a range from some subset of the musculoskeletal system to the entire body. Santos is the only human digital modeling software that incorporates an optimization-based approach for analyzing the human in the loop.

Other human digital models are not readily available in commercial tools but serve to support footwear development (Luximon and Goonetilleke, 2009; Luximon et al., 2010). Other clothing development and physically based grasp models are described (Armstrong et al., 2009; Endo et al., 2007, 2010) and are currently available as specialized tools directly from the researchers.

## 4 ORGANIZATIONAL ASPECTS

The visualization aspect of digital human models has helped the decision maker in an organization to understand potential outcomes based on variations in design. In the past, the level of sophistication of the manikin led some to criticize models that had correct math and science, but were not well visualized. As the DHM field is defined by models that include visualization, the quality of that visualization became a measure of interest within the field. As illustrated in Figure 7, as recently as 2006, the visualizations in commercially available CAE and PLM software packages were still not well refined.

Cheng showed that recent research has contributed to more realism and an improvement in predicted shapes for certain manikin poses (Figure 8) (Cheng et al., 2010). A summary of available human digital modeling packages and characteristics is given in Li (2009) with criteria to help in the assessment.

Ways in which various human digital modeling tools could be utilized in an industrial workstation assessment of occupational ergonomics are described in the literature (Du and Duffy, 2007; Lamkull et al. 2009a, 2009b; Raschke et al., 2001). These are mainly in the context of manufacturing ergonomics. Commercially available tools now are distinguishing themselves by noting the improved manikin and visualizations. See Figure 9. Examples of emerging areas and newly developed tools are described in Section 6.

### 4.1 DHM Applications

In this section applications are grouped according to the three areas of development outlined in Bubb and Fritzsche (2009): anthropometric models, biomechanical models, and models for production design. When including cognitive models as one of the categories,

**Figure 7** Representations of a computer manikin (Jack); the linked segments are visible on the extreme left, in the wire frame third from left, and in the shaded frame second from right. (From Sundin and Ortengren, 2006. Courtesy of H. Sjoberg, Chalmers University of Technology/Wiley.)
**Figure 8** Predicted shapes in poses demonstrated in recent related research have more realism (Cheng et al., 2010).

**Figure 9** Delmia's new manikin within V.6 of CATIA is shown (left) and in various product promotions including one recently on You Tube. Initially the new manikin is moving side by side with the less sophisticated prior manikin and then suggests the other move to ''retirement'' (Dassault Systemes, 2010).

they suggest that all of the human models would fit within one of the categories, though some features may have crossover between categories. Cognitive models previously were reviewed in Section 2.2. These models have been typically developed for application in workplace design, product design, safety evaluation, and documentation of planning and/or production.

### 4.1.1 Anthropometric

Anthropometric models consider especially shape and size. Anthropometric and anatomical models will be combined and a distinction will be briefly made for anatomical models related to shape. Efforts to measure male and female hand, arm, and leg lengths are

intended to better design products and workstations with a focus on minimizing the number of people excluded (Konz and Johnson, 2008). Frey Law et al. (2009) summarize the body of literature related to modeling human physical capability, including joint strength and range of motion. Comfort reach, maximum reach, and unreachable areas are summarized for standing, kneeling, and prone positions in task and military equipment design for Chinese soldiers (Dong et al., 2010). Researchers in Sweden have demonstrated keen interest in the further development of human digital models for production (Lamkull et al., 2009b). Bertilsson et al. (2010) recently interviewed personnel from car companies about anthropometric diversity in the early stages of development. They generalize the results and suggest that only one or a few human models are actually considered. Personnel claim it is a time-consuming process to create and correctly position the model in the computer-aided design (CAD) environment. A matrix describing important model capabilities and the ability of certain commercial packages to meet those is provided. The challenges described highlight the need for current research, such as that by Green and Hudson (2010) demonstrating specialized methods for positioning such models in airplane passenger seats.

### 4.1.2 Biomechanical

Biomechanical models can consider the mass, inertia, spring, and damping elements that represent the body parts connected by joints (Bubb and Fritzsche, 2009). Section 3 included a brief review of available methods, models, and technology related to lifting biomechanics (LaFiandra, 2009). Park's (2009) overview of data-based human motion simulation gives insight into empirically or data-driven modeling techniques for reach, motion prediction, and obstruction avoidance. Suggestions for future work highlight current limitations, including the cost of determining optimum posture, difficulties for simulations to link long sequences of motion behavior, challenges in integrating multiple motion databases and datasets, and constraints due to individual differences in strength, range of motion, or obesity (Park, 2009). Additional insight is provided by optimization-based posture prediction in recent research using joint angles to serve as design variables and vision-based constraints such as eye movement and visual obstacle avoidance (Knake et al., 2010). This research builds on experience from the Virtual Soldier Project.

Other biomechanical models can simulate physical dynamic behavior. Happee and Wismans (2009) summarize issues related to simulations of human body impact to give insight into the prediction of injury mechanisms and injury criteria. The finite-element modeling methods described represent another example of computationally driven modeling that is shaping the field. The MADYMO (Mathematical Dynamic Models) software can be used for accident reconstruction and can substitute in some cases for data that may otherwise be obtained from the use of crash test dummies that are limited in what they can provide (Happee and Wismans, 2009). Practical applications include occupant response to mine blasts. Recent research provides insight into

comparisons of the use of dummies and commercial finite-element software code (Irde et al., 2010). It is suggested that risk assessment is one of the most fundamental methods for designing safe products and work tasks (Marras, 2006; Koizumi et al., 2010). Injury prevention is one of the most important and urgent issues in children's health since the primary cause of death of children is unintentional injury (Koizumi et al., 2010). Efforts in this recent research consider how to incorporate knowledge of child behavior predictions with biomechanical models, biomechanical simulations, and an injury model.

### 4.1.3 Production

Production models can simulate the work process through discrete-event simulation and can predict the necessary working time while incorporating humans in the loop. Those that would be categorized with human digital models would allow some opportunity to visualize and optimize processes. They can help to identify and eliminate bottlenecks and optimize throughput in manufacturing and services; help in the visualization of product movement and material handling; and improve terminal operations in container terminals and streamline patient flow in health care (Flexsim, 2010). In reviewing virtual environments (Alexander and Ellis, 2009), one is reminded that virtual environments are expected to be interactive, and if digital human models could be more than "puppets," there could be additional value in seeing user or model response. For instance, if intelligent agents or avatars or intelligent conversational agents are included, the emotional, psychological, and sociological aspects are referred to as "missing" from current DHM (Boucsein and Backs, 2009).

## 4.2 Educational Aspects

Undergraduate students planning to work in engineering or product design should have access to commercially available tools before graduation. Their participation does not need to be product specific but should center around a set of capabilities that a well-trained human factors and ergonomics specialist would appreciate as a potential time savings in analysis and communication tool within the organization. These students should become aware of ways to create and interpret the visualizations that communicate information about the user aspects of product and process design to key decision makers within the design process. Zhang et al. (2007) presented methods for the design and implementation of an ergonomics evaluation system of a 3D airplane cockpit.

As the work is changing from more physical to more cognitive and opportunities are growing in the services industries, it will be important for students to identify, encourage, and incorporate these models as they become available as specialized tools or in the human modeling packages that incorporate a variety of analysis tools. Earlier in the development of human modeling tools that were part of PLM software suites, such as Dassault Systemes (2010) CATIA/DELMIA and UGS-Siemens/Jack (Siemens, 2010), new tools were incorporated based on a "demand-driven" basis. When clients

had a need for a particular model that was not yet a part of the PLM package, they would request and sponsor their integration. There has recently been some shift in that expectation, in that PLM developers seem to be more willing to seek and incorporate available and tested models and create capacity for human modeling, letting the user ultimately determine which model to use and when. For instance, discomfort measurements incorporated with motion capture systems that are designed to assess consumer products such as dishwashers (see Preatoni et al., 2010) may be of interest in consumer product development. Their model utilizes gesture and gait and is compared to postural loading on the upper body based on joint discomfort and maximum holding time, a method developed by Kee and Karwowski (2001).

Even though the software may be capable of such analyses, there will be an increasing need in the workplace to consider the cross-disciplinary and system aspects of designs. Though some would like to see such tasks relegated to a checklist-type review, ultimately, in the foreseeable future, the analysis and development considering the human aspects of new products and processes will remain an engineering function, particularly in emerging areas and where there are new applications for human digital models. Andreoni et al. (2010) rely on direct observations through motion capture as well as subjective questionnaire data to develop their consumer product dishwasher assessment tool. As interest in safety of products and customization continues to increase, one important market continues to be the product market for children. To design safe products for children, one must measure and understand foreseeable use and children's behavior quantitatively (Nishida et al., 2010). And as the services sector of the economy continues to grow, so too will the need to construct human models to effectively predict user behavior and consumer preferences (Motomura, 2010).

## 5 CURRENT CHALLENGES

As outlined by Badler and Allbeck (2009), current challenges include issues related to sensing and reacting. Currently the manikins are not modeled to account for the impact of talking on a cell phone on performance (Badler and Allbeck, 2009) or the emotional aspects (Backs and Boucsein, 2009; Boucsein and Backs, 2009). Certainly health care is an application area that provides both opportunities and challenges with regard to current and emerging human digital models. At times, modeling the cognitive or procedural aspects of task is straightforward when compared to modeling the parallel physical aspects. Efforts to model patient safety and reduction of medication administration error are currently considered in the literature (Boone-Seals and Duffy, 2005). Anecdotes and the number of documented incidents have shown to be powerful motivators for improving patient safety. It is apparent, however, that human factors–related health care delivery models lack the visualizations that may facilitate decision making to improve patient safety (Duffy, 2010a). Methods such as data mining have separate bodies of literature from

DHM (Liu, 2009). With the emergence of inexpensive sensor technologies, these data-mining techniques could be blended with human models and visualizations to affect decisions in health care and ultimately safety.

Williams et al. (2009) demonstrated a methodology for assessing a high-fidelity DHM with force or haptic feedback during training. Rapala and Novak (2009) have outlined the field of health care delivery and the need for simulation in training. They consider nurses' perspectives in the context of the health care delivery team. Training and experience can affect perception of hazard and risk (Duffy, 2003). The level of fidelity of a simulation can influence medical training. Professional fragmentation and a tradition of individualism provide some barriers to teamwork (Leape and Berwick, 2005). Behaviors and interactions in teams described by Caldwell (2009) highlight successes centered on resource coordination and information flow efficiency that were demonstrated in the aviation industry and that have some applicability to human digital models. DeLaurentis (2009) suggests methods for modeling the role of human behavior as part of a system of systems. His examples again demonstrate insight from air transportation systems that appear to also have applicability to health care, particularly in agent-based simulations.

## 6 EMERGING OPPORTUNITIES

Issues related to improved driver information systems are outlined by Mobus and colleagues (Mobus and Eilers, 2009, 2010; Mobus et al. 2009). Methodologies for text mining (Noorinaeini and Lehto, 2009) may be helpful for predicting human performance in various cognitive-based tasks. As noted by Badler and Allbeck (2009), once one begins to look at human performance at the task level, new issues arise that transcend biomechanical models and simulations of the past. For instance, as shown in Figure 10, new automation can control a vehicle more effectively than the most accident-prone drivers (Eby and Kantowitz, 2006). However, it is not clear when certain vulnerabilities in task performance warrant acceptance of support or an augmented reality (Schmorrow et al., 2009). A whole body of literature on augmented reality and augmented cognition could yield further insights.

Established industries such as mining need advanced methods and technology to measure safety. Methods established in cooperation with NIOSH Pittsburgh are contributing to that effort (Ambrose, 2009). Virtual reality training also provides opportunities for improving human performance (Sadasivan et al., 2009). Workload assessment capabilities, in the context of discomfort due ultimately to early design decisions, can provide insight into system incompatibilities (Grobelny et al., 2009). People's preferences are a crucial part of the decision-making process—both the potential user and the designer. Modeling usability can help to justify a greater emphasis on the user in design (Grobelny and Michalski, 2010). Utilizing optimization in design can give important insight into design trade-offs that may exist (Parkinson, 2009). Emerging needs in human modeling include the need to identify individuals based
**Figure 10** U.S. fatal crash rates per 100,000 population in 2002. As technology improves, drivers may be willing to relinquish control of the vehicle. Predictive models are needed for circumstances when behavior changes and allows the automation to take over. As well, predictive models are needed for how many lives may be saved as the automation improves and the horizontal line in the figure shifts vertically downward with improvements of in-vehicle automation systems that sense the vehicle environment and inform the driver. [Data from the National Highway Traffic Safety Administration (NHTSA), 2002. Adapted from Eby and Kantowitz (2006), which showed the fatality data without the automation curves.]

on biometric measurement technology. An overview of the body of literature in biometrics, including measures of fingerprint, face, iris, voice, and mult-modal efforts, is provided in Du (2009).

Recent research characterizes hand strength while an extravehicular activity (EVA) glove was worn in an extravehicular mobility unit (EMU) suit. Data were collected in various hand postures under bare-handed, gloved with no thermal micrometeoroid garment (TMG) and gloved with a TMG (Mesloh et al., 2010). It was found that the TMG reduced grip strength to 55% of bare-hand strength in the unpressurized condition and 46% in the pressurized condition. Lateral pinch strength increased (>100%, original), as it seems the glove shape contributed to additional support (Mesloh et al., 2010). Space exploration is one emerging area for clothing design and human performance modeling. Human digital models with a data-based grasp synthesis approach support ergonomic assessment for hand-held product design (Kawaguchi et al., 2009). These can enable some additional predictive capability in computer-aided engineering design environments. As previously mentioned, clothing for soldiers is of current interest within the military (Marler et al., 2009) and footwear design (Luximon and Goonetilleke, 2009) is very popular among a more diverse engineering student body. In order to address these emerging application areas, it is important to incorporate lessons from past DHM related to shape and size analysis (Godil and Ressler, 2009) as well as some scanner-based anthropometry methods (Lu and Wang, 2009).

**Arlington, Virginia**

## 1 INTRODUCTION

Virtual environments (VEs) aim to immerse users in realistic settings, allowing them to engage in an intuitive and intimate manner with their digital universe. Even a decade ago, VE technologies and their applications were immature and few in number. This has changed dramatically, with a recent analysis of the virtual simulation training market revealing that today commercial and customized virtual simulation and training products abound (King, 2009). Virtual environment technologies have many advantages, including the ability to provide adaptable, modest cost, deployable, and safe training solutions, offer rehabilitation and medical applications that reach far beyond the conventional, and create learning and game-based virtual experiences that would otherwise be impossible to explore. Yet limitations do exist, in that virtual experiences cannot fully replace the benefits of real experiences, there is not yet a full understanding on how best to use this technology,

and the technology does not always meet the expectations of its users due to issues such as cybersickness and lack of presence. The future looks bright, however, as the gaming industry is pushing the realm of the possible and making it ever more feasible to "learn by doing," "train like we fight," and "involve me and I understand." This chapter reviews the current state-of-the-art in VE technology, provides design and implementation strategies, discusses health and safety concerns and potential countermeasures, and presents the latest in VE usability engineering approaches. Current efforts in a number of application domains are reviewed. The chapter should enable readers to better specify design and implementation requirements for VE applications and prepare them to use this advancing technology in a manner that minimizes health and safety concerns.

## 2 SYSTEM REQUIREMENTS

A VE is a computer-generated immersive environment that can simulate both real and imaginary worlds, oftentimes in three dimensions. Current VE applications are primarily intriguing visual and auditory experiences,

---

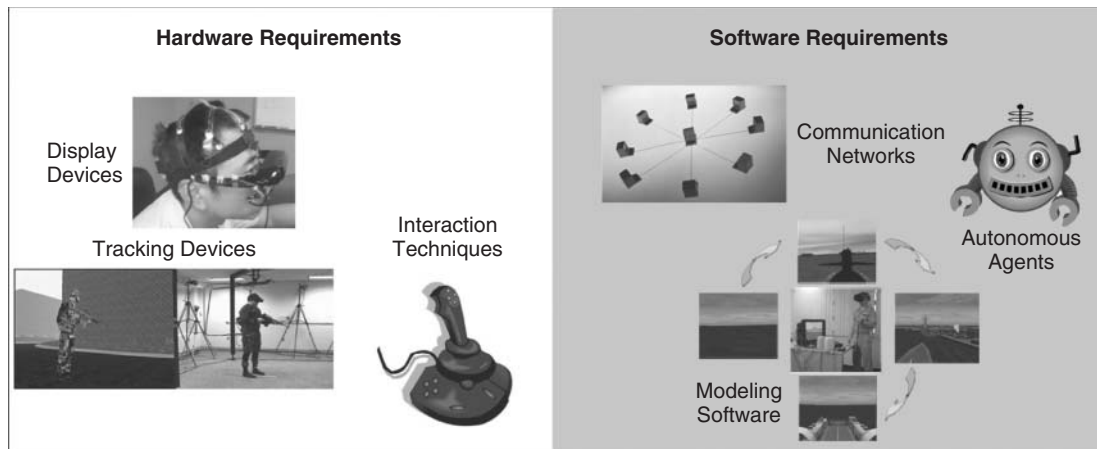
* This chapter represents a modified version of K. M. Stanney and J. V. Cohn, "Virtual Environments," in *Handbook of Human−Computer Interaction* (2012, 3rd Edition), J. Jacko, Ed., Taylor & Francis.


**Figure 1**  Hardware and software requirements for virtual environment generation.

with a smaller number incorporating additional sensory modalities, such as haptics and smell. These worlds are driven by hardware, which provides the hosting platform and multimodal presentation, which allows for physical interaction and tracks the whereabouts of users as they traverse the virtual world, as well as software to model and generate the virtual world and their autonomous agents and support communication networks that link multiple users (see Figure 1).

More specifically, hardware interfaces consist primarily of:

- Interface devices used to present multimodal information and sense the VE
- Tracking devices used to identify head and limb position and orientation
- Interaction techniques that allow users to navigate through and interact with the virtual world

Software interfaces include:

- Modeling software used to generate VEs
- Autonomous agents that inhabit VEs
- Communication networks used to support multiuser virtual environments

## 2.1  Hardware Requirements

Virtual environments require very large physical memories, high-speed processors, high-bandwidth mass storage capacity, and high-speed interface ports for interaction devices (Durlach and Mavor, 1995). These requirements are easily met by today's high-speed, high-bandwidth computing systems, many of which have surpassed the gigahertz barrier. The future looks even brighter, with promises of massive parallelism in multicore and many-core processor architectures (Holmes et al., 2010), which will allow tomorrow's computing systems to be exponentially faster than their ancestors. With the rapidly advancing ability to generate complex

and large-scale virtual worlds, hardware advances in multimodal input/output (I/O) devices, tracking systems, and interaction techniques are needed to support generation of increasingly engaging virtual worlds. In addition, the coupling of augmented cognition and VE technologies can lead to substantial gains in the ability to evaluate their effectiveness.

### 2.1.1  Multimodal I/Os

To present a multimodal VE (see Chapter 14), multiple devices are used to present information to VE users. In terms of VE projection systems, the one that has received the greatest attention, both in hype and disdain, is almost certainly the head-mounted display (HMD). One benefit of HMDs is their compact size, as an HMD when coupled with a head tracker can be used to provide a similar visual experience as a multitude of bulky displays associated with spatially immersive displays (SIDs) and desktop solutions. In addition, HMDs are suggested to enhance situation awareness, enable correct decision making, and reduce workload by allowing users to turn their head and eyes to fully perceive the environment, decreasing multimodal clutter, providing an intuitive means of presenting spatialized multimodal warnings and alerts, and redundantly coding critical cues (e.g., external threats, navigational waypoints), for example, by using audio cues to direct visual attention (Melzer and Rash, 2009).

There are three main types of HMDs: monocular (e.g., one image source is viewed by a single eye), biocular (e.g., one image source viewed by both eyes), and binocular (e.g., stereoscopic viewing via two image generators, with each eye viewing an independent image source) (Melzer et al., 2009). A monocular HMD design is best when projecting moving maps or text information that must be read on the move (e.g., dismounted Warfighter) or to allow viewing of imagery with the simplest, lightest (in terms of head-supported weight/mass), and least costly (both monetarily and in terms of power consumption) solution. The downside of monocular displays is that they have a small field of view (FOV),

convey no stereoscopic depth information, have the potential for a laterally asymmetric center of mass (CM), and may have issues associated with focus, eye dominance, binocular rivalry, and ocular-motor instability. For a wide FOV, more effective target recognition, and a more comfortable viewing experience, a biocular or binocular solution is needed. Biocular solutions present no interocular rivalry and are lighter, easier to adjust, and less expensive than binocular solutions. The disadvantages of biocular displays are that they are heavier, more complex to align, focus, and adjust, and have reduced luminance as compared to monocular displays. Binocular displays have a symmetrical CM and can present stereo viewing (via field-sequential single-screen displays with shutter glasses, single-screen polarized displays, or dual-screen HMDs), which provides for better depth information than monocular and biocular solutions. On the downside, binocular solutions are heavy, require more complex alignment, focus, and adjustments than monocular, and are expensive. Biocular and binocular solutions are particularly well suited when creating fully immersive VEs for gaming or training systems, as their large FOV provides a more compelling sense of immersion.

When coupled with tracking devices, HMDs can be used to present three-dimensional (3D) visual scenes that are updated as a user moves his or her head about a virtual world. Although this often provides an engaging experience, due to poor optics, sensorial mismatches, and slow update rates, these devices are also often associated with adverse effects such as eyestrain and nausea (Stanney and Kennedy, 2008). In addition, while HMDs have come down substantially in weight, rendering them more suitable for extended wear, they are still hindered by cumbersome designs, obstructive tethers, suboptimal resolution, and insufficient FOVs. These shortcomings may be the reason behind why, in a review of HMD devices, approximately a third had been discontinued by their manufacturers (Bungert, 2007). Nevertheless, of the HMDs available, there are several low- to mid-cost models, which are relatively lightweight and provide a horizontal FOV and resolution far exceeding predecessor systems.

Low-technology stereo viewing VE display options include anaglyph methods, where a viewer wears glasses with distinct color-polarized filters, usually with the left-image data placed in the red channel of an electronic display and the right-image data in the blue channel; parallel or cross-eyed methods, in which right and left images are displayed adjacently (parallel or crossed), requiring the viewer to actively fuse the separate images into one stereo image; parallax barrier displays, in which an image is made by interleaving columns of two images from a left- and right-eye perspective image of a 3D scene; polarization methods, in which the images for the left and right eyes are projected on a plane through two orthogonal linearly polarizing filters (e.g., the right image is polarized horizontally; the left is polarized vertically) and glasses with polarization filters are donned to see the 3D effect; Pulfrich methods, in which an image of a scene moves sideways across the viewer's FOV and one eye is covered by a dark filter so

that the darkened image reaches the brain later, causing stereo disparity; and shutter glass methods in which images for the right and left eyes are displayed in quick alternating sequence and special shutter glasses are worn that "close" the right or left eye at the correct time (Konrad and Halle, 2007; Vince, 2004). All of these low-technology solutions are limited in terms of their resolution, the maximum number of views that they can display, and clunky implementation; they can also be associated with pseudoscopic images (e.g., the depth of an object can appear to flip inside out).

Other options in visual displays include SIDs (e.g., displays that surround viewers physically with panoramic large FOV imagery generally projected via fixed front or rear projection display units; Konrad and Halle, 2007; Majumder, 2003), desktop stereo displays, and volumetric displays that fill a volume of space with a "floating" image (Konrad and Halle, 2007). Examples of SIDs include the Cave Automated Virtual Environment (CAVE) (Cruz-Neira et al., 1993), Blue-c, ImmersaDesk, PowerWall, Infinity Wall, and VisionDome (Majumder, 1999). Issues with SIDs include a stereo view that is correct for only one or a few viewers, noticeable overlaps between adjacent projections, and image warp on curved screens. Blue-c addresses some of these concerns by combining simultaneous acquisition of multiple 3D video streams with advanced 3D projection technology (Gross et al., 2003). Desktop display systems have advantages over SIDs because they are smaller, easier to configure in terms of mounting cameras and microphones, easier to integrate with gesture and haptic devices, and more readily provide access to conventional interaction devices, such as mice, joysticks, and keyboards. Issues with such displays include stereo that is only accurate for one viewer and a limited-display volume. Volumetric displays provide visual accommodation depth cues and vertical parallax, which are particularly useful for scenes that require viewing from a multitude of viewing angles, generally without the need for goggles; however, they do not maintain accurate occlusion cues (often considered the strongest depth cues) for all viewers (Konrad and Halle, 2007). Perspecta is an example of a swept-volume display that uses a flat, double-sided screen with a rotating projected image to sweep out a hemispherical image volume (Favalora, 2005). DepthCube is an example of a static-volume display that uses electronically addressable elements [i.e., a digital micromirror device (DMD) imaging system] to scan out the image volume (Sullivan, 2004). Issues with volumetric displays include low resolution and the tendency for transparent images to lose interposition cues. Also, view-independent shading of objects is not possible with volumetric displays, and current solutions do not exhibit arbitrary occlusion by interposition of objects (Konrad and Halle, 2007). The way of the future seems to be direct virtual retinal displays, where images are projected directly onto the human retina with a low-energy laser or liquid crystal displays (LCDs) (McQuaide et al., 2003), as well as displays that represent the physical world around us, such as autostereoscopic omnidirectional light field displays,

which present interactive 3D graphics to multiple simultaneous viewers 360° around the display (Jones et al., 2007). If designed effectively, these next-generation devices should eliminate the tethers and awkwardness of current designs while enlarging the FOV and enhancing resolution.

When virtual environments provide audio (see Chapter 9), the interactive experience is generally greatly enhanced (Shilling and Shinn-Cunningham, 2002). Audio can be presented via spatialized or nonspatialized displays. Just as stereo visual displays are a defining factor for VE systems, so are "interactive" spatialized audio displays (e.g., those with "on-the-fly" positioning of sounds). VRSonic's SoundScape3D (http://www.vrsonic.com/), Firelight's FMod (http://www.fmod.org/), and AuSIM3D (http://ausim3d.com/) are examples of positional 3D audio technology. There have been promising developments in new sound modeling paradigms (e.g., VRSonic's ViBe technology) and sound design principles that will hopefully lead to a new generation of tools for designing effective spatial–audio environments (Fouad, 2004; Fouad and Ballas, 2000; Jones et al., 2005).

Developers must decide if sounds should be presented via headphones or speakers. For nonspatialized audio, most audio characteristics (e.g., timbre, relative volume) are generally considered to be equivalent whether projected via headphones or speakers. This is not so for spatialized audio, in which the presentation technique impacts how audio is rendered for the display and presents the developer with important design choices.

While in the past headphone spatialization required expensive, specialized hardware to achieve real-time rates, modern multicore processors as well as the availability of powerful graphics processing units (GPUs) have made it possible to render complex audio environments over headphones using general-purpose computers. With binaural rendering, a sound can be placed in any location, right or left, up or down, near or far, via the use of a head-related transfer function (HRTF) to represent the manner in which sound sources change as a listener moves his or her head (Begault, 1994; Butler, 1987; Cohen, 1992). For optimal results, however, the HRTFs used for rendering must be personalized for each individual user. One method of doing this is to actually measure each user's HRTF for use in rendering. This approach generally involves a fairly lengthy measurement procedure using specialized hardware. Recently, there have been efforts to develop fast and low-cost approaches to HRTF measurements (Zotkin et al., 2006) that may, in the future, make personalized HRTF rendering practical for general use. An alternative approach to measured HRTFs is to use a best-fit HRTF selection process in which one finds the nearest matching HRTF in a database of candidate HRTFs by either comparing the physiological characteristics of stored HRTFs to those of a target user (Algazi et al., 2001) or using a subjective selection process to find the best-fit HRTF (Seeber, 2003). Other considerations that should be taken into account when choosing headphone rendering are that, for immersive displays, head trackers must be used to

achieve proper relative positioning of sound sources. Also, rendering spatial audio for groups of users over headphones may not be practical for more than a few users.

An alternative approach to headphone spatialization is the use of loudspeaker arrays (Ballas et al., 2001). Loudspeaker arrays can range in size from relatively small surround-sound configurations with 2, 4, 5, 7, or 10 loudspeakers up to hundreds of loudspeakers. The differentiating factors among loudspeaker arrays are the speaker layouts, number of loudspeakers comprising the array, and algorithms used to render spatial audio. Generally speaking, increasing the number of loudspeakers in the array results in more accurate spatialization. The manner in which loudspeakers are laid out in the listening area is closely related to the size of the array. Planar loudspeaker configurations require a smaller number of loudspeakers but are only capable of creating a 2D sound field. Volumetric configurations, on the other hand, can create a 3D sound field but require a larger number of loudspeakers and a more elaborate setup. Recently, VRSonic introduced a spherical loudspeaker array system called the AcoustiCurve. It provides a volumetric array in a spherical configuration around the listening space.

The rendering algorithm used for spatialization is also closely tied to the loudspeaker array size and configuration. Pairwise panning algorithms are the simplest form of spatialization and create a positional sound source by manipulating the amplitude of the signal arriving at two adjacent loudspeakers in the array (Mouba, 2009). An extension to this idea is vector base amplitude panning (VBAP), where the source is panned among three loudspeakers forming a triangle in a volumetric array (Pulkki, 1997). Another spatialization algorithm that is gaining popularity is wave field synthesis (WFS), a technique based on Huygens's principle (Spors and Ahrens, 2010). The WFS technique creates a positional source within the listening space by re-creating the incident wave front of a virtual source using a loudspeaker array. The advantage of WFS is that it does not suffer from the "sweet spot" problem so listeners can get an accurate impression of the synthesized sound field at any location within the listening space; this is not the case with pairwise panning (Shilling and Shinn-Cunningham, 2002). The primary drawback of WFS is that it requires a large number of loudspeakers and considerable processing power to re-create the incident wave front.

Whether using headphones or loudspeaker arrays, spatialization is only one component of simulating a sound field and developers should carefully consider the level of fidelity required by the application when choosing an audio rendering system. Properly synthesizing a virtual soundscape requires modeling the full propagation path of sound, including source model, spreading loss, air absorption, material absorption, and material reflection. Accurately modeling the full propagation path in real time is beyond the capabilities of current computers. There is, however, promising research in the use of GPU processors to achieve real-time rates using ray casting methods (Jedrzejewski, 2004).

While not as commonly incorporated into VEs as visual and auditory interfaces, haptic devices (see Chapter 10) can be used to enhance aspects of touch and movement of the hand or body segments while interacting with a virtual environment. Haptic devices have been classified as passive (unidirectional, e.g., keyboard, mouse, trackball) versus active (bidirectional, thereby supporting two-way communications between human and interactive system; Hale and Stanney, 2004; e.g., force reflecting robotic arm), grounded (e.g., joystick) versus ungrounded (e.g., exoskeleton-type haptic devices), net-force (e.g., PHANTOM device or textured surfaces) versus tactile devices (e.g., tactile pin arrays), and impedance control (i.e., user's input motion is measured and an output force is returned) versus admittance control (e.g., user's input forces are measured and motion is fed back to the user) (Basdogan and Loftin, 2008). In general, haptic displays are effective at alerting people to critical tasks (e.g., warning), providing a spatial frame of reference within one's personal space, and supporting hand–eye coordination tasks. Texture cues, such as those conveyed via vibrations or varying pressures, are effective as simple alerts and may speed reaction time and aid performance in degraded visual conditions (Akamatsu, 1994; Biggs and Srinivasan, 2002; Massimino and Sheridan, 1993; Mulgund et al., 2002). Kinesthetic devices are advantageous when tasks involve hand–eye coordination (e.g., object manipulation), where haptic sensing and feedback are key to performance. Currently available haptic interaction devices include static displays (e.g., convey deformability or Braille); vibrotactile, electrotactile, and pneumatic displays (e.g., convey tactile sensations such as surface texture and geometry, surface slip, surface temperature); force feedback systems (e.g., convey object position and movement distances); and exoskeleton systems (e.g., enhance object interaction and weight discrimination) (Hale and Stanney, 2004). Minamizawa et al. (2008) suggest that to provide natural haptic feedback, such interfaces should be bimanual and wearable and aim to enhance the existence and operability of virtual objects while not disturbing the motion and behavior of users. Currently, there are several wearable haptic displays that can be used in virtual environments, such as Cyber-Glove Systems' CyberGlove, CyberTouch, CyberGrasp, and CyberForce (http://www.cyberglovesystems.com/) and Immerz's KOR-fx (Kinetic Omnidirectional Resonance effect) acousto-haptic technology, the latter of which translates the audio signals from an interactive environment into vibrations that can be felt throughout the body and experienced as the sensation of rain, wind, weight shift, and G-forces (www.Immerz.com). Beyond supporting hand–eye coordination tasks and conveying simple alerts, haptics can be used to communicate grammar structured strings of tactile symbols (Fuchs et al., 2008). Such a tactile language has been used at a concept level to support urban military operations, specifically in support of unit coordination and room clearing tasks (Johnston, Hale, & Axelsson, 2010). Beyond communicating a command-based vocabulary, haptics can also be used to provide exteroceptive feedback, for example, by presenting tactile cues to enhance situation awareness

or optimize human performance. It has been suggested that such a solution could more closely couple operators with unmanned aerial systems (Johnston et al., 2010). The future may bring volumetric haptic displays, which project a touch-based representation of a surface onto a 3D volumetric space and allow users to feel the projected surface with their hands (Acosta and Liu, 2007) through haptic rending techniques (Basdogan et al., 2008), tearables that allow users to experience the real sense of tearing paper (Maekawa et al., 2009), and other such interactive tactile solutions.

The "vestibular system can be exploited to create, prevent, or modify acceleration perceptions" in virtual environments (Lawson et al., 2002, p. 137). For example, by simulating acceleration cues, a person can be psychologically transported from his or her veridical location, such as sitting in a chair in front of a computer, to a simulated location, such as the cockpit of a moving airplane. While vestibular cues can be stimulated via many different techniques in VEs, three of the most promising methods are physical motion of the user (e.g., motion platforms), wide FOV visual displays that induce vection (e.g., an illusion of self-motion), and locomotion devices that induce illusions of self-motion without physical displacement of the user through space (e.g., walking in place, treadmills, pedaling, foot platforms) (Hettinger, 2002; Hollerbach, 2002; Lawson et al., 2002). Of these options, motion platforms are probably the most advanced. For example, Sterling et al. (2000) integrated a small motion-based platform with a VE designed for helicopter landing training and found it to be comparable to a high-cost, large-scale helicopter simulator in terms of training effectiveness. Motion platforms are generally characterized via their range of motion/degrees of freedom (DOF) and actuator type (Isdale, 2000). In terms of range of motion, motion platforms can move a person in many combinations of translational (e.g., surge-longitudinal motion, sway-lateral motion, heave-vertical motion), and rotational (e.g., roll, pitch, yaw) DOF. A single-DOF translational motion system might provide a vibration sensation via a "seat shaker." A common 6 DOF configuration is a hexapod, which consists of a frame with six or more extendable struts (actuators) connecting a fixed base to a movable platform. In terms of actuators, electrical actuators are quiet and relatively maintenance free; however, they are not very responsive and they cannot hold the same load as can hydraulic or pneumatic systems. Hydraulic and pneumatic systems are smoother, stronger, and more accurate; however, they require compressors, which may be noisy. Servos are expensive and difficult to program.

Olfaction could be added to VE systems to stimulate emotion or enhance recall (Basdogan and Loftin, 2008). There have been several efforts made to support advances in olfactory interaction (Gutierrez-Osuna, 2004; Jones et al., 2004; Washburn and Jones, 2004; Washburn et al., 2003). One example of an olfactory system is the Scent Pallet (http://www.enviroscent.com/), which is a computer peripheral, universal serial bus (USB) device that uses up to eight scent cartridges, fans, and an air compressor to deliver different types

of scents. This system has been incorporated into the Full Spectrum Virtual Iraq/Afghanistan PTSD Therapy Application to provide the smell of rubber, cordite, garbage, body odor, smoke, diesel fuel, gunpowder, and other scents of the battlefield (S. Rizzo et al., 2006). These scents can be used as direct stimuli (e.g., scent of burning rubber) or as general cues to increase immersion (e.g., ethnic food cooking). The Scent Pallet was used to present vanilla, pizza, coffee, whiskey, beer, brandy, tequila, gin, scotch, red wine, white wine, cigarette smoke, and pine tree scents in an alcohol cue reactivity assessment system, which was found to be highly effective in stimulating subjective alcohol cravings (Bordnick et al., 2008). While several have mentioned the incorporation of gustatory stimulation, there are currently no functioning systems (Basdogan and Loftin, 2008).

### 2.1.2 Tracking Systems

Tracking systems allow determination of users' head or limb position and orientation or the location of handheld devices in order to allow interaction with virtual objects and traversal through 3D computer-generated worlds (Foxlin, 2002). Tracking is what allows the visual scene in a VE to coincide with a user's point of view, thereby providing an egocentric real-time perspective. Tracking systems must be carefully coupled with the visual scene, however, to avoid unacceptable lags (Kalawsky, 1993). Advances in tracking technology have been realized in terms of drift-corrected gyroscopic orientation trackers, outside-in optical tracking for motion capture, and laser scanners (Foxlin, 2002). The future of tracking technology is likely hybrid tracking systems (http://www.intersense.com/hybrid_technology .aspx), such as optical-inertial, GPS-inertial, magnetic-inertial, digital acoustic-inertial, and optical-magnetic hybrid solutions.

Tracking technology also allows for gesture recognition, in which human position and movement are tracked and interpreted to recognize semantically meaningful gestures (Turk, 2002). Gestures can be used to specify and control objects of interest, direct navigation, manipulate the environment, and issue meaningful commands. Gesture tracking devices that are worn (e.g., gloves, bodysuits) are currently more advanced than passive techniques (e.g., computer vision), yet the latter hold much promise for the future, as they can provide more natural, noncontact, and less obtrusive solutions than those that must be worn; limitations need to be overcome in terms of accuracy, processing speed, and generality (Erol et al., 2007).

### 2.1.3 Interaction Techniques

While one may think of joysticks and gloves when considering VE interaction devices, there are many techniques that can be used to support interaction with and traversal through a virtual environment. Interaction devices support traversal, pointing and selection of virtual objects, tool usage (e.g., through force and torque feedback), tactile interaction (e.g., through haptic devices), and environmental stimuli (e.g., temperature, humidity) (Bullinger et al., 2001).

Supporting traversal throughout a VE, via motion interfaces, is of primary importance (Hollerbach, 2002). Motion interfaces are categorized as either active (e.g., locomotion) or passive (e.g., transportation). Active-motion interfaces require self-propulsion to move about a virtual environment (e.g., treadmill, pedaling device, foot platforms). Passive-motion interfaces transport users within a VE without significant user exertion (e.g., inertial motion, as in a flight simulator, or noninertial motion, such as in the use of a joystick or gloves). The utility, functionality, cost, and safety of locomotion interfaces beyond traditional options (e.g., joysticks) have yet to be proven. In addition, beyond physical training, concrete applications for active-motion interfaces have yet to be clearly delineated. There are, however, some example applications, such as Arch-Explore, which is a real walking user interface that adapts redirected walking to allow exploration of large-scale virtual models of architectural scenes in a room-sized virtual environment (Bruder et al., 2009).

Another interaction option is speech control (see Chapters 8 and 35). Continuous speech recognition systems are currently under development, such as Parakeet (Vertanen and Kristensson, 2009), PocketSphinx (Huggins-Daines et al., 2006), and PocketSUMMIT (Hetherington, 2007). For these systems to provide effective interaction, however, additional advances are needed in acoustic and language-modeling algorithms to improve the accuracy, usability, and efficiency of spoken language understanding; such systems are still a ways away from offering conversational speech.

To support natural and intuitive interaction, a variety of interaction techniques can be coupled. For example, combining speech interaction with nonverbal gestures and motion interfaces can provide a means of interaction that closely captures real-world communications.

### 2.1.4 Augmented Cognition Techniques

Augmented cognition is an emerging computing paradigm in which users and computers are tightly coupled via physiological gauges that measure the cognitive state of users and adapt interaction to optimize human performance (Stanney et al., 2009). If incorporated into VE applications, augmented cognition could provide a means of evaluating their validity and compelling nature. For example, neuroscience studies have established that differential aspects of the brain are engaged when learning different types of materials and the areas in the brain that are activated change with increasing competence (Carroll et al., 2010a; Kennedy et al., 2005). Thus, if VE users were immersed in an educational experience, augmented cognition technology could be used to gauge if targeted areas of the brain were being activated and dynamically modify the content of a VE learning curriculum if desired activation patterns were not being generated. Physiological measures could also be used to detect the onset of cybersickness (see Section 4.1) and to assess the engagement, awareness, and anxiety of VE users, thereby potentially providing much more robust measures of immersion and presence (see Section 5.2). Such techniques could prove invaluable to entertainment VE applications (cf. Badiqué et al., 2002)

that seek to provide the ultimate experience, military training VE applications (cf. Knerr et al., 2002) that seek to emulate the "violence of action" found during combat, medical training applications (Wiecha et al., 2010) that seek to enhance traditional lab-based and classroom training practices, and therapeutic VE applications (cf. North et al., 2002; Strickland et al., 1997) that seek to overcome disorders such as fear of heights or flying.

## 2.2 Software Requirements

Software development of VE systems has progressed tremendously, from proprietary and arcane systems to development kits that run on multiple platforms (e.g., general-purpose operating systems to workstations). Virtual environment system components have become modular and distributed, thereby allowing VE databases (e.g., editors used to design, build, and maintain virtual worlds) to run independently of visualizers and other multimodal interfaces via network links. Standard APIs (application program interfaces) (e.g., OpenGL, Open Inventor, Direct3D, Mesa3D) allow multimodal components to be hardware independent. Virtual environment programming languages are maturing, with APIs, libraries (OpenGL Performer), and scripting languages (e.g., JavaScript, Lua, Linden, Mono, Perl, Python, Ruby) allowing nonprogrammers to develop virtual worlds (Stanney and Zyda, 2002). Advances are also being made in modeling of autonomous agents and communication networks used to support multiuser virtual environments.

### 2.2.1 Modeling

A VE consists of a set of geometry, the spatial relationships between the geometry and the user, and the change in geometry invoked by user actions or the passage of time (Kessler, 2002). Generally, modeling starts with building the geometry components (e.g., graphical objects, sensors, viewpoints, animation sequences) (Kalawsky, 1993). These are often converted from computer-aided design (CAD) data. These components then get imported into the VE modeling environment and rendered when appropriate sensors are triggered. Color, surface textures, and behaviors are applied during rendering. Programmers control the events in a VE by writing task functions, which become associated with the imported components.

A number of 3D modeling languages and toolkits are available that provide intuitive interfaces and run on multiple platforms and renderers (e.g., 3D Studio Max, AC3D, ZBrush, modo 401, Nexus, AccuRender, 3d ACIS Modeler, Ashlar-Vellum's Argon/Xenon/Cobalt, Carrara, CINEMA 4D, DX Studio, EON Studio, solidThinking) (Ultimate 3D Links, 2010). In addition, there are scene management engines (e.g., OpenSceneGraph, NVIDIA's SceniX) and game engines (e.g., Real Virtuality) that allow programmers to work at a higher level, defining characteristics and behaviors for more holistic concepts (Karim et al., 2003; Menzies, 2002). There have also been advances in photorealistic rendering tools (e.g., EI Technology's Amorphium), which are

evolving toward full-featured physics-based global illumination rendering systems (e.g., RenderPark). Taken together, these advances in software modeling allow for the generation of complex and realistic VEs that can run on a variety of platforms, permitting access to VE applications by both small- and large-scale application development budgets.

### 2.2.2 Autonomous Agents

Autonomous agents are synthetic or virtual human entities that possess some degree of autonomy, social ability, reactivity, and proactiveness (Allbeck and Badler, 2002; also see Chapter 15). There are several types of agents (Serenko and Detlor, 2004), including user agents (i.e., assist users by interacting with them, knowing their preferences and interests, and acting on their behalf), service agents (i.e., seamlessly collaborate with different parts of a system and perform more general tasks in the background, unbeknownst to users), embedded agents (i.e., interact with user and system to hide task complexity and make the overall user experience more exciting and enjoyable), and stand-alone agents (i.e., employ leading edge technologies and lay down the foundation for new architectures, standards, and innovative formats of agent-based computing). Autonomous agents can have many forms (e.g., human, animal), which are rendered at various levels of detail and style, from cartoonish to physiologically accurate models, and the form of the agent has been found to influence behavior both during and post VE exposure (i.e., the Proteus effect, where people infer their expected behaviors and attitudes from observing the appearance of their avatar; Yee et al., 2009). Such agents are a key component of many VE applications involving interaction with other entities, such as adversaries, instructors, or partners (Stanney and Zyda, 2002). Considerable work is being done to enhance the believability of such agents. For example, Heylen et al. (2008) found that when humanlike eye gaze behavior was incorporated into agents, that users communicated with such agents more effectively, and of utmost importance, human performance was also found to be enhanced with the more lifelike agents. As our understanding of how best to design autonomous agents evolves, such principles will be important to incorporate into their design to enhance the overall engagement and effectiveness of virtual worlds.

There has been significant research and development in modeling embodied autonomous agents. As with object geometry, agents are generally modeled off-line and then rendered during real-time interaction. While the required level of detail varies, modeling of hair and skin adds realism to an agent's appearance (Allbeck and Badler, 2002). There are a few toolkits available to support agent development, with one of the most notable offered by Boston Dynamics, Inc. (BDI) (http://www.bostondynamics.com/bd_diguy.html/), a spin-off from the MIT Artificial Intelligence Laboratory. BDI's DI-Guy allows VE developers to quickly integrate humans into their VEs, providing artificial intelligence to the characters, thereby enabling agents to autonomously navigate and react to their changing environment. Another option is ArchVision's 3D Rich

Photorealistic Content (RPC) People (http://www.archvision.com/RPCPeople.cfm).

### 2.2.3 Networks

Distributed networks allow multiple users at diverse locations to interact within the same virtual environment. Improvements in communication networks are required to allow realization of such shared experiences in which users, objects, processes, and autonomous agents from diverse locations interactively collaborate (Durlach and Mavor, 1995). Yet the foundation for such collaboration has been built within Internet2 (http://www.internet2.edu/), a next-generation Internet Protocol (IP) that delivers production network services for research and education institutions. This optical network could meet the high-performance demands of VEs, as it allows user-based allocation of high-capacity data circuits over a fiber-optic network. In addition, the Large Scale Networking (LSN) Coordinating Group (http://www.nitrd.gov/subcommittee/lsn.aspx) aims to develop leading-edge networking technologies and services, including programs in network security, new network architectures, heterogeneous networking (optical, mobile wireless, sensornet, etc.), federation across networking domains, grid and collaboration networking tools and services, with a goal of assuring that the next generation of the Internet will be scalable, trustworthy, and flexible. There are additional novel network technologies, including IP multicasting (i.e. a routing technique to prioritize one-to-many communication over an IP infrastructure in a network), quality of service (i.e., resource reservation control mechanisms), and IPv6 [i.e., also called IPng (or IP Next Generation), is a next generation IP addressing system] that could support distributed VE applications, which can leverage the special capabilities (e.g., high bandwidth, low latency, low jitter) of these advancing network technologies to provide shared virtual worlds.

## 3 DESIGN AND IMPLEMENTATION STRATEGIES

While many conventional HCI techniques can be used to design and implement VE systems, there are unique cognitive, content, product liability, and usage protocol considerations that must be addressed (see Figure 2).

### 3.1 Cognitive Aspects

The fundamental objective of VE systems is to provide multimodal interaction or, when sensory modalities are missing, perceptual illusions that support human

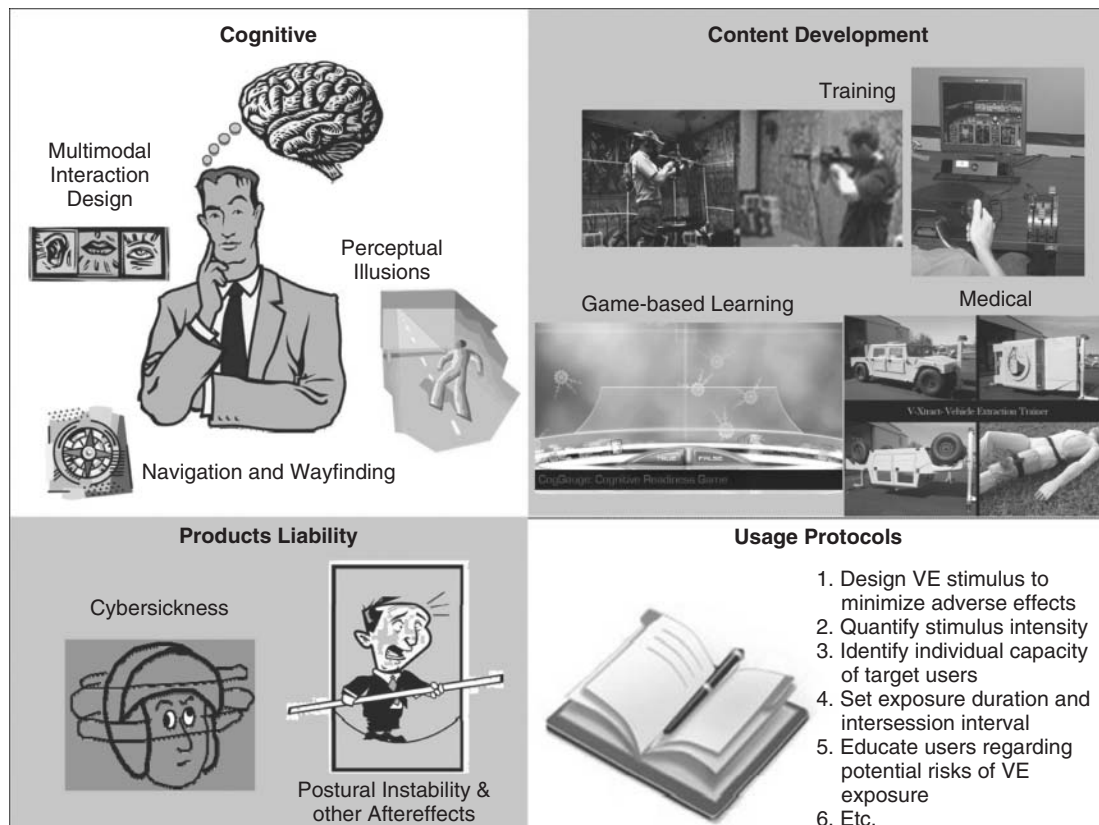

**Figure 2** VE design and implementation strategies.

information processing in pursuit of a VE application's goals, which could range from training to entertainment. Ancillary yet fundamental to this goal is to minimize cognitive obstacles, such as navigational difficulties, that could render a VE application's goals inaccessible.

### 3.1.1 Multimodal Interaction Design

Virtual environments are designed to provide users with immersive experiences that allow for direct manipulative and intuitive interaction with multisensory stimulation (Bullinger et al., 2001). The goals of providing this multimodal interaction within a VE are to achieve human–human communication/human–system interaction that is as natural as possible and to increase the robustness of this interaction by using redundant or complementary cues (Reeves et al., 2004). If designed effectively, engagement in such immersive multimodal VE experiences can lead to high levels of situation awareness and in turn high levels of human performance; however, the multimodal interaction within the VE must be appropriately designed to lead to this enhanced awareness. Specifically, the number of sensory modalities stimulated and the quality of this multisensory interaction are critical to the immersiveness and potential effectiveness of VE systems (Popescu et al., 2002). There are some emerging guidelines in the design of such multimodal interaction. For example, Stanney et al. (2004) provided a set of preliminary cross-modal integration rules. These rules consider aspects of multimodal interaction, including (a) temporal and spatial coincidence, (b) working memory capacity, (c) intersensory facilitation effects, (d) congruency, and (e) inverse effectiveness. When multimodal sensory information is provided to users, it is essential to consider such rules governing the integration of multiple sources of sensory feedback. VE users have adapted their perception–action systems to "expect" a particular type of information flow in the real world; VEs run the risk of breaking these perception–action couplings if the full range of sensory is not supported or if it is supported in a manner that is not contiguous with real-world expectations. Such pitfalls can be avoided through consideration of the coordination between sensing and user command and the transposition of senses in the feedback loop. Specifically, command coordination considers user input as primarily monomodal and feedback to the user as multimodal. Designers need to consider which input modalities are most appropriate to support execution of a given task within the VE, if there is any need for redundant user input, and whether or not users can effectively handle such parallel input (Stanney et al., 1998a, 2004). Additional multimodal design guidelines have been provided by Hale et al. (2009), who have outlined how a number of sensory cues may effectively be used to enhance specific situation awareness (SA) components (i.e., object recognition, spatial, temporal) within a VE, with the goal of optimizing SA development.

A limiting factor in supporting multimodal sensory stimulation in VEs is the current state of interface technologies. With the exception of the visual modality, current levels of technology simply cannot even begin to reproduce virtually those sensations, such as haptics and olfaction, which users expect in the real world. One solution to current technological shortcomings, sensorial transposition, occurs when a user receives feedback through senses other than those expected, which may occur because a command coordination scheme has substituted available sensory feedback for those that cannot be generated within a virtual environment. Sensorial substitution schemes may be one for one (e.g., visual for force) or more complex (e.g., visual for force and auditory; visual and auditory for force). If designed effectively, command coordination and sensory substitution schemes should provide multimodal interaction that allows for better user control of the virtual environment. On the other hand, if designed poorly, these solutions may in fact exacerbate interaction problems.

### 3.1.2 Perceptual Illusions

When sensorial transpositions are used, there is an opportunity for perceptual illusions to occur. With perceptual illusions, certain perceptual qualities perceived by one sensory system are influenced by another sensory system (e.g., "feel" a squeeze when you see your hand "grabbing" a virtual object). Such illusions could simplify and reduce the cost of VE development efforts (Storms, 2002). For example, when attending to a visual image coupled with a low-quality auditory display, auditory–visual cross-modal perception allows for an increase in the perceived quality of the visual image. Thus, in this case if the visual image is the focus of the task, there may be no need to use a high-quality auditory display.

There are several types of perceptual illusions that can be used in the design of virtual environments (Steinicke and Willemsen, 2010). Visual illusions can be used to substitute for missing proprioceptive and vestibular senses, as vision usually dominates these senses. For example, vection (i.e., a compelling illusion of self-motion throughout a virtual world) is known to be enhanced via a number of visual display factors, including a wide field of view and high spatial frequency content (Hettinger, 2002), as well as visual jitter (Kitazaki et al., 2010). In addition, change blindness (i.e., failing to notice alterations in a visual scene) can be used to apply subtle manipulations to the geometry of a VE and direct movement behavior, such as redirecting a user's walking path throughout a virtual environment (Suma et al., 2010). Other such illusions exist and could likewise be leveraged if perceptual and cognitive design principles are identified that can be used to trigger and capitalize on these illusory phenomena. For example, acoustic illusions (e.g., a fountain sound; Riecke et al., 2009) could also be used to create a sense of vection in a VE, even when no such visual motion is provided. In addition, haptic illusions (Hayward, 2008) could be used to provide users with the impression of actually feeling virtual objects when they are in fact touching real-world props or traveling along a trajectory path that may even vary in size, shape, weight, or surface from their virtual counterparts without users perceiving these discrepancies (e.g., feel an illusory bump when actually touching a flat surface [Robles-De-La-Torre and Hayward, 2001]; feel an illusory sharp edge when

hand actually travels along a smooth trajectory [Portillo-Rodríguez et al., 2006]).

### 3.1.3  Navigation and Wayfinding

Effective multimodal interaction design and use of perceptual illusions can be impeded if navigational complexities arise. Navigation is the aggregate of wayfinding (e.g., cognitive planning of one's route) and the physical movement that allows travel throughout a virtual environment (Darken and Peterson, 2002). A number of tools and techniques have been developed to aid wayfinding in virtual worlds, including maps, landmarks, trails, and direction finding. These tools can be used to display current position, current orientation (e.g., compass), log movements (e.g., "breadcrumb" trails), demonstrate or access the surround (e.g., maps, binoculars), or provide guided movement (e.g., signs, landmarks) (Chen and Stanney, 1999). For example, Burigat and Chittaro (2007) found 3D arrows to be particularly effective in guiding navigation throughout an abstract virtual environment. Darken and Peterson (2002) provided a number of principles concerning how best to use these tools. If effectively applied to VEs, these principles should lead to reduced disorientation and enhanced wayfinding in large-scale virtual environments.

### 3.2  Content Development

Content development is concerned with the design and construction of the virtual objects and synthetic environment that support a VE experience (Isdale et al., 2002). While this medium can leverage existing HCI design principles, it has unique design challenges that arise due to the demands of real-time, multimodal, collaborative interaction. In fact, content designers are just starting to appreciate and determine what it means to create a full sensory experience with user control of both point of view and narrative development. Aesthetics is thought to be a product of agency (e.g., pleasure of being), narrative potential, presence and co-presence (e.g., existing in and sharing the virtual experience), as well as transformation (e.g., assuming another persona) (Murray, 1997). Content development should be about stimulating perceptions (e.g., sureties, surprises) as well as contemplation over the nature of being (Isdale et al., 2002).

Existing design techniques, for example, from entertainment, video games, and theme parks, can be used to support VE content development (see Chapters 43 and 46). Game development techniques that can be leveraged in VE content development include but are not limited to providing a clear sense of purpose, emotional objectives, perceptual realism, intuitive interfaces, multiple solution paths, challenges, a balance of anxiety and reward, as well as an almost unconscious flow of interaction (Isdale et al., 2002). From theme park design, content development suggestions include (a) having a story that provides the all-encompassing theme of the VE and thus the "rules" that guide design, (b) providing location and purpose, (c) using cause and effect to lead users to their own conclusions, and (d) anchoring users in the familiar (Carson, 2000a, 2000b). While these suggestions provide guidelines for VE content development,

considerable creativity is still an essential component of the process.

While the content incorporated into the virtual worlds of today is mostly quite separate from the real world, in recent years life and technology have been more tightly coupled, the result being that computers are starting to have an awareness of themselves as well as the people who interact with them in 3D virtual spaces that are evolving into a "second life." Virtual worlds are in fact penetrating our native space and content development for future generations will likely aim to allow us to seamlessly use our own native language, with its wide range of verbal and physical gestures and emotions, thereby more fully entwining our first and second (virtual) lives (Rolston, 2010).

### 3.3  Product Liability

Those who implement VE systems must be cognizant of potential product liability concerns. Exposure to a VE system often produces unwanted side effects that could render users incapable of functioning effectively upon return to the real world. These adverse effects may include nausea and vomiting, postural instability, visual disturbances, and profound drowsiness (Stanney et al., 1998b). As users subsequently take on their normal routines, unaware of these lingering effects, their safety and well-being may be compromised. If a VE product occasions such problems, liability of VE developers or system administrators could range from simple accountability (e.g., reporting what happened) to full legal liability (e.g., paying compensation for damages) (Kennedy and Stanney, 1996; Kennedy et al., 2002). In order to minimize their liability, manufacturers and corporate users should design systems and provide usage protocols to minimize risks, warn users about potential aftereffects, monitor users during exposure, assess users' risk, and debrief users after exposure.

### 3.4  Usage Protocols

To minimize product liability concerns, VE usage protocols should be carefully designed. A comprehensive VE usage protocol will involve the following activities (see Stanney et al., 2005):

1. Designing VE stimulus to minimize adverse effects by minimizing lags and latencies, optimizing frame rates, and providing an adjustable interpupillary distance on visual display.

2. Quantifying stimulus intensity of a VE system using the Simulator Sickness Questionnaire (Kennedy et al., 1993) or other means and comparing the outcome to other systems (see Stanney et al., 2005). If a given VE system is of high intensity (say the 50th or higher percentile) and is not redesigned to lessen its impact, significant dropouts can be expected.

3. Identifying individual capacity of target user population to resist adverse effects of VE exposure via the Motion History Questionnaire (Kennedy and Graybiel, 1965) or other means.

4. Setting exposure duration and intersession interval to minimize adverse effects by limiting the duration of initial exposures, setting intersession exposure intervals two to five days apart, and moderating the stimulus intensity of virtual experiences (see Stanney et al., 2005).

5. Educating users regarding potential risks of VE exposure (e.g., inform users they may experience nausea, malaise, disorientation, headache, dizziness, vertigo, eyestrain, drowsiness, fatigue, pallor, sweating, increased salivation, and vomiting).

6. Educating users regarding potential adverse aftereffects of VE exposure (e.g., inform users they may experience disturbed visual functioning, visual flashbacks, and unstable locomotor and postural control for prolonged periods post-exposure).

7. Instructing users to terminate VE interaction if they start to feel ill.

8. Providing adequate air flow and comfortable thermal conditions.

9. Adjusting equipment to minimize fatigue.

10. For strong VE stimuli, warning users to avoid extraordinary maneuvers (e.g., flying backward or experiencing high rates of linear or rotational acceleration) during initial interaction.

11. Providing an attendant to monitor users' behavior and ensure their well-being.

12. Specifying amount of time post-exposure that users must remain on premises before driving or participating in other such high-risk activities. Do not allow individuals who fail post-exposure tests or experience adverse aftereffects to conduct high-risk activities until they have recovered (e.g., have someone else drive them home).

13. Calling users the next day or having them call to report any prolonged adverse effects.

Regardless of the strength of the stimulus or the susceptibility of the user, following a systematic usage protocol can minimize the adverse effects associated with VE exposure.

## 4 HEALTH AND SAFETY ISSUES

The health and safety risks associated with VE exposure complicate usage protocols and lead to product liability concerns. It is thus essential to understand these issues when utilizing VE technology. There are both physiological and psychological risks associated with VE exposure, the former being related primarily to sickness and aftereffects and the latter primarily being concerned with the social impact.

### 4.1 Cybersickness, Adaptation, and Aftereffects

Motion-sickness-like symptoms and other aftereffects (e.g., balance disturbances, visual stress, altered hand–eye coordination) are unwanted byproducts of VE exposure (Stanney and Kennedy, 2008). The sickness related to VE systems is commonly referred to as "cybersickness" (McCauley and Sharkey, 1992). Some of the most common symptoms exhibited include dizziness, drowsiness, headache, nausea, fatigue, and general malaise (Kennedy et al., 1993). More than 80% of users will experience some level of disturbance, with approximately 12% ceasing exposure prematurely due to this adversity (Stanney et al., 2003). Of those who drop out, approximately 10% can be expected to have an emetic response (e.g., vomit), however, only 1–2% of all users will have such a response. These adverse effects are known to increase in incidence and intensity with prolonged exposure duration (Kennedy et al., 2000). While most users will experience some level of adverse effects, symptoms vary substantially from one individual to another as well as from one system to another (Kennedy and Fowlkes, 1992). These effects can be assessed via the Simulator Sickness Questionnaire (Kennedy et al., 1993), with values above 20 requiring due caution (e.g., warn and observe users) (Stanney et al., 2005).

To overcome such adverse effects, individuals generally undergo physiological adaptation during VE exposure. This adaptation is the natural and automatic response to an intersensorily imperfect VE and is elicited due to the plasticity of the human nervous system (Welch, 1978). Due to technological flaws (e.g., slow update rate, sluggish trackers), users of VE systems may be confronted with one or more intersensory discordances (e.g., visual lag, a disparity between seen and felt limb position). In order to perform effectively in the VE, they must compensate for these discordances by adapting their psychomotor behavior or visual functioning. Once interaction with a VE is discontinued, these compensations persist for some time after exposure, leading to aftereffects.

Once VE exposure ceases and users return to their natural environment, they are likely unaware that interaction with the VE has potentially changed their ability to effectively interact with their normal physical environment (Stanney and Kennedy, 1998). Several different kinds of aftereffects may persist for prolonged periods following VE exposure (Welch, 1997). For example, hand–eye coordination can be degraded via perceptual–motor disturbances (Kennedy et al., 1997; Rolland et al., 1995), postural sway can arise (Kennedy and Stanney, 1996), as can changes in the vestibulo-ocular reflex (VOR) or one's ability to stabilize an image on the retina (Draper et al., 1997). The implications of these aftereffects are:

1. VE exposure duration may need to be minimized.

2. Highly susceptible individuals or those from clinical populations (e.g., those prone to seizures) may need to avoid or be banned from exposure.

3. Users should be closely monitored during VE exposure.

4. Users' activities should be closely monitored for a considerable period of time post-exposure to avoid personal injury or harm.

## 4.2 Social Impact

Virtual environment technology, like its ancestors (e.g., television, computers), has the potential for negative social implications through misuse and abuse (Kallman, 1993; also see Chapter 61). Yet violence in VE is nearly inevitable, as evidenced by the violent content of popular video games. Such animated violence is a known favorite over the portrayal of more benign emotions such as cooperation, friendship, or love (Sheridan, 1993; also see Chapter 4). The concern is that users who engage in what seems like harmless violence in the virtual world may become desensitized to violence and mimic this behavior in the look-alike real world.

Currently, it is not clear whether or not such violent behavior will result from VE exposure; early research, however, is not reassuring. Calvert and Tan (1994) found VE exposure to significantly increase the physiological arousal and aggressive thoughts of young adults. Perhaps more disconcerting was that neither aggressive thoughts nor hostile feelings were found to decrease due to VE exposure, thus providing no support for catharsis. Such increased negative stimulation may then subsequently be channeled into real-world activities. The ultimate concern is that VE immersion may potentially be a more powerful perceptual experience than past, less interactive technologies, thereby increasing the negative social impact of this technology (Calvert, 2002). A proactive approach is needed which weighs the risks and potential consequences associated with VE exposure against the benefits. Waiting for the onset of harmful social consequences should not be tolerated. Koltko-Rivera (2005) suggests that a proactive approach would involve determining (1) types and degree of VE content (e.g., aggressive, sexual), (2) types of individuals or groups exposed to this content (e.g., their mental aptitude, mental conditioning, personality, worldview), (3) circumstances of exposure (e.g., private experience, family, religion, spiritual), and (4) effects of exposure on psychological, interpersonal, or social function.

## 5 VIRTUAL ENVIRONMENT USABILITY ENGINEERING

Most VE user interfaces are fundamentally different from traditional graphical user interfaces, with unique I/O devices, perspectives, and physiological interactions. Thus, when developers and usability practitioners attempt to apply traditional usability engineering methods to the evaluation of VE systems, they find few if any that are particularly well suited to these environments (for notable exceptions see Gabbard et al., 1999; Hix and Gabbard, 2002; Stanney et al., 2000). There is a need to modify and optimize available techniques to meet the needs of VE usability evaluation as well as to better characterize factors unique to VE usability, including sense of presence.

## 5.1 Usability Techniques

Assessment of usability for VE systems must go beyond traditional approaches, which are concerned with the determination of effectiveness, efficiency, and user satisfaction (Bowman et al., 2002; see Chapter 55). Evaluators must consider whether multimodal input and output are optimally presented and integrated, navigation is supported to allow the VE to be readily traversed, object manipulation is intuitive and simple, content is immersive and engaging, and the system design optimizes comfort while minimizing sickness and aftereffects. The affective elements of interaction also become important when evaluating VE systems (see Chapter 58). It is an impressive task to ensure that all of these criteria are met.

Gabbard et al. (1999) have developed a taxonomy of VE usability characteristics that can serve as a foundation for identifying and evaluating usability criteria particularly relevant to VE systems. Stanney et al. (2000) used this taxonomy as the foundation on which to develop an automated system, MAUVE (Multicriteria Assessment of Usability for Virtual Environments), which assesses VE usability in terms of how effectively each of the following are designed: (a) navigation, (b) user movement, (c) object selection and manipulation, (d) visual output, (e) auditory output, (f) haptic output, (g) presence, (h) immersion, (i) comfort, (j) sickness, and (k) aftereffects. MAUVE can be used to support expert evaluations of VE systems, similar to the manner in which traditional heuristic evaluations are conducted. Due to such issues as cybersickness and aftereffects, it is essential to use these or other techniques (cf. Modified Concept Book Usability Evaluation Methodology; Swartz, 2003) to ensure the usability of VE systems, not only to avoid rendering them ineffective but also to ensure that they are not hazardous to users. Recently, guidelines have been evolving for enhancing the design of social VEs (e.g., Second Life by Linden Labs, Whyville by Numedeon, Inc.), such as those promoted by the Center for Disease Control and Prevention (CDC, 2010) for reaching individuals with timely health information that may relate to campaigns and upcoming events.

## 5.2 Sense Of Presence

A usability criterion unique to VE systems is sense of presence. Virtual environments have the unique advantage of leveraging the imaginative ability of individuals to psychologically "transport" themselves to another place, one that may not exist in reality (Sadowski and Stanney, 2002). To support such transportation, VEs provide physical separation from the real world by immersing users in the virtual world via, for example, an HMD, then imparting sensorial sensations via multimodal feedback that would naturally be present in the alternate environment. Focus on generating such presence is one of the primary characteristics distinguishing VEs from other means of displaying information.

Presence has been defined as the subjective perception of being immersed in and surrounded by a virtual world rather than the physical world one is currently

situated in (Stanney et al., 1998b). Virtual environments that engender a high degree of presence are thought to be more enjoyable, effective, and well received by users (Sadowski and Stanney, 2002). High-presence VEs are also suggested to be effective learning environments (Mantovani and Castelnuovo, 2003), as well as to enhance behavioral modeling outcomes and lead to greater imitation in the physical world (Fox et al., 2009b). Presence can be "broken" (i.e., lost) by external interference (e.g., people talking in the real-world during VE exposure), internal interference (e.g., daydreaming), inconsistent mediation (e.g., lag, distortions), contradictory mediation (e.g., when the virtual does not behave like the real), or unrefined mediation (e.g., information overload; Chertoff, Schatz, McDaniel, and Bowers, 2008). To enhance and maintain presence, designers of VE systems should spread detail around a scene, let user interaction determine when to reveal important aspects, maintain a natural and realistic, yet simple appearance, and utilize textures, colors, shapes, sounds, and other features to enhance realism (Kaur, 1999). To generate the feeling of immersion within the environment, designers should isolate users from the physical environment (use of an HMD may be sufficient), provide content that involves users in an enticing situation supported by an encompassing stimulus stream, provide natural modes of interaction and movement control, and utilize design features that enhance vection (Stanney et al., 2000). To enhance presence in learning environments, the design of perceptual features (i.e., perceptual realism, interactivity and control), individual factors (i.e., imagination and suspension of disbelief, identification, motivation and goals, emotional state), content characteristics (i.e., plot, story, narration, and dramaturgy), and interpersonal, social, and cultural context should be carefully considered (Mantovani and Castelnuovo, 2003). Presence can be assessed via Witmer and Singer's (1998) Presence Questionnaire or techniques used by Slater and Steed (2000) as well as a number of other means (Sadowski and Stanney, 2002).

## 6 APPLICATION DOMAINS

Virtual environments have been adopted by an ever-growing number of domains. Originally primarily used as a training platform, recent times have seen VEs in as diverse areas as operating rooms and courtrooms. These applications can provide adaptable, modest cost, deployable, and safe selection and training solutions, create game-based and learning virtual experiences that would otherwise be impossible to explore, and offer rehabilitation and medical applications that reach far beyond the conventional.

### 6.1 VE as a Selection and Training Tool

If one looks at training as a continuum across which a trainee matures in their declarative, procedural, and strategic knowledge, as well psychomotor skills and attitudes, then VE training is thought to be most suitable once the trainee has foundational declarative knowledge instantiated and some rudimentary procedural knowledge (Cohn et al., 2007). In general, van Merriënboer

and Kester (2005) recommend following the "fidelity principle," where learning is supported via a gradual increase in the fidelity of the training environment. Similarly, many training strategies reduce fidelity early in the training lifecycle to minimize complexity and avoid overloading the trainee (Regian et al., 1992). These suggestions are paralleled by stress-exposure training paradigms that suggest moving trainees through three stages, with an early focus on information provision and knowledge acquisition, followed by skills acquisition, and then culminating with practice of acquired skills under conditions that gradually approximate the stress environment (Driskell and Johnston, 1998). Taken together, these theories suggest the following (Cohn et al., 2007):

- Classroom lectures and low-fidelity training solutions (e.g., schematics, mock-ups) are most suitable for initial acquisition of declarative knowledge (i.e., general facts, principles, rules, and concepts) (Kelly et al., 1985; Rouse, 1982; 1991). VE training simulators would generally be less effective for such initial training, as they can be overly complex and confusing (Andrews, 1988; Boreham, 1985; Jones, 1990).

- Medium-fidelity VE training solutions, such as desktop VEs, are suggested to be suitable for training basic procedural knowledge and problem solving skills, and practice of such skills to mastery (Patrick, 1992; Pappo, 1998).

- High-fidelity VE training solutions, such as fully immersive VEs, can be used for consolidation of learned declarative knowledge and basic skills and procedures, practice of acquired knowledge and skills (e.g., mission rehearsal), as well as development of more advanced strategic knowledge and tactical skills (Forrest et al., 2002; Maran and Glavin, 2003; Vozenilek et al., 2004).

- High-fidelity VE training solutions, which are fully immersive and multisensory, may also be suitable for behavioral conditioning with stressors. Once basic knowledge and skills are mastered, attitudes and stress-induced behaviors are likely most appropriately trained in immersive and engaging solutions, which have the authenticity to generate realistic responses from trainees; yet there is limited research on this topic (Driskell and Johnston, 1998).

Beyond the ability of various forms of VEs to support several stages along the trainee continuum, they also offer the ability to immerse trainees in multiple contexts. This is important because learning is context specific (Anderson et al., 2000). By providing training in multiple context and from multiple points of view, VEs can be used in an effort to avoid the "reductive tendency" of learners to over-simplify new concepts, especially those gleaned in dynamic, highly-interactive environments, as well as the development of "knowledge-shields" erected to confirm simplified beliefs and understandings

(Feltovich et al., 2004). Consequently, while high fidelity VE training simulations oftentimes may be considered as the ultimate training solution, they are not suitable for all types of training and it is essential to determine the optimal level of fidelity that is required for a given training solution.

In terms of applying VE to enhance human performance, training is thus actually the second stage of a two-stage process. Ideally, one would like to select those individuals that have a certain degree of "performance capability" and are, in turn, ready for immersive VE training. Traditional approaches to selection focus on social and psychophysical assessments. For example, aptitude tests, ranging from traditional pen-and-paper-type to psychomotor tests to computer-based (but not VE!) assessments (Carretta and Ree, 1993; 1995), have all been used with varying levels of success. The single most important criticism of each of these approaches is that they are designed to be predictive of future performance and as such are more often than not abstractions of aspects of the larger task(s) for which the individual is being selected. An alternate approach would be to provide selectees with a method that provides a direct indication of their performance abilities. This distinction, essentially between a test being predictive of performance ability versus indicative of performance ability, has a great impact on selection. A meta-analysis performed within the aviation domain, where much of selection research has focused, found that typical predictive validities (most often reported as either the correlation coefficient $r$ or the multiple correlation coefficient $R$ and representing the degree to which given predictor/set of predictors and performance metrics are related) for such assessments range from a low of 0.14 to a "high" of about 0.40 (Martinussen, 1996). Yet, when a virtual simulation component is added to this mix, these values have been shown to improve considerably, pushing correlations towards the 0.60 level (Gress and Willkomm, 1996). This suggests that VE systems should be used as part of a comprehensive performance enhancement program that focuses on selecting those users with the correct set of knowledge, skills, and abilities (KSAs) and then providing, when needed, training to fine tune those KSAs. One approach to accomplishing this goal would be to assess trainee readiness by immersing them in virtual game-based cognitive assessment tools. For example, CogGauge immerses trainees in a mock spaceship cockpit in which the trainees must perform cognitive tasks at various celestial bodies and in so doing gain rewards that can culminate in the creation of a space station (Carpenter et al., 2010; Johnston, Carpenter, and Hale, 2011). The engaging nature of CogGauge serves to motivate trainees, making the KSA assessment process more interesting and engaging. Such immersive assessment tools can be used to determine where in the progression from novice to expert a given trainee is and then provide the most suitable form of training.

The suitability of virtual training solutions has been explored in a wide variety of areas, such as perceptual and cognitive performance (Carroll et al., 2010b), decision making under stress (Carroll et al., 2010a; Hill et al., 2003), operational readiness (Barba et al.,

2006), and cross-cultural communication (Deaton et al., 2005; Stanney et al., 2010). Similarly, VE applications are being used as interactive tools for teaching medical students, nurses, and doctors knowledge and skills as varied as the basics of human anatomy, complicated surgical procedures, communication skills, decision-making skills, and location of medical equipment within critical care vehicles (Grantcharov et al., 2004; Johnsen et al., 2005; Jones et al., 2010; Segal and Fernandez, 2009; Fried et al., 2010; Hassinger et al., 2010). As VE technology has matured, the breadth of VE training applications has likewise grown (King, 2009).

Flight skills are often trained in simulators and virtual environments (e.g., Aerosim's Virtual Flight Deck™, Microsoft Flight Sim, RealFlight®). Such applications provide a good example for demonstrating a key advantage of immersive training, which is the breadth of performance data that can be collected to evaluate training effectiveness. For example, behavioral and neurophysiological measures can be assessed during VE training and used to assess a learner's perceptual and cognitive processes (Carroll et al., 2010b; 2010c). These data can include such things as measurement and synching of eye tracking and electroencephalography (EEG) data with behavioral metrics (e.g., the actions taken in the VE) to capture unobservable performance characteristics, such as learner cognitive state (i.e., workload, engagement, distraction) and perceptual performance (i.e., scan data) during VE training. These data can, in turn, be used to identify the root cause of performance breakdowns and present instructors/ learners with performance summaries, such as scan data heat maps and cognitive replays illustrating how perceptual and cognitive processes contributed to performance breakdowns. The analysis can go even further, spatially correlating eye tracking data with VE scenario specific objects (e.g., specific flight gauges) and then diagnosing such things as the appropriateness of attention allocation (e.g., is the pilot scanning relevant instruments at the correct time?), root cause of performance errors (e.g., is the error due to inadequate scanning, lack of detection of critical events, or inappropriate actions?), and issues with cognitive state (e.g., is the pilot disengaged, overloaded, or distracted?). Thus, interactive VE training solutions allow trainees to not only consolidate their knowledge and practice their skills but also to provide adaptive training based on individual learner performance. The granular level of performance data available to VE training applications can also support "precision" training of various aspects of performance, such as perceptual skills used in search and detection task (e.g., security baggage screening, imagery analysis, threat detection, medical diagnostics; Carroll et al. 2010b, 2010c; Hale et al., 2007). In such applications, trainees can be shown not only the 'right' way to search a scene within a VE, but also how their specific search techniques differed from an expert and demonstrate the types of strategies that would be most helpful in improving an individual trainee's search strategies.

One might ask if the benefits of VE selection and training are worthwhile given the level of effort necessary to develop such immersive applications. In

the U.S. Air Force the cost of a single individual student pilot failing to complete basic flight school can run to $100,000 (Siem et al., 1988). Student failure can be attributed to both inadequate selection techniques and deficient training techniques. Clearly, both selection and training play critical roles in producing effective pilots. The challenge is to develop a training program that ensures a smooth union between the two, a solution that identifies the best candidates and then provides the optimum training. VE training solutions can be used to address both of these aspects of training by using immersive cognitive assessment tools to ensure the trainee is indeed ready for the complexities presented by immersive training and then providing detailed performance diagnostics that can realize "precision" training solutions that are uniquely tailored to a given trainee's performance deficiencies.

While VE applications may prove effective in selecting training candidates and providing them with training that is tailored to their given capabilities, the bottom-line for assessing the value of VE selection and training likely lies in how transferrable the skills from such training are to their target domain. A constant thread in training research is the notion that, in order for training to be effective, the basic skills being taught must show some degree of transfer to real-world performance. Over 100 years ago, Thorndike and Woodworth (1901) laid down the most basic training transfer principle when they proposed that transfer was determined by the degree of similarity between any two tasks. Applying this heuristic to VE design, one might conclude that the most basic way to ensure perfect transfer is to ensure that the real-world performance elements that are meant to be trained should be replicated perfectly in a virtual environment. This notion of "identical elements" could easily create a serious challenge for system designers even by today's technology standards, as VEs are still not able to perfectly duplicate the wide range of sensorial stimuli encountered during daily interactions with our world (Stoffregen et al., 2003). Countering this somewhat simplistic design approach is Osgood's (1949) principle that greater similarity between any two tasks along certain dimensions will not guarantee wholesale, perfect transfer. The challenge, as noted by Roscoe (1982), is to find the right balance between technical fidelity and training effectiveness. These issues are explored in detail by Stanney and Cohn (2012).

## 6.2 VE as an Entertainment and Education Tool

Virtual environments have reached beyond their original applications, primarily as military training tools, and have extended into a wide variety of entertainment applications. From interactive arcades to cybercafes, the entertainment industry has leveraged the unique characteristics of the VE medium, providing dynamic and exciting experiences in a multitude of forms. Virtual environment entertainment applications have found their way into games, sports, movies, art, online communities, location-based entertainment, theme parks, and other venues (Badiqué et al., 2002; Nakatsu et al., 2005). By

exploiting the unique interactive characteristics of VEs compared to more traditional entertainment media (e.g., film, play), VE technology provides a more immersive medium for entertainment through the use of simple artificial virtual characters (i.e., avatars), engaging narrative, and dynamic control to create an immersive interactive experience.

There are many forms of virtual entertainment, including:

- **Video games**. Immersive video games have become omnipresent (Chatfield, 2010). Generally, these games require their users to formulate hypotheses, learn game rules via trial-and-error, multitask, interactively develop strategies, and dynamically solve problems. These are skills that have life-relevance and thus the use of video games for edutainment has been widely considered. In fact, serious games, which are video games aimed at learning and other productive endeavors, are being taken much more *seriously* in recent years (Gunter, Kenny, and Vick, 2008). So, while some lambaste the amount of time young people are engaged in video games and suggest they are living in a media-saturated world (Rideout, Foehr, and Roberts, 2010), others are focused on leveraging this intense interest in productive ways, with one of the primary focuses being the use of interactive games in education (Aldrich, 2009; Squire, 2005). Some even suggest that such games can be used to get over the prepubescent literacy slump that leads to educational failures (Glee, 2008).

- **Computer role-playing games**. Computer role-playing video games (CRPGs; e.g., *Dungeons & Dragons*, *Ultima Underworld*, *Might and Magic*, *The Elder Scrolls*, *Diablo*), involve players in controlling one or more characters (i.e., a "party") as they seek to fulfill a series of quests (Barton, 2007). They involve fantasy, story-telling, and narrative progression, as well as evolving player character development (e.g., health, dexterity, strength). In 3D CRPGs, players typically navigate the game world from a first or third-person perspective. As with video games, CRPGs have been adapted to education purposes such as teaching literacy skills (Adams, 2009) and helping students craft interactive short stories (Carbonaro et al., 2008).

- **Massively multiplayer online role-playing games (MMORPGs)**. MMORPGs (e.g., *EverQuest*, *Meridian 59*, *Ultima Online*, *Final Fantasy*, *World of Warcraft*) are a genre of CRPGs that involve a very large number of players interacting with one another within a virtual game world (Bartle, 2003). They are similar to GRPGs in their makeup but are differentiated by the volume of players involved and the persistence of the virtual world, which evolves continuously, even when players are offline. The psychology of these games has become a topic of interest for academic researcher, with players being

classified into various psychological groups (i.e., achievers, explorers, socializers, killers; Bartle, 2003) and categories of motivation (i.e., immersion, cooperation, achievement, competition; Radoff, 2011). MMORPGs are starting to be used for educational applications, such as teaching science and English (Eustace et al., 2004), as well as supporting cooperative learning activities and exploring research questions (Childress and Braswell, 2006).

- **Massively multiplayer virtual worlds (MMVWs)**. Massively multiplayer virtual worlds (e.g., *Second Life*, *Active World*, *Twinity*, *Smeet*) have been developed that lack the inbuilt narrative, goals/objectives, and rule-based structure of games and instead provide the opportunity to explore and engage with other residents and avatars of the world through socializing, participating in activities, exploring other lands, and creating and trading virtual property and services with one another (Guest, 2008). Such virtual worlds have been used as a platform for educational purposes, scientific research, and the arts, as well as for launching personal relationships that can even lead to marriage (Dickey, 2005; Hayes, 2006).
- **Alternate reality games (ARGs)**. ARGs (e.g., *Dreadnot*, *The Art of the Heist*, *I Love Bees*, *The Beast*) are virtual games that involve intense player involvement with a real-time story that evolves according to the types of actions participants take in the virtual world (Kim, Allen, and Lee, 2008). Players, which can form into Guilds – associations of players, interact directly with characters, which are controlled by game designers (as opposed to AI), to solve plot-based challenges and puzzles. The ARG community can reach beyond the virtual through such means as websites, email messages, faxes, and voicemail messages, with players working together to analyze the story and coordinate real-life, as well as online activities. ARGs have extended into interactive television (e.g., *The Fallen Alternate Reality*, *ReGenesis Extended Reality*). An intriguing extension is to serious ARGs that focus on real-world problem solving, such as *World Without Oil* that focused on solving the issue of a global oil shortage (Egner, 2009) and *Foldit*, an ARG that reframes nettlesome scientific challenges as a competitive multiplayer computer game, the latter of which amazingly led to a breakthrough in HIV research (Khatib et al., 2011).

The crossover from purely entertainment to edutainment and real-world problem solving suggests that virtual interactive games have the potential to harness the ingenuity of game players into a formidable force that can be directed toward educational purposes, as well as solving a wide range of scientific problems. The future of interactive games is thus most intriguing . . . one cannot help but wonder where this creative energy will be directed in the future.

## 6.3 VE as a Medical Tool

What makes virtual reality application development in the assessment, therapy, and rehabilitation sciences so distinctively important is that it represents more than a simple linear extension of existing computer technology for human use. Virtual reality offers the potential to create systematic human testing, training, and treatment environments that allow for the precise control of complex, immersive, dynamic 3D stimulus presentations, within which sophisticated interaction, behavioral tracking, and performance recording are possible (A. Rizzo et al., 2006, p. 36).

Much has been written about applications for VE within the medical arena (cf. Moline, 1995; Satava and Jones, 2002). While some of these applications represent unique approaches to harnessing the power of VE, many other applications, such as simulating actual medical procedures, reflect training applications and therefore will not be discussed anew here. One area of medical application for which VE is truly coming into its own is medical rehabilitation. In particular, two areas of rehabilitation, behavioral/cognitive and motor, show strong promise.

### 6.3.1 Behavioral/Cognitive Rehabilitation Applications

In terms of behavioral rehabilitation applications, VE applications have been gaining prominence in behavioral science research over the past several years. For example, VE cue reactivity programs have been successfully tested for feasibility in nicotine (Bordnick et al., 2005), opiates (Kuntze et al., 2001), and alcohol (Bordnick et al., 2008) dependent individuals, as well as those with eating disorders (Gutiérrez-Maldonado et al., 2006). VE applications have also shown promise in modifying exercise behavior (Fox and Bailenson, 2009) and retirement savings behavior (Ersner-Hershfield et al., 2008) and managing pain (Dahlquist et al., 2007; Gold et al., 2007; Hoffman et al., 2008). Perhaps the fastest growing application for VEs in behavioral rehabilitation is in the area of exposure therapy (Fox et al., 2009a; Gregg and Tarrier, 2007; Parsons and Rizzo, 2008; Powers and Emmelkamp, 2008). For example, VE applications have been used to treat acrophobia (the fear of heights; Coelho et al., 2006), agoraphobia (fear of open spaces; Botella et al., 2007), arachnophobia (fear of spiders; Cote and Bouchard, 2005), aviophobia (fear of flying; Rothbaum et al., 2000), combat-related posttraumatic stress disorder (Reger and Gahm, 2008), panic disorder (Botella et al., 2007), public speaking anxiety (Harris et al., 2002), and social phobia (Roy et al., 2003). The reason for this broad use of VE technology for exposure therapy is likely due to the ideal matching between VE's strengths (presenting evolving information with which users can interact in various ways) and such therapy's basic requirements (incremental exposure to the offending environment). Importantly, compared to previous treatment regimens, which often-times simply required patients to mentally revisit their fears, VEs offer a significantly more immersive experience. In fact, it is quite likely that many of VE's

shortcomings, such as poor visual resolution, inadequate physics modeling underlying environmental cues, and failure to fully capture the wide range of sensorial cues present in the real world, will be ignored by the patient, whose primary focus is on overcoming anxiety engendered by her or his specific phobias. On a practical level, VEs enable patients to virtually visit their therapist's office, where they can be provided an individually tailored multimodal treatment experience (Rothbaum et al., 1996; Emmelkamp et al., 2001; Anderson et al., 2003).

Beyond behavioral rehabilitation, VE applications are being developed for the study, assessment, and rehabilitation of various types of cognitive processes, such as perception, attention, and memory. For example, VE applications are being used as perceptual skills trainers, such as for elderly drivers who have degraded visual scanning behavior (Romoser and Fisher, 2009) and for rehabilitating stroke victims who suffer from unilateral spatial neglect, where an individual fails to perceive stimuli presented to the contralesional hemivisual field even though they are not "blind" to this area (Katz et al., 2005). In terms of attention, attention-deficit hyperactivity disorder (ADHD) is an example of a cognitive dysfunction that has been addressed via VE rehabilitation applications (Parsons et al., 2007). Brooks and Rose (2003) suggest that VE rehabilitation applications can be used both in terms of assessment of memory impairments and memory remediation (e.g., use of reorganization techniques), where it has been found to promote procedural learning of those with memory impairments; importantly, this learning has been found to transfer to improved real-world performance. Examples of memory remediation in VEs include its use to enhance the ability of stroke victims to remember to perform actions in the future (Brooks et al., 2004), as well as its use in enhancing the performance of an individual with age-related impairment in memory-related cognitive processes (Optale et al., 2001). VEs have also been shown to uncover subtle cognitive impairments that might otherwise go undetected (Tippett et al., 2009). In general, VE applications can provide precisely controlled means of assessing cognitive impairments that are not available using more traditional evaluation methods. Specifically, VEs can deliver an assessment environment, where controlled stimuli can be presented at varying degrees of perception/attention/memory challenge and level of deficit can be assessed. This level of experimental control allows for the development of both cognitive impairment assessment and rehabilitation applications that have a high level of specificity and ecological validity.

### 6.3.2 Motor Rehabilitation Applications

Many of VE's qualities that make it an ideal tool for providing medical training—such as tactile feedback and detailed visual information (Satava and Jones, 2002)—also make it an ideal candidate for supplementing motor rehabilitation treatment regimens for such conditions as stroke (Deutsch and Mirelman, 2007; Yeh et al., 2007), cerebral palsy (Bryanton et al., 2006), and

amblyopia (i.e., lazy-eye; Eastgate et al., 2006). Specifically, Fox et al. (2009a) suggest that VEs have three features that make them uniquely suited to facilitating motor rehabilitation: the ability to review one's physical behavior and interactively examine one's progress, see one's own avatar from a third-person perspective in real time, and safely re-create real environments that cannot otherwise be experienced (e.g., crossing a busy intersection). In determining how best to apply VE in physical rehabilitation treatment regimens, Holden (2005) suggested considering three practical areas in which VE is strongest: repetition, feedback, and motivation. All three elements are critical to both effective learning and regaining motor function. The application of VE, in each case, provides a powerful method for rehabilitation specialists to maximize the effect of a treatment regimen for a given session and, because they may reduce the time investment required by therapists (one can simply immerse the patient, initiate the treatment, and then allow the program to execute), to also expand the access of such treatments to a wider population.

Since VE is essentially computer based, patients can effectively have their attention drawn to a specific set of movement patterns they may need to make to regain function; conducting this in a "loop" provides unlimited ability to repeat a pattern while using additional visualization aids, such as a rendered cursor or "follow-me" types of cues, to force the patient into moving a particular way (cf. Chua et al., 2003). As well, it is a relatively simple matter to digitize movement information, store it, and then, based on comparisons to previously stored, desired, movement patterns, to provide additional feedback to assist the patient. In terms of motivation, treatment scenarios can be tailored to capture specific events that individual patients find most motivating: a baseball fan can practice her movement in a baseball-like scenario; a car enthusiast can do so in a driving environment.

There are certain caveats that must be considered when exploiting VE for rehabilitation purposes, most significantly the potentially rapid loss of motor adaptations following VE exposure. Lackner and DiZio (1994) demonstrated that certain basic patterns of sensorimotor recalibrations learned in a given physical environment can diminish within an hour, postexposure, although subsequent findings (DiZio and Lackner, 1995) suggest that there are certain transfer benefits that are longer lasting. Brashers-Krugg et al. (1996) provided additional evidence that sensorimotor recalibrations of the type likely to be required for rehabilitation have postexposure periods in excess of 4 h during which their effects can be extinguished. Most importantly, Cohn et al. (2000) demonstrated that such recalibrations, when learned in VE, have essentially no transfer to real-world conditions postexposure. Clearly, more research is needed to understand the conditions under which such transfer effects can be made most effective within the clinical setting.

This is just a small glimpse of the potential applications for VE technology, the limit of which is bound only by our imagination. Recently, they have even been suggested as having potential value as a simulation of experience to enhance courtroom practice (Leonetti and

Bailenson, 2010). It will be interesting to see the vast variety of future VE applications that evolve.

## 7 CONCLUSIONS

Virtual environments have made substantial advances over the past decade, both in terms of the hardware and software used to generate them, as well as the breadth of their application. Yet, despite significant revolutions in component technology, many of the challenges addressed by incipient systems, such as multimodal sensori-interaction, visual representation, and scenario generation, have yet to be fully resolved. At the same time, our understanding of the potential such tools have to offer has advanced considerably. No longer simple amusements, these powerful machines can provide educational value, assist in treating physical and cognitive maladies, and even help design better VE systems. As the uses for which VEs are ideally suited continue to be defined and refined, one can anticipate that current development challenges will be resolved, allowing for a greater reach and more beneficial impact from applications of VE technology.

*Despite moments of insight and even genius, the human mind often seems to fall far below its full potential. The level of human thought varies greatly in awareness, efficiency, creativity, and accuracy. Our physical and sensory capabilities are limited . . . [Moreover], our tools are difficult to handle, rather than being natural extensions of our capabilities. In the coming decades, however, converging technologies promise to increase significantly our level of understanding, transform human sensory and physical capabilities, and improve interactions between mind and tool.*

Roco and Bainbridge (2002, p. 4)

## 1 INTRODUCTION

Realizing the full potential of the human mind is arguably the goal of neuroergonomics. This burgeoning field evolved from a need to increase the intimacy of the coupling between human and system in an effort to alleviate costs that less sensitive approaches to augmenting human performance have imposed. Our implements are intended to be intuitive, natural extensions of human capabilities; yet more often than not support solutions fall far short of this goal. For example,

---

[*] Current affiliation: Fraunhofer Institute for Communication, Information Processing and Ergonomics FKIE, Wachtberg, Germany.

in the modern era, as tools evolved, they brought to light the physical limitations of the human and, in turn, the field of ergonomics emerged to address these limitations (Stanney, in press). Consequently, with proper ergonomic design, an anatomical fit between human and system is achieved. With the information age, massive data revealed the cognitive limitations of the human and in response the field of cognitive ergonomics (also called human–computer interaction, usability, human–systems integration) arose and provided for a better cognitive fit between human and system (Hoc, 2008). Yet, even with the gains provided by these fields, the systems of today often stretch human capabilities, rendering the solutions far less powerful than intended. Current predictions are grim, with some forecasting that by "2030 machine capabilities will have increased to the point that humans will have become the weakest component in a wide array of systems and processes" (Dahm, 2010, p. x).

In an effort to avoid this inauspicious outcome and, in turn, realize the human potential, the nature of human–system couplings is evolving. Whereas in the past efforts to resolve incompatibilities between human and system have been tackled from the "outside in," providing support via better cognitive and physical design, current efforts are delving inward peering into the brain and translating neural signals into models that can precisely support the current cognitive and physical state of the human. Thus, the third ergonomic era has emerged—that of neural ergonomics (also called neuroergonomics; Parasuraman 2003; Parasuraman and Wilson, 2008), which seeks to direct and adapt human–system interaction based on real-time knowledge of human brain function, thereby achieving precise optimization of the fit between human and system. This era aims to overcome the constraints that human cognitive and physical limitations present and add the brain as another physical structure around which ergonomic principles can be applied for optimizing interactive system design (Hancock and Szalma, 2004; Fafrowicz and Marek, 2007). The result is the design of a neuro-sustainable environment that embraces the human potential rather than one that creates meaningless conflict with our fastidious, built-in human software (Tolja, 2010).

While much work still needs to be done to formalize the neuroergonomics field of study, Parasuraman and Hancock (2004, p. 4) have suggested that the tenets of this field include the view that "(a) the human brain implements cognition and action, (b) the brain is itself shaped by the physical environment, and (c) both brain and behavior (e.g., action) must be examined in order to understand fully how human cognition and action are coordinated with the world of artifacts." Neuroergonomics is seen as an expansion of the communication channels between human and system (Hancock and Szalma, 2004), one that is based on a deep knowledge of the brain in its situated environment. The power of neuroergonomics thus lies in the validity of its measurement of cognitive activity, established by correlating neurophysiological signatures to cognitive measures (e.g., workload, engagement, distraction) and associating these indicators with a given environmental context

(Hettinger et al., 2003). This, in turn, allows for adaptation of the environment to better fit the capabilities of the human. One can easily see the value of such neuroadaptive systems in the context of a monitoring task, such as airport baggage screening (Carpenter et al., 2010), where a change in brain state indicating inattentiveness to a monitoring event could be detected and the screener's attention could be appropriately redirected to an item of interest. Such adaptations are not limited to the cognitive domain, as possible applications of neuroadaptive systems extend to physical activity, where sensing equipment could be used to detect physical limitations (e.g., muscular fatigue, musculoskeletal injury, physical disability) and adapt human input requirements accordingly (Karwowski et al., 2003). In such cases, an individual would no longer have to use muscular activity (e.g., press a key, move a mouse) to interact with the environment but could instead direct their mental activity and use unique brain electrical "signatures" to control external devices (Parasuraman and Wilson, 2008). Such synergy between human and system has brought about ethical concerns. Specifically, as the coupling between human and system becomes more intimate and the number of direct links between brain activity and system activity increases, the boundaries of human identity blur; such philosophical matters have been discussed in detail elsewhere (Hancock and Szalma, 2004, 2006; Keebler et al., 2010).

Neuroadaptive systems thus promise to provide a very tightly coupled feedback loop in which the system modifies its behavior to effectively accommodate meaningful variations in the state of the user, thereby remediating the fundamental communications disconnect that so often exists between humans and their support systems (Hettinger et al., 2003). Such systems aim to achieve highly synergistic communication between human and system by directly detecting and recognizing situations in which the user's cognitive and/or physical state has changed in a manner that affects system interaction and then balancing information flow and interaction demands on a moment-by-moment basis to precisely match the dynamic state of the user. This dynamic synergy may ultimately bring us closer to realizing the full potential of the human mind. To realize this goal, it is essential to first understand human information processing and how best to dynamically adapt information flow and interaction demands given the human's capabilities and limitations.

## 1.1 Human Information-Processing Limitations

Current understanding of human information processing suggests that information is perceived through multiple sensory processors. This information is then perceptually encoded (i.e., stimulus is identified and recognized), processed by a working memory (WM) subsystem that is regulated and controlled by attention via the executive function (EF), which may be supported by long-term memory (LTM), to arrive at a decision, which in turn triggers a human response (Baddeley, 1986, 1990, 2000; Wickens, 1992). Within human information processing there are several "bottlenecks" or points of limited

processing capacity, including sensory memory, WM, attention, executive function, and response execution.

### 1.1.1 Sensory Memory Bottleneck

Sensory memory is responsible for encoding information and converting it to a usable mental form (Atkinson and Shiffrin, 1968, 1971). Research suggests there may be different sensory memory system for each of the human senses, including visual, auditory, tactile (haptic), olfactory, and gustatory. Behavioral studies suggest that human information processing begins with information being perceived on average in about 100 ms (Cheatham and White, 1954; Harter, 1967) by one of the sensory processors. The visual *iconic* sensory memory modality has been suggested to have an average capacity of about 17 items, and this iconic percept is fleeting, decaying completely, on average, in about 200 ms if it does not transfer to WM (Sperling, 1960, 1963; Averbach and Coriell, 1961; Neisser, 1967). Audition, or *echoic* sensory memory, is suggested to have an average capacity of five items and is a bit more persistent, with the "internal echo" lasting an average of about 1.5 s (Neisser, 1967; Darwin et al., 1972). *Haptic* sensory memory is very limited in terms of capacity (Watkins and Watkins, 1974; Mahrer and Miles, 2002) and has a decay rate between 2 and 8 s (Bliss et al., 1966; Posner and Konick, 1966; Lachman et al., 1979). Little is known about olfactory and gustatory sensory memories. In general, a considerable amount of information can be perceived if it is allocated across *multiple* sensory systems. Thus, *given the limited capacity of sensory memory, neuroergonomics seeks to enhance sensory perception by exploiting multiple sensory channels for increased input capacity* (see Table 1). Sensory stimuli that have passed the sensory memory bottleneck and are rapidly decaying must then compete for the drastically limited resources of WM and attention.

### 1.1.2 Working Memory Bottleneck

Working memory allows people to maintain and manipulate information that has been perceived by sensory memory and is currently available in a short-term memory store. In general, WM is described as a functional component of cognition "that allows humans to comprehend and mentally represent their immediate environment, to retain information about their immediate past experience, to support the acquisition of new knowledge, to solve problems, and to formulate, relate, and act on current goals" (Baddeley and Logie, 1999, p. 29). It is considered a temporary active storage area where information is manipulated and maintained for executing simple and complex tasks (e.g., serial recall, problem solving). Working memory is divided into separate processes that are required for short-term storage [according to Baddeley and Logie's (1999) model, these include the phonological loop and visuospatial sketchpad] and for allocating attention and coordinating maintained information (i.e., the executive function).

Working memory is still being defined, and research has suggested dissociations in both the phonological loop (i.e., phonological store vs. articulatory rehearsal mechanism) (Baddeley and Logie, 1999) and visuospatial sketchpad (visual form and color recognition vs. localization) (Carlesimo et al., 2001; Mendez, 2001; Pickering, 2001). Further definition of the visual component of working memory has recently suggested that only one *high-resolution* object representation can be maintained in visual working memory (while many high-resolution representations can be maintained in iconic sensory memory and visual short-term memory; Sligte et al., 2010). Such capacity has recently been found to depend on the informational maximum rather than an item number maximum (Alvarez and Cavanaugh, 2004; Luria et al., 2010; Sligte et al., 2010). In general, WM is said to have a limited capacity of about seven chunks, a rapid decay rate of about 200 ms, and a recognize–act processing time of 70 ms, on average (Miller, 1956; Card et al., 1983). Research suggests, however, that presenting information multimodally can in fact enhance human information processing via an increase in WM capacity, with gains on the order of three times Miller's (1956) "magical number" of 7 being realized in one such study (Samman et al., 2004). These gains could be tempered if the costs for modality switching are high; this is discussed in the next two sections.

**Table 1 Neuroergonomics Approaches to Overcoming Human Information-Processing Bottlenecks**

| Human Information- Processing Bottleneck | Objective |
| --- | --- |
| Sensory memory | Enhance sensory perception by exploiting multiple sensory channels for increased input capacity |
| Working memory | Support simultaneous processing of competing tasks by allocating data streams strategically to various multimodal sensory systems while maintaining multimodal information demands within working memory capacity |
| Attention | Equip computers such that they become aware of subtle cues emanating from humans indicating how they are prioritizing incoming information (i.e., directing attention) and capitalize on these cues to enhance human information processing |
| Executive function | Enhance information processing by directing the recall of contextual information that cues the optimal interpretation of incoming information and moderates the effects of modality switching |
| Response execution | Expand available response modalities by allowing for direct brain–computer interaction |

Given separable WM components and WM capacity enhancements based on modality, Wickens's (1984) multiple resource theory (MRT) can be expanded to suggest that *modality-based* resources can be utilized strategically at different points in user interaction to streamline a user's cognitive load (Stanney et al., 2004). In such a case, total WM capacity will depend on how dissimilar streams of information are in terms of modality. An expanded MRT would address how to allocate multimodal WM resources, particularly during multitasking, in such a way as to allow attention to be time shared among various tasks. Thus, *neuroergonomics seeks to support simultaneous processing of competing tasks by strategically allocating data streams to various multimodal sensory systems while maintaining multimodal information demands within WM capacity* (see Table 1).

### 1.1.3 Attention Bottleneck

Three general categories of attention theories can be found in the literature: (1) "cause" theories, in which attention is suggested to modulate information processing (e.g., via a spotlight that functions as a serial scanning mechanism or via limited resource pools); (2) "effect" theories, in which attention is suggested to be a by-product of information processing among multiple systems (e.g., stimulus representations compete for neuronal activation); and (3) hybrids that combine cause-and-effect theories (Fernandez-Duque and Johnson, 2002). In general, attention is suggested to be a selective process via which stimulus representations are transferred between sensory memory and WM and then contribute to the processing of information once in working memory. Attention improves human performance on a wide range of tasks, minimizes distractions, and facilitates access to awareness (i.e., focused attention). In the best case, attention helps to filter out irrelevant multimodal stimuli. In the worst case, critical information is lost due to overload of incoming information, stimulus competition, or distractions. Thus, if one were to try to enhance WM via multimodal interaction, such stimulation would impose a trade-off between the benefits of incorporating additional sensory systems and the costs associated with dividing attention between various sensory modalities (Makovski and Jiang, 2007). Thus, while directed attention can modulate maintenance of specific representations in WM and help define the interplay between attention and WM (Lepsien and Nobre, 2007), attention must be moderated judiciously if it is to support enhanced human performance. Further, "executive" attention (McCabe et al., 2010), also known as executive control (Logan, 2003), attentional control (Balota et al., 1999), controlled attention (Engle et al., 1999), cognitive control (Depue et al., 2006; Jacoby et al., 2005), and inhibitory control (Hasher et al., 2007), among others, is thought to be *the* cognitive ability underlying performance on complex cognitive tasks, and thus its correct modulation is essential if a high level of human–computer symbiosis is to be achieved. Specifically, neuroergonomics seeks to "build systems that sense, and share with users, natural signals about attention to support … fluid mixed-initiative collaboration with computers … an assessment of a user's current

and future attention (could thus) be employed to triage computational resources" (Horvitz et al., 2003, p. 52). Thus, *with neuroergonomics, computers will become aware of subtle cues emanating from humans indicating how they are prioritizing incoming information (i.e., directing attention) and will capitalize on these cues to enhance human information processing* (see Table 1).

### 1.1.4 Executive Function Bottleneck

The EF system is suggested to be responsible for selection, initiation, and termination of human information-processing routines (e.g., encoding, storing, and retrieving) (Matlin, 1998; Baddeley, 2003). It controls (i.e., focuses, divides, and switches) attention, integrates information from WM subcomponents, and connects WM with contextually triggered information from LTM. The EF is thus associated with regulatory processes underlying the control of human information processing and sheds light on operational costs associated with these control activities (Zakay and Block, 2004). The EF is thought to be especially active in handling novel situations (i.e., those with contextual ambiguity), such as those involving planning or decision making, error correction or troubleshooting, novel sequences of actions or responses, danger or technical difficulty, or the need to overcome habitual responses (Norman and Shallice, 1980; Shallice, 1982). When a person faces such contextual ambiguity during human information processing, high-level control functions of the EF become engaged. During such processing, a person will retrieve the multiple interpretations associated with a given uncertain situation, choose the more likely interpretation based on context and frequency of occurrence, discard alternative interpretations, and mark that point in their information representation as a choice point (Zakay and Block, 2004). Reducing contextual ambiguity, and thus effortful EF processing, would involve easing selection among multiple interpretations by increasing the number of contextual cues associated with any given alternative.

As indicated previously, frequent switching between one modality or task and another will incur a cost of switching that will be associated with inhibitions of responses to the previous modality stimuli or task, selection and activation of the response best associated with the new modality or task context, and resequencing of these stimuli. Since more frequent switching may entail greater contextual changes, it is expected to engage effortful EF processing. Thus, it is important during modality switching to consider the cost of such contextual changes. However, recent research has demonstrated that executive control is plastic and adaptive in terms of its interference resolution process and thus increased efficiency of this process can be obtained through training and could be used to support such modality switching (Persson and Reuter-Lorenz, 2008). Such gains could prove particularly helpful during high-load information processing. *Neuroergonomics seeks to enhance information processing by directing recall of contextual information that cues optimal interpretation of incoming information and moderates the effects of modality switching* (see Table 1).

### 1.1.5 Response Execution Bottleneck

At a choice point, if the EF selects an action, decision information moves into the response execution stage where action commences via a response modality (manual, vocal, eye gaze). Stimulus–central processing–response (SCR) compatibility theory suggests that multimodal stimuli are processed in modality-specific codes and that information will be processed faster if a stimulus (S) is matched with an appropriate response (R) modality (Wickens, 1992). Specifically, tasks that demand verbal WM, such as interpretation of system status, are thought to be best presented via speech and require a *verbal* response, while those that require visual WM, such as remembering the location of a threat on a radar screen, are best presented visually and responded to *manually* (Wickens and Hollands, 2000). However, these mappings may not be as straightforward during multitasking, as response performance (e.g., time, accuracy) tends to break down during complex, high-workload task conditions (Jones et al., 2004). Thus, there is a need to expand response modalities and provide control mechanisms that are effortless and intuitive for use in multitasking environments. Neuroergonomics provides the potential for such a solution by allowing control of interactive systems via neural signals [e.g., electroencephalography (EEG) signals, event-related potentials (ERPs)]. Such neurally based response systems, called brain–computer interfaces, accept commands directly from the human brain without requiring a physical action from the user and use these commands to operate and direct interactive technologies (Hettinger et al., 2003). In its ultimate instantiation, where technology can reliably recognize a multitude of human thought patterns, the interactive system becomes "an extension of the mind itself" (Lusted and Knapp, 1996, p. 82). Such systems could open up the world of computing for those with physical disabilities and limitations (Karwowski et al., 2003). *Neuroergonomics thus seeks to expand the available response modalities by allowing for direct brain–computer interaction* (see Table 1).

## 2 COGNITIVE STATE ASSESSORS

Neuroergonomics seeks to enhance human–system interaction substantially by adopting a paradigm shift from primarily passive systems dependent on user input to proactive systems that gauge and detect, via diagnostic psychophysiological sensors, human information-processing bottlenecks and then employing augmentation strategies to overcome these limitations. To realize this paradigm shift, one must first be able to characterize *cognitive state* such that the noted bottlenecks can be monitored and regulated appropriately. Research in psychophysiology, principally through brain-imaging techniques, has established a correspondence between cognitive processors and particular brain structures that have an identifiable locus in the brain. This allows use of neural signals from those structures as a diagnostic tool of *cognitive load*, which can be measured in real time while a person is engaged with an interactive

system. Such psychophysiological data streams can be used to characterize cognitive state, specifically current load on information-processing bottlenecks.

## 2.1 Psychophysiological Techniques for Capturing a Cognitive State

Many human–system interactive situations do not provide sufficient human performance information that can be used to infer cognitive state or what shall herein be called an operator's functional state (OFS). This is especially true of highly automated systems, which for the most part put the human in a monitoring role (Byrne and Parasuraman, 1996). Because system monitoring does not require overt behavioral responses, it is difficult to assess user state. Thus, a user may not be in an optimal state at all times, and system corrections or malfunctions may not be detected and responded to correctly. A methodology is needed that provides accurate assessment of OFS in the absence of overt performance data and to provide additional information when performance data are available. Psychophysiological measures have been suggested to fill this role.

Psychophysiological signals are always present and can often be collected unobtrusively, thereby providing a source of uninterrupted information about user state (Kramer, 1991; Wilson and Eggemeier, 1991; Scerbo et al., 2001; Wilson, 2002a; Gratton et al., 2008). Correlations between psychophysiological measures and OFS have been described (Wilson and Schlegel, 2003). Although these correlations do not prove causality, they do suggest that psychophysiological measures can be used to assess OFS and, further, that this information can be used to modify system parameters to meet the momentary needs of users (i.e., cognitive augmentation via adaptive aiding). Of the several criteria for implementation of OFS-driven adaptive aiding, three crucial ones are that (1) significant and meaningful system performance improvements must be demonstrated; (2) the sensors used must be nonintrusive to a user's primary task, as this would hinder human–system performance; and (3) their use must be acceptable to users.

For widespread adoption, it must be demonstrated that OFS assessment and aiding either (1) improve human performance and enhance job success for work-related applications or (2) enhance the interactive experience for entertainment-based or other such experiential applications. An example of a successful application of adaptive aiding is the use of antigravity (anti-*g*) suits, which require wearing additional gear that inflates at predetermined *g*-levels. These suits have been proven to save lives because they can prevent *g*-induced loss of consciousness in jet pilots and have therefore met with wide acceptance.

### 2.1.1 Current Status

In the past, the typical approach when using psychophysiological measures to assess OFS was to collect one or more measures and demonstrate that statistically significant differences exist between at least two levels of task demand or human state such as fatigue. Most

of this research has been conducted in the laboratory. However, a growing body of research is expanding into operational environments. Psychophysiological measures have been applied successfully in driving, flight, and other test and evaluation environments (Wilson, 2002a). For example, heart rate has been shown to be increased significantly under high-mental-workload conditions compared to low-mental-workload conditions during flight (Wilson, 2002b; Kobus et al., 2005). EEG, a physiological measure of the momentary functional state of cerebral structures, provides useful information about both high cognitive workload and inattention (Kramer, 1991; Wilson and Eggemeier, 1991; Gundel and Wilson, 1992; Sterman and Mann, 1995; Gratton et al., 2008). Specifically, theta-band EEG activity has been reported to increase with increased task demands (Gundel and Wilson, 1992; Gevins et al., 1998; Hankins and Wilson, 1998). While much work has been done on cognitive state sensors, the current maturity of neuroergonomic measures varies widely (Fidopiastis and Wiederhold, 2008; Hale et al., 2012). Some measures are still in technology development, such as functional near-infrared imaging (fNIR), posture tracking, and pupilometry. Others are in technology demonstrations, such as electrodermal response (EDR), EEG, electromyography (EMG), and galvanic skin response (Kobus et al., 2005). Still others have made their way into the operational system and/or subsystem, such as electrocardiography (ECG; Schnell et al., 2008a, 2008b) and eye/gaze tracking (Carroll et al., 2009; Carroll, Fuchs, Hale et al., 2010). Several efforts have demonstrated real-time state measures over the past 10 years that meet the requirements of (1) sensitivity to different brain states and/or processes, (2) reliability, and (3) practicality in fielded use (Stanney et al., 2010). The current challenge with cognitive state measurement is in developing means to substantially advance real-time data fusion and classifier construction techniques (Fidopiastis and Wiederhold, 2008; Hale et al., 2012).

### 2.1.2 Current Technology for Recording Psychophysiological Data

Numerous psychophysiological measures have been shown to provide valuable information concerning OFS in real-world operational environments (Wilson, 2002a; Wilson and Schlegel, 2003; Gratton et al., 2008). Because of the restrictions of the operational environment, some psychophysiological methods cannot be used. For example, positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and magnetoencephalography (MEG) are not practical OFS gauges because the associated recording equipment is too restrictive, too large, and requires special shielding, among other prohibiting conditions. Even those measures that are less prohibitive have drawbacks. Almost all currently available, operationally useful psychophysiological sensors require contact with a user's body and use some form of electrolyte sensors. This is the case for EEG, ECG, EMG, and electrooculography (EOG). Users typically do not like to wear such sensors and associated equipment. Further, the sensors are usually attached to the skin with some type of adhesive, and repeated application in a day-to-day operational environment may cause skin irritation. There are less invasive options, such as pupillometry and eye point of regard, which are making their way into current applications (Hale et al., 2012).

An area of concern for all psychophysiological measures is that of artifacts. This is especially the case in operational environments where operators move, talk, walk, and engage in other activities that produce artifacts in recorded data. Techniques are available for detecting and removing certain artifacts, for example, EOG contamination of EEG (He et al., 2007). Other artifacts are difficult to remove, such as EMG in EEG, and may require the removal of the contaminated data. Artifact-free data must be provided in real time, which requires immediate detection and removal of the offending artifacts.

### 2.1.3 New Sensor Technologies

New sensor technologies promise to provide users with more acceptable recording methods and valuable OFS data. Sensors that require only "dry" (no electrolyte or adhesive) contact with the skin have been developed (Kingsley et al., 2002; Trejo et al., 2003) and tested (Christensen et al., 2009, 2010b). Two approaches that are being explored for dry EEG sensors are capacitive coupled and optical sensors. These technologies can also be used to record ECG, EMG, and EOG. Currently, dry-sensor EEG can be recorded from non–hairy skin areas such as the forehead, and low-cost consumer-grade devices have emerged that utilize this technology for entertainment purposes like gaming, but these solutions have also been used in research studies (cf. Rebolledo-Mendez et al., 2009). For most research applications, however, larger numbers of sensors may be necessary, and the goal is to be able to record EEG from anywhere on the scalp using these sensors. A step towards this is products that use moist pads instead of conductive gel, such as the headset described in Campbell et al. (2010). Eye activity can be recorded using video cameras that image the face from a distance, requiring no actual contact with users (Carroll et al., 2009). Recent advances include tracking devices that feature motorized cameras that follow the eyes of the user to better compensate for head movements (http://www.interactive-minds.com/en/eye-tracker/eyefollower). Additionally, sensor technology has been developed that provides measures of brain activity using blood flow technology. For example, fNIR sensors provide information about brain oxygen levels, cortical blood volume, and neuronal activity (Izzetoglu et al., 2003, 2005; Wildey et al., 2010).

### 2.1.4 Functional Near-Infrared Sensors

Using near-infrared light emitters, near-infrared energy can be directed through the scalp and skull and reflected from underlying cerebral tissue. Two types of cerebral information can be obtained from fNIR. The first type is hemodynamic response, reflecting oxyhemoglobin and deoxyhemoglobin concentrations in the brain. The consensus is that increased brain activity results in
**Figure 1** Locations of the infrared emitter and detector area important to ensure that cortical tissue is imaged. (From Downs and Downs, 2004.)

increased levels of local oxyhemoglobin and decreased levels of deoxyhemoglobin (Gratton and Fabiani, 2001; Gratton et al., 2008). These responses have been used to investigate cognitive activity (Hock et al., 1997; Villringer and Chance, 1997; Takeuchi, 1999; Izzetoglu et al., 2003, 2005). The second type of information that can be obtained from fNIR is to detect changes in the optical characteristics in brain tissue that are related to neuronal activity (Gratton and Fabiani, 2001; Gratton et al., 2008). The exact cause of these optical changes is not totally understood. This latter method is said to provide millisecond temporal resolution; the first method is much slower. For either procedure the infrared emitters and sensors have only to touch the scalp rather than being affixed to it (see Figure 1). The emitter–sensor unit can be held in place using a strap or cap arrangement. Conventional fNIR systems may be impaired by absorption from the subject's hair and thus they are most often applied to nonhairy regions, such as the forehead. Recent work in fNIR hairbrush sensors has improved the sensitivity over hairy regions by redesigning the optrode with fiber tips designed to thread through the hair, which provides better scalp contact (Wildey et al., 2010). These systems function on hairy areas of the scalp and so are not restricted to the forehead region. This developing technology holds a great deal of promise for advancing our understanding of cognition and may be used more readily in operational environments than sensor technologies that require adhesives.

## 2.2 Transforming Sensors into Cognitive State Gauges

To be useful, real-time assessment of cognitive activity by means of psychophysiological measures must be transformed from individual measures to cognitive gauges. Whereas consideration of individual measures provides valuable information, neuroergonomics requires gauges that are composite estimates characterizing the functional state of a user (such as those to gauge load on the human information-processing bottlenecks, as well as others, such as Kolmogorov entropy of EEG signals and task load, which are mentioned in Sections 3.1.3 and 3.1.4). Given the complexity inherent to most operational environments, it is not sufficient simply to be aware that statistical changes exist in several measures. Measures or gauges must be able to characterize

the functional state of a user such that this information can be used to implement adaptive aiding (i.e., triggering of augmentation strategies) in real time in real-world situations. In 2003, the U.S. Defense Department Defense Advanced Research Project Agency (DARPA) conducted a technology integration experiment (TIE) with various psychophysiological sensors [i.e., EEG, event-related potential, fNIR, pupil dilation, heart rate variability (HRV), arousal, galvanic skin response] to demonstrate the feasibility of simultaneous data collection (Morrison et al., 2003). The TIE demonstrated that real-time computation of sensor data to produce online gauge information was feasible and further confirmed that several sensor technologies could be combined with minimal interference. However, substantial variability between human participants in gauge sensitivity suggested the need for additional research. The unique, individual participant psychophysiological response characteristics are well known and no doubt contribute to this variability. Additional research has thus focused on how to transform sensors to specific OFS gauges. One such example is the composite stress gauge (Raj et al., 2003), which uses a weighted average of pupillometry ECG and electrodermal response (EDR) to detect a participant's response to changes in cognitive load. The New Workload Assessment Monitor (NuWAM) sensor suite is another example and is based on an artificial neural network (ANN) cognitive state classifier and combines EEG, ECG, and EOG sensors (Krizo et al., 2005; Wilson and Russell, 2006). The Cognitive Cockpit (CogPit) sensor suite is yet another example; this suite gauges cognitive–affective status in near-real time as derived from four main sensor sources, including behavioral measures, EEG, subjective measures, and contextual information (Dickson, 2005). More recently, there have been a number of systems that have integrated eye tracking and EEG (Tucker and Luu, 2009). One such example is the sensor suite integrated into the Auto-Diagnostic Adaptive Precision Training (ADAPT) framework, which combines EEG, eye tracking, heart rate, and behavioral measures to capture cognitive state on a second-by-second basis and evaluate an individual as they progress from novice to expert (Carroll et al., 2010a).

*Thus, neuroergonomics seeks to leverage a set of psychophysiological gauges that allow for real-time assessment of cognitive state, particularly current load on information-processing bottlenecks, which can then be transformed directly into computer control commands for triggering implementation of augmentation strategies. A further goal is to develop procedures that provide predictions of future bottlenecks so that corrective actions can be taken before system performance degradation. Reactive systems, which detect and respond to current bottleneck conditions, will be very useful but may result in uneven system performance because they react to already poor OFS. Systems that can accurately predict upcoming bottlenecks will be able to maintain continuous optimal system performance without the possible perturbations of a reactive system. These systems will be able to detect trends in the physiological signals that can predict OFS breakdowns.*

## 3  HUMAN−SYSTEM AUGMENTATION

In Section 1, various human information-processing bottlenecks were discussed (i.e., sensory memory, WM, EF, attention). In Section 2, means of gauging the current cognitive load on a person were considered. Neuroergonomics seeks to overcome the noted points of limited capacity processing through the utilization of human−system augmentation strategies, which will be triggered by cognitive state gauges. It is suggested that through dynamic augmentation strategies the cost of these bottlenecks (e.g., degraded human performance due to overload, underload, stress, losses in situational awareness, or emotional state) can be overcome.

When designing dynamic augmentation strategies, designers should target individualized approaches for their selection and configuration. To optimize the effectiveness of augmentations and develop trusted, adaptable, and flexible task allocation schemes and seamless and elegant interruption management strategies, augmentations should consider not only the cognitive state of the user but also individual learning/operating styles and preferences that may develop over time during system use. The relationship between the human user and an intelligent augmentation system should be viewed as a team environment; in turn, a "shared mental model" (Cannon-Bowers et al., 1993) should be instilled, including the system's understanding of the user's styles, preferences, capabilities, and intent. Shared mental model components (cf. Mathieu et al., 2000) that current adaptive systems often do not account for but that could be considered for inclusion in neuroadaptive systems include interaction patterns, communications channels, role interdependencies, and task strategies, as well as the knowledge, attitudes, preferences, and tendencies of teammates. Thus, to optimally augment human−system interaction, the system must be able to detect and learn (1) its user's intent and information needs at any given time, (2) the individual styles and behavioral patterns exhibited by the user and his or her teammates, (3) which cognitive state patterns are likely to impact performance in specific users, and (4) the cognitive limitations and preferences of user and teammates, including individual cognitive capacity, information-processing styles, attention span, and other relevant attributes.

## 3.1  Augmentation Strategies

In conventional human−system interaction, an excessive amount of cognitively demanding tasks can be imposed on a user. In such situations, human information processing can break down at any of the identified bottlenecks. Instead of overloading users, interactive systems should seek to achieve cognitive congeniality (Kirsh, 1996) by (1) *presenting* an optimal level of task-relevant information and ensuring that it is readily perceived, (2) optimizing cognitive load on WM by *sequencing* and *pacing* tasks appropriately, and (3) reducing the number and cost of mental computations required for task success by *delegating* tasks when appropriate. Taken together, these strategies should increase the speed, accuracy, and robustness of human−system interaction. Each of

these augmentation strategies (i.e., task presentation, sequencing, pacing, and delegation) is discussed below. It should be noted that other such strategies can and should be identified. Additional augmentation strategies to consider include but are not limited to techniques for supporting information filtering and triage, multitasking, mixed-initiative interaction, and context-sensitive interaction (Horvitz et al., 2003).

### 3.1.1  Task Presentation

When designing interactive systems, a central question is which information should be conveyed via which modality. Conventional interactive systems present information to users primarily via visual cues, sometimes offering auditory accessories. Yet to optimize sensory processing, thereby relieving the sensory memory bottleneck, one should consider the types of information each modality is particularly suited to display. Table 2 presents theorized suitability of sensory modalities for conveying various information sources. In addition to suitability, one must consider capacity. As aforementioned, Samman et al. (2004) demonstrated that multimodal WM capacity can reach levels nearly three times that of Miller's (1956) magical number 7. Thus, rather than overloading a single modality, by distributing information across multiple modalities, the WM bottleneck can be relieved. Table 3 represents the WM capacity of various modalities based on several studies (Bliss et al., 1966; Sullivan and Turvey, 1974; Smyth and Pendleton, 1990; Keller et al., 1995; Livermore and Laing, 1996; Woodin and Heil, 1996; Feyereisen and Van der Linden, 1997; Matsuda, 1998; Jinks and Laing, 1999; Laska and Teubner, 1999; Frenchman et al., 2003). The numbers in Table 3 suggest the upper limit on the number of items that should be presented via each modality, as individual modality capacity tends to decline during multimodal multitasking even though overall capacity increases (Samman et al., 2004). Thus, with knowledge of the information sources constituting a given application, a determination of optimal modalities can be made to direct multimodal task presentation. More specifically, after characterizing a given application's information sources via a task analysis, first a matching to the optimal modality can be determined using Table 2. Then, given the outcome of the related OFS gauges (i.e., current load on sensory and WM bottlenecks), a determination of reserve capacity can be estimated using Table 3 and a selection of the optimal modality made (i.e., the one with the best match from Table 2 and adequate reserve capacity). If real-time (e.g., physiologically based) workload measures from the user are available, these estimates can be compared to actual onset of an overload condition. Additionally, the effectiveness of changes in task presentation can be evaluated with respect to specific modalities. The system could then dynamically adjust the augmentation parameters and thresholds to account for the individual's cognitive capacity and preferences. The applied implication is that in cognitively demanding task environments, the information should be presented not only in a modality that is most suitable but also in one that is not currently fully loaded, thereby easing the sensory memory and WM bottlenecks. Thus, the first augmentation strategy is to *identify the optimal modality*

**Table 2  Theorized Suitability of Modalities for Conveying Various Information Sources**[a]

| Information Source | Sensory Modality | | | | | |
| --- | --- | --- | --- | --- | --- | --- |
| | Visual | Verbal | Tactile | Kinesthetic | Tonal | Olfactory |
| Spatial acuity (size, distance, position) | + + | □ | + | + | | – – |
| 2D localization (absolute/relative location in 2D) | + + | + | + | □ | + | – – |
| 3D localization (absolute/relative location in 3D) | | □ | + | □ | + | – – |
| Change over time | + + | + | + | | □ | – – |
| Persistent attention | + + | – – | + + | | – – | |
| Absolute quantitative parameters | + + | + | – – | – – | – – | – – |
| Temporal (e.g., duration, interval, rhythm) | □ | | + | + | + + | – – |
| Instructions | + | + + | | | | |
| Rapid cuing (e.g., alerts, warning) | + | + | + + | | + + | |
| Surface characteristics (e.g., roughness, texture) | + | | + + | | | |
| Hand–eye coordination (e.g., object manipulation) | | | + + | | | |
| Memory aid (e.g., recognition of a formerly perceived object) | + | + | – | – | + + | + + |
| Affective or ambient information | □ | □ | | | + | + + |

[a]*Key:* + +, best modality; +, next best; □, neutral; –, not well suited, but possible; – –, unsuitable.

**Table 3  WM Capacity of Various Sensory Modalities**

| WM Subsystem | Capacity |
| --- | --- |
| Visual | 2–5 |
| Verbal | 4–7 |
| Spatial | 5–7 |
| Tactile | 3–5 |
| Kinesthetic | 3–5 |
| Tonal | 4–6 |
| Olfactory | 3–4 |

*by which to present information based on consideration of suitability principles as well as current psychophysiological measures of cognitive load and demonstrated effectiveness of modality augmentations for a given operator* (see Table 4).

### 3.1.2  Task Sequencing

Once the modality by which to present an information source is determined, the information event can be scheduled. The MRT (Wickens, 1984) suggests that people are more efficient in time-sharing tasks when different resources are utilized in terms of sensory stimuli modality (e.g., visual, auditory), WM processing codes (e.g., spatial, verbal), and response modality (e.g., vocal, manual). For example, various studies have suggested that a person can recall more in two tasks with different types of modalities combined than in a single task, especially if the modalities or types of representation are very different (Klapp and Netick, 1988; Penney, 1989; Baddeley, 1990; Cowan, 2001; Sulzen, 2001). More recent MRT efforts have suggested that task interference can be minimized by leveraging opposite ends of four task dimensions, including processing stages (perception, cognition, response): perceptual (sensory), modality (visual, verbal, spatial, tactile, kinesthetic,

tonal, olfactory), visual processing channels (focal, ambient), and WM processing codes (spatial, verbal) (Wickens, 2002). An applied implication of this theory is that time sharing of tasks should be more effective with cross-modal as compared to intramodal information displays. Thus, through systematic sequencing of tasks, simultaneous processing of competing tasks can be allocated strategically across various multimodal sensory systems in an effort to maintain multimodal information demands within WM capacity. Beyond addressing the WM bottleneck, this augmentation strategy can assist in prioritizing incoming information by sequencing cues according to priority, thereby directing attention. When applying this strategy, it is essential to ensure that there is a means to avoid the adaptive state from oscillating too frequently. This can be done through the application of robust controllers (see Section 4). Through systematic control of the adaptive state, this strategy also addresses the EF bottleneck by moderating the effects of modality switching.

To determine task sequencing (i.e., ordering and combining of tasks), a conflict matrix could be calculated following Wickens's (2002) approach, in which the amount of conflict between resource pairs for task couplings is determined. This calculation factors in both conflict and task difficulty (i.e., resource demands), resulting in a task interference value. This could be done in conjunction with a timeline analysis (Sarno and Wickens, 1995), which calculates resource demand levels of time-shared tasks over the time during which the tasks are to be performed. In allocating resources, these principles could be coupled with a scheme of task priorities (as derived through an a priori task analysis), which taken together could guide task ordering and combining given current resource constraints (i.e., task interference values and OFS gauge outputs from all four bottlenecks). Such a system could be further optimized by accounting for individual cognitive capacities and preferences of the user that are measured

**Table 4  Augmentation Strategies**

| Augmentation Strategy | Description | Human Information-Processing Bottleneck Addressed |
|---|---|---|
| Task presentation | Identify optimal modality by which to present information based on consideration of suitability principles, current psychophysiological measures of cognitive load, and demonstrated effectiveness of modality augmentations for a given user | Sensory and working memory |
| Task sequencing | Assign modalities to information sources and schedule them, considering priority, such that they minimize interference over the performance period while leveraging robust controllers to moderate effects of modality switching | Sensory and working memory, attention, executive function |
| Task pacing | Provide external pacing of tasks, which could be achieved by monitoring behavioral entropy, while accounting for individual strategies, preferences, and tendencies | Working memory, attention, executive function |
| Task delegation | Direct assisted explicit task delegation based on psychophysiological indexes of task load and an individual user's knowledge, preferences, and performance | Attention, executive function |

and interpreted by the system during use. The second augmentation strategy is thus to *assign modalities to information sources and then schedule them, considering priority, such that they minimize interference over the performance period while leveraging robust controllers to moderate the effects of modality switching* (see Table 4). This should help relieve the sensory, WM, attention, and EF bottlenecks.

### 3.1.3  Task Pacing

Time management is an essential component of many dynamic task situations (and is also critical to feedback stability of closed-loop systems; see Section 4). Yet, in cognitively demanding task environments, pacing skills can decline rapidly, as temporal judgments depend on the amount of attentional resources allocated to a temporal processor (Casini and Macar, 1999). Further, internal (self) pacing has been shown via EEG signals to impose higher human information-processing demands compared to externally (e.g., via metronome) paced tasks (Gerloff et al., 1998). Disruption of an orderly rhythm is thought to increase the entropy of the human information-processing system, thereby increasing information content due purely to asynchronous pacing of a task. Such disruption can occur when a person becomes overloaded with information, as this often results in delayed event detection and more corrective responses (Boer, 2001). Interestingly, Boer (2001) developed a simple but highly predictive linear model based on Wickens and Hollands's (2000) MRT, which predicted the effect of various tasks on steering entropy and driver performance. The model demonstrated that steering entropy was affected primarily by loading of spatial tasks, as would be predicted by MRT because driving is a highly spatial task. Thus, to achieve effective time management, a potential augmentation strategy would be to *provide external pacing of tasks, which could be achieved by monitoring behavioral entropy, while accounting for individual strategies, preferences, and tendencies* (see Table 4). Specifically, the Kolmogorov entropy (K-entropy) of EEG signals can be

used to assess information flow (Pravitha et al., 2003). K-entropy is proportional to the rate at which information about the state of a dynamical system is lost in the course of time. This entropy index has been shown to fluctuate with changes in the complexity of human information processing, such as that imposed by fatigue (leading to a lesser extent of information flow through particular brain regions) (Rekha et al., 2003) or information overload (King, 1991) while remaining quite stable during performance of demanding cognitive tasks (Pravitha et al., 2003). Thus, using K-entropy of EEG signals to direct task pacing should help relieve the WM, attention, and EF bottlenecks, as it could help optimize the pace of the processing of incoming information and minimize disruptions.

### 3.1.4  Task Delegation

In the context of neuroergonomics, the purpose of dynamic task delegation would be to increase information throughput by balancing the utilization of human resources across a network of users. Task delegation allows for distribution of task demands across individuals as well as coordination between humans and automated systems. In task delegation, certain actions required by a particular task performer are delegated to another performer or back to the system itself once task load gets above some threshold or other types of cognitive breakdowns (e.g., loss of situation awareness, critical performance decrements) are detected (Dearden et al., 2000; Hoc, 2001; Debernard et al., 2002). Such handing off can be implicit (i.e., imposing an allocation based on current OFS load predictions or real-time measurements) or explicit, in that it requires an action from the task performer prior to allocation. Although it has been shown to lead to better performance than explicit allocation, implicit allocation does not always meet with user acceptance, as humans like to maintain control of dynamic task situations and become anxious when they lose control (Hoc et al., 2001). This, in turn, could affect behavioral entropy, thereby affecting system pacing. Taken together, this could affect system

stability properties negatively (see Section 4). Assisted explicit allocation is a compromise, where after detecting an overload using an OFS gauge of task load, such as the task engagement index used by Prinzel et al. (2000, 2003), the interactive system would make an allocation proposal which the human would be able to veto but would not be in charge of allocating. This cooperative task allocation strategy generally leads to effective performance while avoiding complacency by requiring the human to cooperate in the allocation process. Alternatively, the consequences and effects of task delegation could be measured to gauge user acceptance in certain situations, so that such strategies can be used in contexts where no detrimental effects are expected. Thus, a fourth potential augmentation strategy would be to *direct assisted explicit task delegation based on psychophysiological indexes of task load and an individual user's knowledge, preferences, and performance* (see Table 4). This should help relieve the attention and EF bottlenecks, as it eases the need to determine what to attend to.

## 4 ROBUST CONTROLLERS

Although augmentation strategies have the potential to enhance human performance through reducing the load on human information-processing bottlenecks, they could also lead to an adaptive state that oscillates too frequently, thereby destabilizing human–system interaction over time. Thus, there is a need to identify techniques for ensuring that changes requested through the augmentation strategies are implemented so as to maintain system stability and enhance human performance. Mathematical system theory deals with the modeling, analysis, and design of complex dynamic systems. Robust control theory is a discipline of mathematical system theory that is concerned with the analysis and design of feedback controllers for situations where there is only partial or incomplete knowledge of the underlying system dynamics. In the work discussed in this chapter, whereby a user's display/input is adapted based on his or her measured cognitive load, it is important to note that a feedback loop is being *closed* around the human. Moreover, since the underlying system dynamics involve the human, it is certainly true that only partial knowledge concerning a user's state will be available, hence the need for this section on robust control.

### 4.1 Control System Models

Recent developments in the field of cognitive neuroscience have heralded a great deal of change in what is known about human mental operations (Posner and DiGirolamo, 2000; McCabe et al., 2010). As has been discussed, these advances have the potential to allow psychophysiological indicators to direct human–system interaction (Farwell and Donchin, 1988). The ability to use sensors to measure the cognitive performance of a user immediately through psychophysiological characteristics, and virtually instantly adapt a system to meet user needs, presents an exciting new paradigm in interactive systems. The introduction of such real-time adaptive aiding offers the prospect of radically altering how

humans interact with computer technology. However, one important aspect of such a potential change in the nature of human–system interaction is the inherent difference between open- and closed-loop systems.

Even well-understood, stable open-loop systems will show very different performance under closed-loop operation. A simple example of this effect can be seen when bringing a speaker and a microphone (connected to each other) too close together. A well-known audio feedback effect occurs as the signal from the speaker runs through the microphone, back out of the speaker, back into the microphone, and so on. The resulting feedback loop is (typically) unstable and produces a familiar (and unpleasant) sound. The volume of this sound may grow or decay (corresponding to unstable and stable feedback systems, respectively), depending on the proximity of the microphone to the speaker (which implicitly sets the loop gain in the feedback system). Thus, two perfectly well-behaved open-loop systems (speaker and microphone) may or may not be closed-loop stable, depending on how feedback is applied. A more precise quantitative example of such behavior for a neuroergonomic system will be provided later, where it is shown that a stable open-loop system may generate a stable or unstable closed-loop system, depending on how feedback is designed.

Although a great deal about human performance may be understood, the nature of the shift from an open- to a closed-loop system is a unique type of change. As a result, many standard predictable aspects of cognitive and motor performance may operate in drastically different ways in closed-loop systems. A prime candidate for understanding such closed-loop circumstances is through the use of engineering control systems theory. [For a discussion of the pros and cons of various types of models, see Baron et al. (1990).] Control systems theory deals with fundamental properties of systems as described (typically) by mathematical models. It provides a framework and tools for analyzing fundamental system properties, such as performance, noise rejection, and stability, and offers systematic approaches for designing systems with these desired properties.

The idea of applying control theory to humans has some history, with Wiener (1948) widely considered to be the first person to draw parallels between control systems in machines and the organization present within some living systems. However, few attempts have been made to apply control systems theory to human–system interaction (Flach, 1999; Jagacinski and Flach, 2003; Young et al., 2004), and thus this is an exciting area of research where much remains to be done. One notable exception that the current effort draws from is Card et al.'s (1983) model human processor (MHP). The MHP is a human information-processing model consisting of a basic block diagram interconnect model of a human, with an associated estimate of the time taken by each processing stage to process relevant data. For neuroergonomic purposes, the three most relevant stages (i.e., blocks) are probably the perceptual, cognitive, and motor processors. This is illustrated in Figure 2, which shows a human operator piloting a vehicle. In this example, information from the operator's system display
**Figure 2**  Human information-processing model.

would first pass through the operator's perceptual (i.e., sensory) processor, being perceived, on average, in about 100 ms (Cheatham and White, 1954; Harter, 1967). Perceived information would then be available to the cognitive processor, which has an average cycle time of 70 ms. The cognitive processor would then make a decision, and that decision would be implemented by the motor processor, which has an average cycle time of 70 ms, with a resulting action on the vehicle controls. Note that these three blocks provide an internal model of the operator's interaction with the external vehicle displays and controls. This block diagram model not only characterizes the flow of information and commands between the vehicle and operator but also enables us to access the internal state of the operator at various stages in the process. This allows modeling of what a neuroergonomic system might have access to (internal to the human; e.g., load on human information-processing bottlenecks) and how those data might be used to direct closed-loop human–system interaction.

If one considers a control systems model incorporating the flow of human information processing, the time taken by each block adds time delay to the model. However, it does much more than that. As indicated in the early discussion on bottlenecks, it also implies a certain *bandwidth* for the system, both in terms of channel capacity and because signals that vary more rapidly than the time constant of the system (i.e., high-frequency signals) do not pass through it. Hence the processing blocks act as low-pass filters, only allowing through signals that

**Figure 3**  Block model for each component.

are below the system bandwidth. For example, humans do not generally perceive the flicker on a computer monitor because it typically occurs at a frequency (100 Hz) higher than that of the perceptual processor's bandwidth of only about 10 Hz. As a first attempt at modeling such a phenomenon, the effects of time lags in human perceptual, cognitive, and motor processing blocks are considered. This results in a dynamic model of the form shown in Figure 3.

Note that the setup depicted in Figure 3 is a generic dynamic model of any one of the MHP components (perceptual, cognitive, motor) shown in Figure 2 (although the model parameters will be different for each). The dynamic models associated with each MHP component ("first-order lag" and "time delay") of the block model are given, respectively, in the time domain (i.e., convolution representation) as

$$y(t) = \frac{1}{\tau} \int_0^t e^{-(t-\gamma)/\tau} u(\gamma)\, d\gamma$$
$$z(t) = y(t - \tau)$$

for each processing block [with overall input $u(t)$ and output $z(t)$], with the time constant $\tau$ taken from the relevant processing time in the MHP model. The first-order lag models the dynamic relationship between input and output signals, which captures the bandwidth effect described earlier. This is most easily seen using the Laplace transform to transform this model from the time domain to an equivalent frequency-domain representation:

$$Y(s) = G(s)U(s)$$

where the function $G(s)$ is given as

$$G(s) = \frac{1}{1 + s\tau}$$

This is known as the *transfer function* of the system. [See Phillips and Parr (1999) for an overview of transform methods for signals and systems; see Ogata (2002) for an overview of the application of these techniques to dynamic systems and feedback control.] A key point is that the time-domain convolution operator has been transformed into a simple multiplication operator in the frequency domain. That multiplication operator, $G(s)$, is both complex valued and frequency varying. The function $G(s)$ captures the frequency response of the system in both magnitude and phase.

To see this, one can evaluate the transfer function along the imaginary axis, that is, substitute $s = j\omega$ into the model (equivalent to specializing the Laplace transform to a Fourier transform) to yield

$$G(j\omega) = \frac{1}{1 + j\omega\tau} = \frac{1}{\sqrt{1 + (\omega\tau)^2}} e^{-j\tan^{-1}\omega\tau}$$

which is the frequency response of the system (with $\omega$ the real-valued frequency). This has the desired low-pass frequency response. Low-frequency (slowly varying) signals pass through almost unattenuated, but higher frequency (rapidly varying) signals are more and more attenuated until hardly any of the signal passes through the system at all. This variation of the magnitude response with frequency in the first-order lag block is what accounts for the computer monitor effect (i.e., lack of perceiving flicker) described earlier (one could not account for this effect with a time delay block alone because the frequency response of a pure time delay is flat, i.e., no variation of magnitude with frequency).

Note that this magnitude response comes with an associated phase response. Low-frequency signals pass though this system with almost undistorted phase. However, as frequency increases, the signals start to incur phase lag, which ultimately reaches $90°$ at high frequency. Phase lag has a destabilizing effect on closed-loop feedback systems, so understanding the relationship between the magnitude and phase of different frequency signals as they pass through the system is of crucial importance in designing any feedback control system.

These various steps have provided the separate pieces necessary to build a model of an entire open-loop system. Since transfer functions operate by multiplication, models for the individual blocks can be cascaded. These are linear models and therefore they commute, so the order of cascade can be changed, and hence time delays can be accumulated into a single block if desired. This now provides a quantitative dynamic model for the human as illustrated in Figure 4. Note that, as discussed above, this model captures the gain–phase relationship with frequency, which is crucial if the model is to be used in a feedback control loop.

This model should allow accurate predictions of open-loop performance and other properties of the system to be made. However, it is important to note that this control theory–based model is in a form that will also allow for prediction of how performance and properties are modified when transforming to a closed-loop setup, which is described in the following section.

### 4.1.1 Closed-Loop Models

Neuroergonomics aims to provide display and information systems that take measurements from OFS gauges,

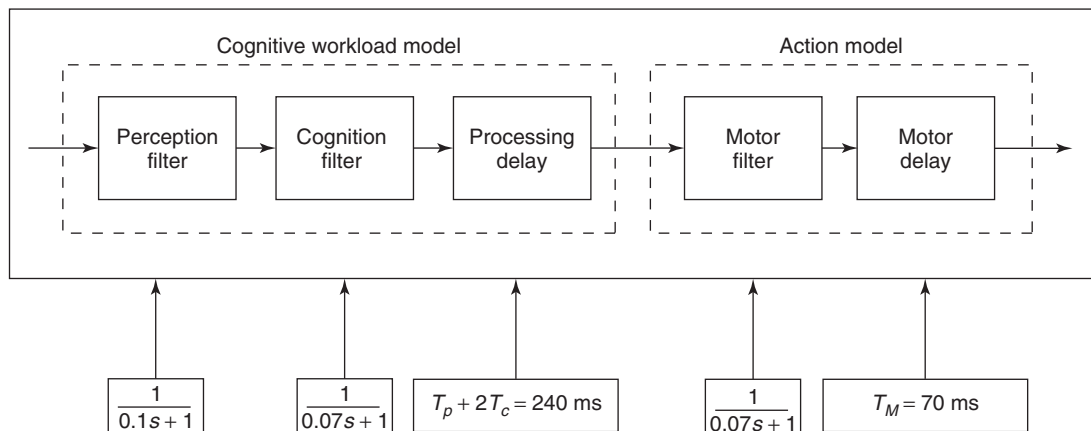

**Figure 4** Dynamic control system model of the human.

such as those described in Section 2, and use these data to dynamically adapt human–system interaction. The sensor dynamics of any future OFS gauges are still to be determined, so as a starting point such sensors are modeled here as simple first-order lags with a time constant $\tau = 1$ s. The sensor data would be used to dynamically change inputs to a user by directing instantiation of augmentation strategies, such as those described in Section 3. As an example, consider an application where workload is reduced via the *task delegation* augmentation strategy (Wickens et al., 1998). In such an application, using OFS gauges to detect cognitive overload (e.g., through a EEG-derived index of task engagement) (Prinzel et al., 2003), lower priority tasks would be offloaded to automated agents, with the goal of maintaining users working at their maximum capacity. Such a closed-loop human–system interaction model was implemented in the Matlab/Simulink simulation environment, which is illustrated in Figure 5.

Various pieces of a neuroergonomic system can be seen in the model in Figure 5, including the human perceptual, cognitive, and motor processors. Note both the OFS gauge that detects the state of the human user (i.e., cognitive work overload measurement) and the augmentation strategies [i.e., within the proportional–integral–derivative (PID) controller] that will alter the input to the human. The rest of the model contains task inputs to the system, displayed outputs at various points (e.g., actual vs. measured cognitive workload), and a simple model of performance errors resulting from cognitive overload. The feedback loop being closed is now apparent in this simulation model, which drives the need for a systematic control theory approach.

### 4.2 Controller Analysis and Design

Even this simple model has already produced some important findings. In particular, one major finding from initial efforts with the model is to show how dynamic instability can result from introducing feedback

within the system. That is to say that rapid detection of cognitive state under high workload might result in input being removed, which would reduce workload and hence information would be added, which would once again result in high workload, and the cycle repeats. This simple illustration indicates how users might find their display cycling rapidly through cluttered and decluttered states as a result of changes detected in workload. Control theory offers a means to remove such instability and optimize performance.

Figure 6 shows results from three simulations of a task overload situation. The input to each of these simulations is the same: Initially, the user is fully loaded (and making no errors), and then a step increase in workload is introduced 1 s into the simulation. This results in task overload from that point on, with subsequent performance errors. Note that each of these simulations uses the same system model, so the only difference is how (or if) the feedback control (i.e., augmentation strategy) is applied.

Starting from the left, the first plot of Figure 6 shows the resulting performance errors for an open-loop simulation (i.e., with the neuroergonomic system disabled). As the workload of the task increases, the plot shows how the number of errors quickly rises to a certain level and stays there. The next panel shows a poorly designed neuroergonomic system. This system utilizes simple proportional control; that is, the control action $c(t)$ that reduces task workload to the user is just directly proportional to measured overload $m(t)$. Thus, the controller is of the form

$$c(t) = Km(t)$$

and the control designer simply chooses the proportionality constant or controller gain $K$, which determines when an augmentation strategy (i.e., task delegation in this case) is to be implemented. High-gain controllers, with large $K$ values, use a high-magnitude feedback

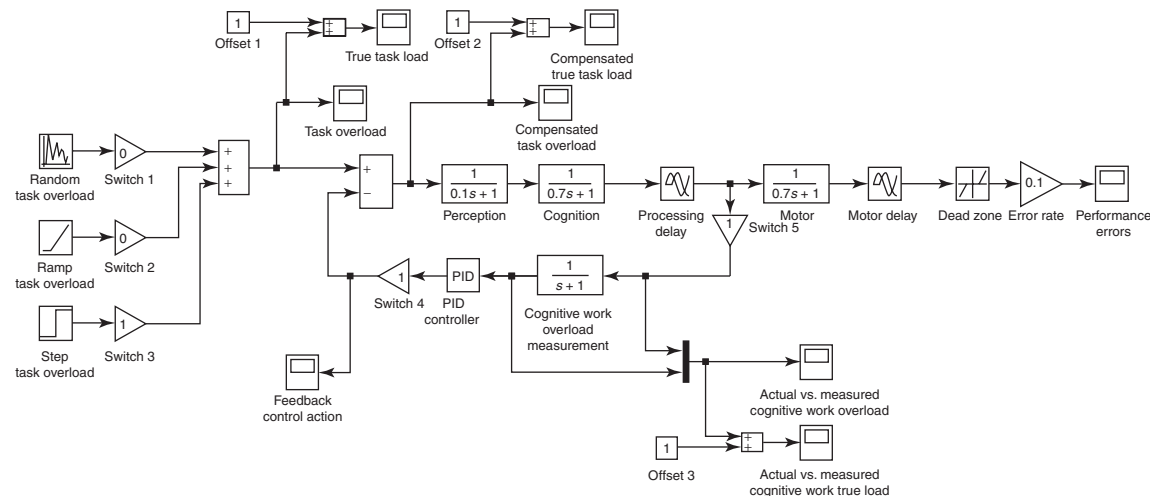

**Figure 5**  Matlab/Simulink model of closed-loop human–system interaction.
**Figure 6** Simulation results for a closed-loop dynamic model.

signal that tries aggressively to drive the control loop to the desired point (for fast or high performance). If $K$ is chosen too aggressively, however, the closed-loop system will approach (or even exceed) stability margins. In this example, the gain $K$ is chosen poorly, resulting in instability of the type described above, with the input being reduced rapidly and then increased, resulting in highly fluctuating performance from the user. Note that the precise values of $K$ that drive the system into instability depend on the specific problem (and can be predicted accurately with control theory methods), but they can certainly occur at plausible real-world values (in this example, $K = 2.8$).

Proportional control is what people often think of when they consider feedback. A simple version is the cruise control in a car, which moves the gas pedal in a manner proportional to the difference between the desired and actual speeds. However, this simple control strategy can deliver only limited performance improvements, even when designed correctly. For instance, one could never get steady-state errors down to zero with this type of control. This approach is limited because it utilizes the same gain for all frequencies (and hence all signals), so one does not have sufficient degrees of freedom to exploit any trade-offs in the design. A very common type of controller used in engineering applications is the PID controller. This generates a corrective action from a measurement of the form

$$c(t) = K_P m(t) + K_I \int_0^t m(\tau)d\tau + K_D \frac{dm(t)}{dt}$$

There are now three constants to be chosen (designed), $K_P, K_I$, and $K_D$, which correspond, respectively, to the amounts of proportional, integral, and derivative feedback used in the closed loop. Note that the integral action effectively includes memory and thus allows better compensation at low frequency and hence improved steady-state performance. The derivative action essentially includes anticipation, which allows for improved high-frequency performance, resulting in better transient response and improved stability properties. The overall controller has frequency-varying

gain, which allows design trade-offs to be exploited more properly. The right panel of Figure 6 shows a functional closed-loop system using a well-designed PID controller to deliver closed-loop stability and good performance. It is clear that even maximum errors never reach the level of the open-loop (automation-free) system and that they quickly drop to minimal levels (asymptotically approaching zero) without any undesirable oscillatory transient response.

### 4.2.1 Human Dynamics and Achievable Performance

The first benefit of the modeling approach described above is that it provides some *proof of concept* for the neuroergonomic concept: namely, to show precisely how an integrated system of OFS gauges, augmentation strategies, and robust controllers can combine to augment performance. The caveat from this work, however, is to note that such systems need to be designed carefully, with a systematic control theory approach rather than simple heuristic tuning, else neuroergonomics may fail to fulfill its potential.

Fortunately, systematic modeling can offer assistance in terms of determining the nature of information required and parameters necessary for driving specific OFS gauges. The types of questions that could be addressed by this type of analysis include:

- What time constant/bandwidth is necessary for a particular OFS gauge to have a significant useful effect (i.e., how fast)?
- What resolution is required of the OFS gauge (i.e., how accurate)?
- How much noise can reasonably be tolerated on any given measurement?
- What would additional measurements/gauges offer?
- What performance level could be achieved (given the above)?

These questions should be addressed in future work in the area of modeling and analyses. Note that both

qualitative and quantitative analyses can be carried out, and both have their uses (e.g., qualitative analysis might steer one toward a particular technology, whereas quantitative analysis might allow one to design and implement it accurately). Note also that specific scenarios can be carried out in a simulation, which would allow one to test out certain strategies repeatedly and reliably before going to the expense of constructing an experimental setup, including low-probability events that might not occur in an experimental setting. Furthermore, control theory includes powerful analysis tools that go well beyond simple simulation to address fundamental trade-offs and limitations inherent in any feedback loop (Doyle et al., 1992).

Ultimately, the modeling strategies described in this section would aim to predict the impact on human–system performance of various augmentation strategies for changing how information is provided to a user. In addition, they have the potential to highlight areas that would receive particular benefit from such augmentation. Thus, overall, this work can provide the basis for future systematic closed-loop analysis and controller design, bringing to bear powerful tools from engineering control theory. The power of such analysis tools is demonstrated in the next section.

### 4.2.2 Individual Differences and Robustness Analysis

Preliminary robustness analysis was conducted on the closed-loop system with the PID controller modeled in Figure 5. The theory of robust control deals with systems subject to uncertainty such as any closed-loop neuroergonomic system would be subject to due to individual differences (Parasuraman, 2011; Stevens et al., 2007) (among other reasons, as noted above). Control theory provides a means of examining what performance on such a system will be, rather than just an idealized simulation. It also allows for examination of variation between users, since relevant parameters in the model can be varied (e.g., speed of the MHP processors) to determine to what extent a given control scheme is robust against such variations.

The theoretical tools used here to model individual differences were based on the structured singular value (SSV), or $\mu$, and its extensions to handle real parametric uncertainty (Young, 2001). The idea is that one first has to use linear fractional transformations (LFTs) to rearrange the problem into canonical $M - \Delta$ form, as illustrated in Figure 7. Here $M(s)$ collects all the known dynamics of the (closed-loop) system, and $\Delta$ is a (block) diagonal structured perturbation, which in the case of individual differences analysis will consist of real parametric uncertainty representing variation in the parameters of the model. Thus, this approach handles LFT (block diagram) perturbations rather than handing perturbed coefficients directly in a (transfer function) model, but this apparent limitation is readily overcome, as we illustrate below.

Each differences analysis considered variations in two time constants (i.e., speed of the perceptual and cognitive processors). These could arise due to variations among users but could also be introduced through

**Figure 7**   Canonical form for SSV analysis.

**Figure 8**   Variation in time constant as an LFT perturbation.

inaccuracies in the modeling approach. To realize this analysis, these variations were cast as a block diagram perturbation. This can be done by noting the interconnect in Figure 8, which shows an example of rearranging parametric uncertainty as an LFT (block diagram).

Mathematically straightforward block diagram calculations now reveal that the transfer function in Figure 8 is represented by

$$\frac{1}{1 + s(\tau + \Delta\tau)}$$

so that the block diagram perturbation in Figure 8 actually becomes a perturbed coefficient in the transfer function model, and to be specific it represents a perturbation in the time constant of the first-order lag model.

This approach was applied to the closed-loop neuroergonomic system model represented in Figure 5, considering a parametric variation in the time constants of the first-order lag models of the perceptual and cognitive processor blocks. Note that the motor processor block is not in the feedback loop in this scenario, so it does not affect stability and hence was not included in the robustness analysis presented here. The LFT and $\mu$ analysis machinery could then be applied to this block diagram. The mathematics of this approach is quite involved and uses computational complexity theory, complex analysis, and linear algebra among others (Young, 2001). Space constraints prevent going into any kind of detailed explanation here, but the end result of this analysis was to give a parameter range over which (robust) stability is *guaranteed*. This means that no parameter combination in the allowed range can cause instability. For example, in this case one could guarantee that no person with a combination of processing time constants for the perceptual and cognitive processors in the ranges specified would cause the closed-loop neuroergonomic system in

Figure 5 to go unstable. It is important to note the power of this *guarantee*, because one cannot get such guarantees from any amount of exhaustive simulation or testing (it is always possible that a parameter combination is missed, which causes a problem no matter how many variations are tried).

The results of this analysis showed that both the perceptual and cognitive processor time constants could be reduced to very small numbers (practically all the way down to zero), indicating that faster user response than predicted was no problem. The upper limits for the perceptual and cognitive processor time constants were found to be 3.7 and 2.6 s, respectively. Thus, it is possible for the system to go unstable with slower users. However, the degree of robustness afforded by a PID controller is huge. Specifically, in this example the time constants are a factor of more than 37 times greater than those nominally assumed (e.g., the MHP's "slowman" to "fastman" range for the perceptual processor is 150 ms and for the cognitive processor is 145 ms) (Card et al., 1983), meaning that tremendous variability in the perceptual and cognitive processor time constants can be tolerated between users and tasks. These robustness analysis results were also confirmed by a simulation model which showed stable behavior for all parameter variations in the range allowed but which could be driven unstable by parameter combinations outside these ranges (Young et al., 2004). This individual-differences analysis serves to illustrate what could be done when a neuroergonomic system is coupled with a systematic control-theoretic approach.

### 4.2.3 Robust Controller Synthesis

The control theory methods reviewed above can facilitate the design of high-performance closed-loop systems, even for systems whose dynamics are only partially known (Packard and Doyle, 1993; Zhou et al., 1996; Young, 2001). This is not achieved by optimizing nominal performance measures as in classical optimal control techniques such as linear quadratic Gaussian/linear quadratic regulator control (Ogata, 2002). Rather, these new approaches attempt to optimize robust performance measures utilizing techniques such as $\mu$-synthesis (Packard and Doyle, 1993). In this way, systems can be designed which are insensitive (or robust) to variations in the system that are naturally occurring but hard to predict a priori (e.g., differences between users). The mathematical machinery underlying such techniques is quite involved, and the associated optimization problems can be nonconvex and even NP hard. At first sight, such problems may appear to be intractable, and indeed, global minima usually cannot be guaranteed. Nevertheless, practical computation schemes have been developed using approximation schemes such as upper and lower bounds. These schemes are capable of finding very good approximate solutions in a reasonable amount of time. Moreover, there are numerically efficient implementations available of the associated algorithms, usually in convenient Matlab form (Balas et al., 1991), so such designs can readily be carried out (with the appropriate software) in a reasonable time using current computer hardware.

All this adds up to the fact that developers of neuroergonomic systems have at their disposal a number of powerful tools for robust controller analysis and synthesis. These theoretical techniques offer the potential of safely optimizing performance in a neuroergonomic system while maintaining guaranteed closed-loop stability.

## 5 APPLICATION DOMAINS

As with any scientific discovery or technical innovation, there are multiple paths upon which technology components will advance. Identifying specific applications at the dawn of a significant advance in our understanding of a field of study is problematic in that the assumptions on which hypothesized applications are based are very likely to be flawed. The assumptions that must be made (and that are likely to be wrong) include:

- Who will take advantage of emergent technology components?
- What components of the emergent technology will ultimately prove most useful and robust?
- Where will the emergent technology components be found to be most useful?
- When will the various components of the emergent technology be validated sufficiently for incorporation into real-world systems?
- Why will the emergent technology components be seen as beneficial?
- How will the emergent technology components be used?

Given the challenges inherent in answering these questions, a good starting point is to identify potential general application domains and then extract examples from these domains in hopes of describing potential uses of emergent technology components. The general application domains likely to be affected most by neuroergonomic technology components include operational domains that involve massive data and/or vigilance and thus would benefit from real-time cognitive readiness and assessment capabilities; educational domains, such as a scenario-based training system that can adapt in real time to trainee performance, as assessed by both overt behavior and cognitive state (as captured by OFS gauges); and clinical domains such as medical applications, where, for example, the real-time attention processes of children with attention-deficit hyperactivity disorder (ADHD) are monitored and reinforcement interventions for "paying attention" are employed. The value of neuroergonomics to the operational, educational, and clinical application domains should be noted, but the specific examples reviewed below should not be assumed to be predictions of actual application areas.

### 5.1 Operational

A primary objective of neuroergonomics is to use real-time assessment of OFS to optimize cognitive and physical performance during operational activities. This will be particularly important in high-complexity,

information-rich operational environments, such as command and control or stock market analysis, or high-vigilance task environments, such as baggage screening, long-haul truck driving, or power plant operations. The latter can allow for predicting physiologically based variations in sleepiness versus alertness during operational performance and mitigating the associated risks (Warm et al., 2008).

Early examples of neuroergonomics in operational environments focused on adaptive automation, where an operator's state was monitored and when overload was detected, tasks were offloaded. For example, Pope et al. (1995) developed a closed-loop system that leveraged an EEG-based index of task engagement to determine optimal task allocation schemes. Freeman et al. (1999) extended this work by incorporating absolute measures of EEG task engagement, monitoring operator performance, and switching the task to an automatic mode during periods of high task engagement. Prinzel et al. (2003) were one of the first to use multiple physiological indicators (i.e., EEG, ERPs, HRV) to direct task automation in a closed-loop system. Wilson and Russell (2004) demonstrated marked improvements in operator performance by reducing task demands during periods of high operator workload. Similarly, Wilson and Russell (2007) provided physiologically adaptive aiding (i.e., automating some critical task functions) during unmanned vehicle operations and demonstrated a 25% performance improvement as compared to unaided performance. In addition, Berka et al. (2004) derived task allocation schemes between humans and autonomous agents in a naval command-and-control simulation environment by using real-time EEG-based assessment of alertness and memory states. Shaw et al. (2010) tried to use transcranial Doppler sonography (TCD), which measures cerebral blood flow velocity, to trigger adaptive automation in a command-and-control task; it was found to be effective in gauging only the first task workload transitions but not subsequent transitions. Thus, TCD's effectiveness in supporting physiologically driven adaptive automation is uncertain.

Beyond task allocation schemes, neuroergonomics has also been applied to image analysis. For example, ERP has been used to classify when targets are detected, missed, correctly rejected, and/or responded to with false alarms (Cowell, et al., 2007; Fuchs et al., 2007). Similarly, Mathan et al. (2006, 2008) used ERPs and overt physical responses to detect targets within satellite images to achieve a fivefold reduction in target detection time at high accuracy levels, as compared with conventional broad area image analysis. In addition, Touryan et al. (2010) used individualized EEG classifier models to distinguish between targets and clutter in visual images. In addition, real-time measures of cognitive states have been associated with performance while flying an aircraft (Schnell et al., 2006, 2008a, 2008b). Numerous studies in flight and other operational domains have shown that psychophysiological data provide accurate measures of operator fatigue and mental workload (Wilson and Schlegel, 2003; Wilson, 2001, 2002b). Neuroergonomics has also been conceptualized for use in decision support systems (Carroll et al.,

2010a), for air traffic control (Ayaz et al., 2011), and for mitigating the effects of stress on human performance (Hancock and Szalma, 2007; Haufler and Hatfield, 2010).

Neuroergonomic applications extend to the physical domain, as well, where sensing equipment provides a means to extend the manner in which an individual interacts with computing technology by facilitating "direct interaction"... According to Bonadio et al. (2002, p. 181):

> The communication among people and between people and machines or tools has not been fully realized because of the indirect interactions. The external tools need to be manipulated as an independent extension of one's body in order to achieve the desired goal. If machines and devices could be incorporated into the "neural space" as an extension of one's muscles or senses, they could lead to unprecedented augmentation in human sensory, motor, cognitive, and communication performance.

There are many such examples of physically based neuroergonomic applications. For example, brain potentials have been coupled with external devices controlled by the physically handicapped (Farwell and Donchin, 1988), including individuals with little or no motor function (Pfurtscheller et al., 2000). In addition, Felton et al. (2005) developed an electrocorticogram-controlled brain–computer interface that allowed paraplegics to compose letters on a computer. Other such brain–computer interfaces have been used to operate voice synthesizers and move robotic arms (Birbaumer, 2006; Mussa-Ivaldi et al., 2007). Thus, in the psychomotor domain, neuroergonomics expands the available response modalities by allowing for direct brain–computer interaction.

In general, from an operational perspective, neuroergonomics promises to support human performance in such a way that substantially more of the human potential is tapped. However, despite the apparent advantages of physiologically aided operational performance, the interactive relationship between operator and aiding system is a complex one that evolves over time and thus must be supple in design to achieve maximal effectiveness (Christensen et al., 2010a).

## 5.2 Educational

Learning may benefit greatly from the application of neuroergonomics. Specifically, as an individual acquires a new skill, there are associated functional changes in the brain that occur which can be monitored in real time by OFS physiological gauges and then precisely adapted to. Understanding these brain changes could provide a means to achieve "precision training"—where an individual is provided with precisely the right material at precisely the right time in precisely the right format based on an individual's current proficiency level. Such a system would identify a person's current level of expertise and would allow the person to be guided rapidly to heightened levels of sustained performance in a context-independent fashion. Additionally, a person's cognitive performance during training could be

periodically or continuously assessed to ensure that their training was proceeding appropriately. These techniques could be incorporated into a multilevel approach to training, one that capitalizes on being able to observe patterns both at the overt behavioral level and at a deeper structure neuroimaging level, thereby distinguishing between novice and expert behaviors and tracking progression toward "expert" neural activation over time. An application that could characterize expert performance, identify where in the novice–expert continuum a trainee's performance lies, and then mold the trainee's patterns to more closely reflect an expert's would revolutionize training (Stanney et al., 2010).

In terms of educational application examples, neuroergonomics has been integrated into perceptual skills training (Carroll, 2010; Carroll et al., 2008, 2009), instrument flight panel training (Carroll et al., 2010b), cultural communications skills training (Oden et al., 2010; Palmer and Kobus, 2010), and baggage screening training (Carpenter et al., 2010) as well as conceptualized for use in unmanned air vehicle (UAV) operations training (Baldwin et al., 2010; Fuchs et al., 2008; Sibley et al., 2010) and forward air controller training (Fuchs et al., 2009) and for assessing individual differences in human performance to support the development of better selection and training methodologies (Parasuraman & Jiang, 2011), among other examples. Stevens et al. (2007) have pointed out that individual differences in EEG patterns during learning will require incorporation of the individual student's profile into augmentation algorithms.

The use of such physiologically-based adaptive training systems is expected to substantially improve the efficiency and effectiveness of simulation-based training. One example demonstrated an approximate 20% increase in search performance effectiveness when trainees were presented with both expert visual scan patterns and scan feedback strategy based on their own visual scan patterns during search and detect task training (Carroll et al., 2010c). In general, neuroergonomic training applications can be expected to provide a reduction in training cycle time and increased quality of training outcome of at least 30% each [Fletcher (2001) suggests that, compared to conventional classroom instruction, instructional technology reduces time to reach learning objectives by about one-third and increases trainee achievement by about one-third; also see Woolf and Regian (2000)]. Thus, the impacts of neurergonomics on education could include more efficient and effective training, with the anticipated result being substantially deeper learning and more rapid attainment of expertise.

### 5.3 Clinical

Within the clinical domain one can imagine that, by leveraging neuroergonomic technology, clinicians could be better trained in clinical decision making related to the diagnosis and treatment of medical disorders (Rizzo and Parasuraman, 2007). For example, neuroergonomic applications have been conceptualized for use in error monitoring during medical diagnosis (Fedota and Parasuraman, 2010), epilepsy and sleep disorder diagnosis (Casson et al., 2010), mild traumatic brain injury treatment (Stanney et al., 2009), and stroke rehabilitation (Moller and Mikulis, 2007) and as neuroprostheses for individuals with various disabilities (Riener, 2007). The target identification research discussed in Section 5.1 suggests that neuroergonomic procedures could be useful for detecting cancers in diagnostic images. Such levels of improved target identification would be highly useful in medical diagnostics. The possible utility of neuroergomonic procedures in helping paralyzed patients was also mentioned earlier (Karwowski et al., 2003; Parasuraman and Wilson, 2008). To date, developments of emergent neuroergonomic technology components have been least aligned with such potential clinical applications. However, successes in the operational and training domains will likely accelerate application developments in the clinical domain.

In summary, applications of neuroergonomics are in their infancy. Examples of possible applications of underlying technology components can readily be imagined, and some are starting to emerge, mostly in the training community. There is significant evidence to suggest that the technology components are ready for insertion into mature applications and that the operational, educational, and clinical domains have capability gaps that call for technology solutions offered by the field of neuroergonomics. Thus, although mature neuroergonomic science and technology components have now embarked on the path toward application, the only certainty along this journey is that the applications developed will be like no others that have come before them.

## 6 CONCLUSIONS

Neuroergonomics seeks to create a new level of communication between human and support system, where human brains and computing machines are tightly coupled, thereby achieving a partnership that surpasses the information-handling capacity of either entity alone. Such improvement in human–system capability is clearly a worthy goal, whether the context is clinical restoration of function, educational applications, market-based improvements in worker efficiency, or warfighting superiority. Neuroergonomics is an attempt to realize a revolutionary paradigm shift in interactive computing, not by optimizing the *friendliness* of connections between human and computer but by achieving a *symbiotic dyad* of silicon- and carbon-based enterprises, thereby achieving a neurosustainable environment that maximizes the human potential.

# CHAPTER 38

# ACCIDENT AND INCIDENT INVESTIGATION

**Patrick G. Dempsey**
**National Institute for Occupational Safety & Health**
**Pittsburgh, Pennsylvania**

## 1  INTRODUCTION

Of all the applications and benefits of human factors found in a comprehensive handbook, determining how a system led to an accident, minor or catastrophic, is among the least proactive. The systems philosophy of human factors is particularly well suited to investigating accidents and incidents to determine the causative influences so that corrective actions can be taken and future systems designed to be safer. An example of this is commercial air travel, where the accident rate per miles flown has decreased substantially over time, in part due to the corrective actions implemented after accidents. The same can be said of highway safety, as fatality rates per mile driven continue to decrease.

The investigation of accidents can take on a variety of forms, and investigations vary in depth from little or no investigation to multiyear investigations costing millions of dollars. Perhaps the most rudimentary of these approaches are summaries of administrative databases used for insurance or regulatory purposes. Beyer (1928) used accident statistics to provide a sense of the seriousness of the burden of occupational injuries and illnesses, in some cases categorizing data due to the loss sources. Although Beyer's (1928) text (and the preceding first and second editions) may have been one of the first to address industrial safety, the topic of accident investigation was not covered explicitly. However, numerous safety innovations contained within clearly resulted from lessons learned from previous accidents.

At the Silver Jubilee Congress of the National Safety Council in October 1938, S. E. Whiting used a simulated confined-entry scenario of workers entering tanks to demonstrate how carbon dioxide in confined spaces can lead to death (Whiting, 1939). Although these were conceptually the opposite of an accident investigation, a key characteristic of the scenarios is that they went beyond descriptions of hardware, including safety equipment. The scenarios alluded to organizational factors such as inaction by bystanders because of concerns over who had decision authority and cognitive considerations such as flawed mental models of what caused workers to become unconscious. The complexities and interactions between system components were apparent in the descriptions. The realistic nature of the simulations suggests that actual cases were used to develop the scenarios.

Within a few decades, accident prevention and investigation began to take on a more sophisticated and systemic view of causation. Heinrich's (1959) accident sequence depicted by dominos acknowledged that the cause of accidents was multifactorial and involved a sequence of factors. The three factors requisite for an accident were ancestry and social environment, fault of the person, and unsafe act and/or mechanical or physical hazard. Although these components may seem dated relative to contemporary theories and philosophies of accident causation, a broader interpretation of ancestry and social environment to include organizational culture and personal factors would be consistent with more current thought. Unsafe acts continue to occur, although the other components would be replaced by more systemic views, such as how a particular system (humans, environment, and hardware) can lead to errors that ultimately culminate in an incident or accident. Similarly, a more contemporary approach would be to determine which organizational factors increase the propensity for unsafe acts.

On the morning of February 1, 2003, the Space Shuttle *Columbia*, launched by the U.S. National Aeronautics and Space Administration (NASA) a few weeks prior on January 16, broke apart during reentry to Earth's atmosphere, leading to the loss of the lives of the

seven astronauts aboard. A piece of insulating foam that was part of the thermal protection system had separated 81.9 s after launch on January 16. When superheated air penetrated the leading-edge insulation, which eventually melted the aluminum structure of the left wing, the weakening of the structure and increasing aerodynamic forces led to loss of control, wing failure, and eventually breakup of the *Columbia* [Columbia Accident Investigation Board (CAIB), 2003].

The CAIB oversaw an accident investigation process that involved a staff over 120 persons in conjunction with 400 NASA engineers lasting nearly seven months. Over 25,000 searchers worked on the ground to collect debris from the spacecraft (CAIB, 2003). Although the physical cause of the *Columbia* accident was attributed to the piece of insulating foam that separated shortly after launch, the CAIB's conclusions regarding the chain of events that led to the disaster reached much further back in time than the foam separation. Examples of the findings included the conclusion that NASA's safety culture had become reactive, complacent, and too optimistic. During the mission and after the foam strike was known, managers resisted new information; thus, communication within the organization was inhibited. Because there were numerous foam incidents during previous missions that did not result in problems, managers were conditioned to believe that foam strikes were maintenance issues to be solved after landing (CAIB, 2003). These and the other extensive findings illustrate just how intricately accident investigations sometimes need to be conducted and how much accident investigation has matured from earlier forms. This particular case also illustrates many of the concepts to be discussed, ranging from the more traditional fault tree analysis, which is more oriented toward hardware, to investigating organizational influences.

The goal of this chapter is to provide an overview of the numerous approaches to accident and incident investigation in occupational settings, covering a range of approaches that range from using administrative databases to more complex systems approaches. More attention will be given to human-centered approaches, as mismatchs between human capabilities and the demands posed by systems are often a key component of accidents. The type of investigation selected will vary depending on the frequency and severity of the incident(s) in question.

## 2  BASIC PRINCIPLES OF ACCIDENT INVESTIGATION

Although organizations should always strive to prevent accidents, a key component of a safety program is having the resources and procedures ready to respond to an accident if an accident should occur. Prior to an accident, it is critical that factors such as authority for the investigation be established. All of the accident investigation methodologies discussed later rely on details of the accident; thus, collecting the information in a timely and thorough manner is critical. Many organizations have accident report and investigation forms specifically developed to collect information about factors such as the demographics of the injured person(s), location,

and ambient conditions at the time of the accident. All employees should know to whom accidents should be reported, in addition to procedures for calling for emergency response from fire departments or emergency medical technicians when necessary.

An important question that often arises relates to who should conduct the investigation. Vincoli (1994) argues that the manager responsible for the employees involved should lead the investigation, as it is his or her responsibility to ensure the safety of the employees. The reasons for this suggestion is because management can, among other items, marshal resources for the investigation and obtain organizational support, define and implement corrective actions, resolve conflicts, and make employees aware of the outcome as well as conduct follow-up procedures to ensure that corrective actions have been taken (Vincoli, 1994). This does not exclude others from contributing, however, and site safety professionals or safety consultants can and should contribute to the process.

Depending on the severity of an accident, others such as insurance company representatives or government investigators may become involved. For example, the Occupational Safety and Health Administration (OSHA) in the United States must be notified whenever a fatality occurs. OSHA collects information on the individual (demographics, experience, nature of injury, etc.), accident data (measurements, photos, workplace layout, etc.), information on the equipment or process being used (machine type, manufacturer, model, warning devices, etc.), information on potential witnesses, and information on whether the employer has an active safety program and whether or not the program or any of its components address the type of accident that has occurred. Similarly, the Mine Safety and Health Administration (MSHA) in the United States requires that mines inform MSHA within 15 min when what are termed "immediately reportable accidents and injuries" such as fatalities, entrapment of an individual for more than 30 min, an unplanned ignition or explosion of dust or gas, or other types of accidents described in Title 30 § 50.2(h) of the U.S. Code of Federal Regulations.

The information collected should provide a sufficient description of the system, including the personnel, the machine/equipment being used, and the task. It is important to try to ascertain what goal the behavior carried out at the time of the accident was directed at, especially if a nonroutine task was being conducted or the operator was troubleshooting. The importance of the task is addressed in more detail in Section 3.3.

An important component of the investigation is recording the scene through photography or videography. Vincoli (1994) provides a comprehensive overview of what the accident photography kit should include. Aside from the camera, scales, rulers, and a perspective grid are recommended. Ability to preview video and still images at the scene can aid in assessing whether the scene has been captured adequately and geometric issues such as potential parallax problems can be assessed.

## 3  EPIDEMIOLOGICAL APPROACHES

Accident investigation is often thought of only as something conducted for catastrophic events, yet the

combined analysis of similar accidents, even if the accidents are somewhat minor, can be a powerful means of determining underlying causes of a class of accidents. Epidemiology, which is the study of the determinants and distribution of health-related states in populations (Last, 1995), is not typically discussed in the context of accident investigation. However, numerous principles of epidemiology are relevant to the study of common classes of accidents, such as injuries caused by a particular object (e.g., a chainsaw) or associated with a particular task (e.g., meat cutting). Several approaches to the study of injuries resulting from accidents are discussed to provide an overview of how epidemiology can contribute to understanding the causes of accidents. It should be noted that all of the methods discussed are not appropriate for investigating single accidents or incidents but rather are cases where a reasonable sample size is available for study. Although this may seem to be a disadvantage, a clear advantage is that the results of these studies can often be implemented and prevent multiple future incidents or accidents.

## 3.1 Administrative Data

Administrative data collected for other purposes, such as paying Workers' Compensation claims or tracking injuries and illnesses to satisfy regulatory requirements (e.g., OSHA Log of Work-Related Injuries and Illnesses—Form 300 used in the United States) have valuable information on the potential factors associated with the injuries and illnesses recorded. Often, these data have short narratives of the accident scenario and may have administrative codes describing the nature of injury (e.g., contusion, laceration, fracture) and cause (e.g., struck by/against, fall on same level).

As an example of the use of administrative data, Dempsey and Hashemi (1999) analyzed a large sample of Workers' Compensation claims attributed to manual materials handling to determine if the claims suggested specific areas for intervention or future research. Although the majority of the claims were due to musculoskeletal overexertion, a number of high-cost traumatic injuries were uncovered that would be better analyzed through one of the more detailed techniques for rarer events discussed later in the chapter. A large number of acute traumatic injuries to the upper extremity, such as lacerations and contusions, also suggested the need for more widespread use of basic personal protective equipment such as gloves.

Moore et al. (2009) extracted injuries classified as "fall from equipment" from the data reported by the MSHA for all injuries, illnesses, and fatalities during 2006 and 2007. They evaluated the circumstances leading to the fall from equipment injuries to develop research questions for future studies and to identify potential accident scenarios or patterns suggestive of preventive approaches. The majority of injuries identified occurred at surface mining facilities (~60%) with fractures and sprains/strains being the most common injuries occurring to the major joints of the body. Nearly 50% of injuries occurred during ingress/egress, predominately during egress, and approximately 25% of injuries occurred during maintenance tasks. The majority of

injuries occurred in relation to large trucks, wheel loaders, dozers, and conveyors/belts. From the data obtained in this study, several different research areas have been identified for future work, including balance and stability control when descending ladders and equipment design for maintenance tasks.

Another example of a study that utilized administrative data was the analysis of motor vehicle crashes in construction work zones by Sorock et al. (1996). The accident narrative fields from insurance claims were used as the basis of the study. Over 3600 claims were analyzed by categorizing the claims according to precrash activity (stopping, merging, cutting off, reversing, precrash error) and crash types (rear-end impact, hitting large object, hitting small object, side impact, overturning). Of the precrash actions classified, stopping was most common, although the group of claims associated with various precrash errors (e.g., lost control, asleep, failure to yield) had the largest mean and median costs.

One method worth mentioning is the discontinued American National Standards Institute (ANSI) standard, ANSI Z16.2, *Information Management for Occupational Safety and Health* (previously titled *Method of Recording Basic Facts Relating to the Nature and Occurrence of Work Injuries*). This method required collecting items such as nature of injury, part of body, source of injury, agency of accident, and unsafe act, which could then be coded using the coding system provided. Although these are not administrative data per se, older safety texts often mention using the coded data similarly to the suggestions for using Workers' Compensation claims that were discussed earlier.

Although administrative data can provide insights into accidents, the data can be of variable quality, particularly narratives. Since the data are not always for the purposes of gaining an understanding of accident causation, information will be missing. There may also be coding errors, especially for body part and nature-of-injury determinations. Often, the people coding these data do not have medical training; thus, the codes selected may represent the closest to what the coder believes to be correct. Little information is usually available to assess validity. More active approaches discussed throughout the remainder of the chapter can be utilized to overcome these limitations.

## 3.2 Case-Crossover Methodology

The case-crossover method is a study design used to investigate transient risk factors for discrete outcomes such as occupational injury. The method has been used to investigate risk factors for myocardial infarction (Mittleman et al., 1993) and more recently to investigate cell phone use and motor vehicle collisions (Redelmeier and Tibshirani, 1997). The method is based on determining what was different in the time period immediately prior to an accident that is different from "normal" conditions. The hazard period investigated varies with the nature and duration of the exposure being investigated (e.g., an object falling has a very short hazard period, whereas a sedating antihistamine may have effects for several hours) (Sorock et al., 2001a). For some types of accidents there can be multiple risk

factors; thus, the longest period needs to be considered. A key advantage of this approach is that subjects act as their own controls, avoiding the difficulties posed by, for example, finding suitable control subjects for a case–control study. Case–control studies can present difficulties when worker populations are limited, and the cases and controls need to be matched by demographics and exposures.

An example of the case-crossover method applied to occupational problems is the study of acute traumatic hand injury (Sorock et al., 2001b, 2004; Lombardi et al., 2003). Workers with acute traumatic hand injuries seeking treatment at several participating clinics were asked to participate in a telephone interview following treatment, preferably within a day of the accident. Volunteers were called and interviewed about eight transient exposures prior to their accident: using a machine, tool, or work material that performed differently than usual; performing an unusual task; using an unusual work method; being distracted or rushed; feeling ill; working overtime; and glove use at the time. The most important risks suggested were using a machine, tool, or work material that performed differently than usual, unusual work methods, and performing unusual tasks. This methodology is appropriate to use for similar types of accidents, and additional studies are currently underway examining other classes of occupational traumatic injuries, such as eye injuries. Kucera et al. (2008) applied the case-crossover design in a study of hand injuries in commercial fishing. While maintenance work was strongly associated with hand injury risk, gloves did not provide a protective effect, as was suggested by the results of Sorock et al. (2004).

### 3.3 Scenario Analysis

Drury and Brill's (1983) scenario analysis is a task analysis–based approach to accident investigation, developed for investigating consumer product accidents. The intention was to go beyond traditional accident investigation techniques to incorporate consideration of the task in addition to characteristics of the person, equipment, and environment. Since task analysis is the basis, uncovering the mismatch between the task demands and the limitations of the human body subsystem of interest is the goal. Although more descriptive than the analytical case-crossover method, the advantage is that the method allows for more open-ended data collection and is more rooted in ergonomics and human performance. Although the method is not rooted in epidemiological methods, there is a clear link, with the goal being to understand the underlying risk factors for accidents.

The scenario analysis approach is based on classifying accidents into hazard patterns (or scenarios), including a description of the victim, product, environment, and task. This approach was considered useful if no more than six hazard patterns describe more than 90% of the in-depth investigations. Once the generic hazard patterns are developed, a questionnaire to collect information is then developed. In addition to the information on the victim (e.g., age, sex, weight, body part injured), environment (e.g., indoor versus outdoor, lighting, weather conditions), and product (e.g., type, make, shape, weight), detailed information on task performance is collected. This includes information on the action intended prior to the accident; at the moment the task could not be completed as intended; at the moment the victim took a new, perhaps corrective action but before the injury occurred; and at the moment of the injury. The relationship between task demands and operator capacity can be assessed at each stage. The actual interview is somewhat longer than the interview typically used in conjunction with the case-crossover method, but this allows for more in-depth information to be collected.

In summary, Drury and Brill's (1983) approach uses archival data to generate hazard patterns, which then form the basis of data collection for future incidents. This is somewhat analogous to the case-crossover method discussed above in that knowledge of prior accidents or risk factors is necessary to formulate the interview for injured workers. The case-crossover method has the advantage of being more analytic, whereas the scenario analysis technique is more capable of uncovering human factors issues that lead to accidents and injury. Both methods were successful in increasing our understanding of the risk factors for the types of accidents studied.

## 4 SYSTEMS SAFETY TECHNIQUES

There are a number of systems safety techniques that can be utilized for proactive investigations of potential risks in a system to maximize reliability as well as for retrospective accident investigations. These methods sometimes encourage concentrating on hardware failures but are nevertheless useful components of accident investigations. Several of these techniques have been in existence for some time and have been refined considerably, the most common of which are discussed next.

### 4.1 Fault Tree Analysis

Fault tree analysis was developed at Bell Laboratories at the request of the U.S. Air Force due to concern over potential catastrophes associated with the Minuteman missile system being developed by Boeing (Hammer, 1985). Many accident investigators find the method particularly useful because it utilizes deductive logic (Vincoli, 1994), although like the technique discussed in Section 4.2, the method is not widely employed any longer due to the time requirements. The original intention was to develop a method that allowed probabilities of different potential sequences culminating in an accident to be estimated. If an accident probability is available, a risk assessment can be performed by multiplying the probabilities of various undesired events by their predicted costs. The question of the value of human life is often the most difficult question to answer, as this approach requires a common denominator across predictions.

Fault tree analysis is conducted through the use of Boolean logic. The top of the fault tree, in the shape of a

rectangle, represents the end effect under investigation, such as an accident. It should be noted that a safe state can be used as the top event to delineate the factors that need to occur to have a safe system. Symbols are then used to represent the different logic operators, including AND gates and OR gates. All possible sequences of events are then mapped out, and as the procedure becomes more complex, the shape of a tree sometimes becomes apparent. The events or system states that need to occur before failure are mapped out. If probabilities for each logic gate are available or can be estimated, probabilities for different branches can be estimated.

Seven different fault trees were constructed during investigation of the *Columbia* tragedy discussed earlier (CAIB, 2003). The number of elements in the fault trees ranged from 3 to 883, the latter illustrating how complex fault trees are when systems are complex. Although fault trees are not as widely used as they were in the past, they are still a rigorous tool for accident investigation, as evidenced by the *Columbia* investigation.

## 4.2 Management Oversight and Risk Tree

The management oversight and risk tree (MORT) technique has similarities to fault tree analysis in that it also uses Boolean logic in a graphical format. MORT can be used to assess the adequacy of safety program elements, or it can be used retrospectively to investigate accidents, in particular the management components that may have contributed to failure, for example, by creating conditions conducive to being complacent about safety or failure to correct previous safety issues. Rather than simply diagramming a physical system, MORT includes systems issues such as hazard review processes, assumed risks, and safety program review. An extensive discussion of MORT, including examples of completed trees, is provided by Johnson (1973).

## 5 SWISS CHEESE AND HUMAN FACTORS ANALYSIS AND CLASSIFICATION SYSTEM

Reason (1997) used a "Swiss cheese" metaphor to illustrate that the culmination of events in damage to humans or assets depends on failures at different levels. Holes in different layers of defenses that could allow penetration of accident trajectories led to the Swiss cheese metaphor. The holes are the result of what Reason calls either active failures or latent conditions. Reason (1997) defines *active failures* to be unsafe acts by personnel that are likely to have a direct impact on the safety of the system. *Latent conditions* arise from strategic and other top-level decisions (e.g., poor design, undetected manufacturing defects) that spread through organizations and affect the corporate culture. The CAIB (2003) report discussed earlier is an excellent reference for those wishing an in-depth view of latent failures identified during the *Columbia* investigation. Unfortunately, many industrial safety programs often fail to address or investigate these issues, due to an acute focus on procedures, maintenance, and similar factors.

Figure 1 illustrates several of the concepts associated with the Swiss cheese model. The box at the top illustrates the layered defenses concept and the notion that the accident trajectory can be stopped by different defenses or, alternatively, that different components of an organization need to be coordinated to prevent accidents. The triangle is the system that produces the accident, comprised of the personnel (unsafe acts), the workplace, and organizational factors. Causation is bottom up, whereas the accident investigation process is top down.

The Human Factors and Analysis and Classification System (HFACS) (Shappell and Wiegmann, 2001) puts into operational terms the concepts of active and latent failures from Reason's (1997) Swiss cheese model.

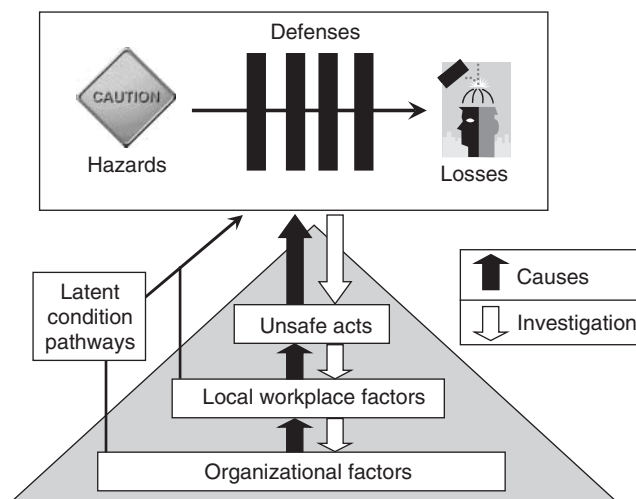

**Figure 1** Stages in the development and investigation of an organizational accident. (Adapted from Reason, 1997.)

Wiegmann and Shappell (2003) provide a comprehensive overview of HFACS, including illustrative case studies of previous accident investigations. HFACS was developed and refined by analyzing accident reports. Although the approach is discussed within the aviation context, some adaptation provides an excellent method that can be applied beyond aviation.

The "unsafe acts" portion of HFACS is broken down into errors and violation. Errors are further broken down into skill-based, decision, and perceptual errors. Regardless of the context in which this taxonomy is used, human factors principles will be critical to understanding the human capabilities or limitations that contributed to the error or errors that led to the accident. Violations are classified as routine or exceptional, with exceptional representing more egregious violations.

The "preconditions for unsafe acts" component of HFACS describes the environmental factors, conditions of operators, and personnel factors that can lead to increased propensity for unsafe acts. Wiegmann and Shappell (2003) provide a broad range of examples for each of these. The "conditions of operators" concept has drawn interest for many occupations over the years, especially in the area of testing operators, particularly in the transportation industry, for what has been termed fitness for duty.

HFACS includes an unsafe supervision component broken down into inadequate supervision, planned inappropriate operations, failure to correct problems, and supervisory violations. Thus, management accountability and culpability is a critical component of HFACS. These factors become particularly important for nonroutine work such as construction, where planning a job and the safety measures taken by supervisors and employees are critical and the lack of such planning has led to accidents.

The last component of HFACS is that of organizational influences, which includes resource management, organizational climate, and organizational process. This is perhaps the most difficult component to describe during an investigation. To truly understand factors such as organizational customs, communication in an organization, and procedural influences, a great deal of data gathering through interviews may be required. The CAIB (2003) report is an excellent example of a comprehensive set of findings regarding organizational influences. The interested reader is strongly encouraged to consult the case studies provided by Wiegmann and Shappell (2003) for in-depth information on application of this taxonomic system for investigating accidents.

Patterson and Shappell (2010) recently used a modified version of HFACS to analyze incident and accident cases from mines in Queensland, Australia. The HFACS nomenclature was modified to better fit language used in the mining industry. The analysis of 508 "high-potential incidents" and lost-time cases revealed that skill-based errors were the most common unsafe act, with no significant differences across mine types. Decision errors, most of which were identified to be procedural errors, did significantly vary across mine types with surface quarries having the highest percentage (48%) and underground coal mines having the lowest percentage (23.1%). Findings for unsafe acts were consistent across the 2004–2008 time period studied. The authors suggested that the results could be used to develop data-driven interventions to address the most significant sources of human factors deficiencies found.

## 6   CONCLUSIONS

Accident investigation can take on many forms, ranging from an analysis of administrative data to investigations of single incidents that last for months. Regardless of the nature or severity of the accident, gaining an understanding of the human capabilities and limitations contributing to the accident is often the key to understanding causation. Even in cases where "hardware faults" were seemingly the cause, there are causative contributions influenced by humans.

One of the best ways to explore different approaches to accident investigation and to gain an understanding of the scope and depth of different investigations is through published case studies. An interesting set of case studies centered around human factors is presented by Casey (1993), with human factors violations highlighted for a range of accident types, from the Bhopal disaster to a medical context. A case study describing how three cosmonauts from the former Soviet Union died in 1971 due to a pressure equalization valve that could not be turned quickly enough following depressurization is presented. Although the valve was intended to be used under such situations, operation had not been tested under the extreme conditions where physical capabilities were greatly reduced. Although the particular physical capabilities required were not difficult to understand or even to define empirically, the underlying issue was why no one had the foresight to test the system under operational conditions (or more realistically, simulated conditions). More in-depth cases studies are also provided, including an analysis of the Bhopal Union Carbide disaster in India in 1984 which killed more than 2500 residents. Perhaps most distressing about many of these case studies is that the actions that would have prevented many of the disasters were not excessively burdensome or technically infeasible.

Kletz (2001) provides an illustrative set of in-depth case studies, many of which are rather famous due to their severity, including the Three-Mile Island and Chernobyl nuclear disasters and the King's Cross railway station fire. The case studies include detailed overviews, in some cases engineering drawings of the relevant physical systems or components. Recommendations for prevention or mitigation at each stage of the accidents are provided, as are comprehensive references for additional sources of information. One advantage of studying such well-known disasters is that there is often detailed information that has been gathered from witnesses, physical evidence, and so on. Although most accident investigations will not reach this level of scope and depth, these case studies provide one of the best means of becoming familiar with accident investigation techniques and the wide array of people, equipment, procedures, and

organizational characteristics that often need to be considered during an accident investigation.

As was mentioned earlier, aviation safety has been increasing, in part due to changes made as a result of accidents. A recent survey of accident investigators from several different industries in Sweden (Rollenhagen et al., 2010) revealed that the phase of developing remedial actions following investigations was comparatively brief. When asked about the existence of particular methods or strategies for developing recommendations, "about 50%" of the respondents answered no. This phase should not be overlooked, particularly since preventing further incidents is the most positive outcome of a previous incident. Many organizations have begun to use commercial products for accident and incident investigation. Examples in the United States include TapRoot® (http://www.taproot.com/) and the "5 Whys" strategy (http://www.mindtools.com/) that has roots in the Toyota production system philosophy.

## 1  PURPOSE

This chapter has two interrelated aims. First, we examine the human–machine tasks of inspecting, checking, and auditing to provide understandings that can guide work design, equipment design, and job aid development. Second, we apply this knowledge to inspecting, checking, and auditing of human factors/ergonomics aspects of human–machine systems. As part of this aim, we provide a detailed review and worked example of recent human factors/ergonomics audit programs. Throughout the chapter examples are given from a wide range of domains, from product usability audits, through aviation preflight checklists, to inspection of products for quality assurance.

## 2  INSPECTING, CHECKING, AND AUDITING

The idea of inspecting is as old as civilization. In the Sumerian epic *Gilgamesh*, almost 5000 years old, the narrator invites the reader to examine the quality of the walls of Uruk, built by Gilgamesh, the king (*Gilgamesh*, Tablet 1):

> Look at its wall which gleams like copper (?),
>
> inspect its inner wall, the likes of which no one can equal!
>
> Take hold of the threshold stone—it dates from ancient times!
>
> Go close to the Eanna Temple, the residence of Ishtar,
>
> such as no later king or man ever equaled!

> Go up on the wall of Uruk and walk around,
>
> examine its foundation, inspect its brickwork thoroughly.
>
> Is not (even the core of) the brick structure made of kiln-fired brick,
>
> and did not the Seven Sages themselves lay out its plans?"

The essence of the examining function is all there already. Bodily senses (look, take hold of) are used to compare the existing item (wall) with some implied or actual standard (e.g., kiln-dried brick). Inspection can have more formal definitions (e.g., in dictionaries and quality control texts), but a simple definition from Drury (2002, p. 27) provides a reasonable modern start: "The [test and] inspection system determines the suitability of a product or process to fulfill its intended function, within given parameters of accuracy, cost and timeliness."

Inspection is thus a decision function, for management, for the general public, and for an individual. Should the process be stopped before it produces more defects? Does this café meet local standards of cleanliness, so that people can eat there safely? Is this aircraft safe for me to fly in? Does this box of strawberries contain any bad fruit? The most basic decision is a go/no-go decision: Does this item or process fulfill its intended function or not? In practice, the amount of inspection, checking, and auditing needed to reach such a simple conclusion may be considerable. For example, a national safety board may need considerable evidence after a major accident to determine that the system (aircraft,

train, ferry, spacecraft) is fit to resume normal operations. As noted above, most inspection decisions are simpler than this.

In principle, inspection can be done by the producer or consumer of the goods or services directly, but this is not always satisfactory. Thus, the person machining a part can determine whether or not it meets standards, or the ultimate end user can inspect the part. Much of the quality revolution from the 1970s onward has been concerned with pushing such decisions back along the production system to ensure that decisions are made at the source (e.g., Evans and Lindsay, 1993; Drury, 1997) to prevent errors from propagating through a production system. Indeed, the preferred solution is to inspect the *process* rather than the *product* to ensure that defects are extremely unlikely to be produced. That is the aim of in-process statistical process control (e.g., Devor et al., 1992). Unlike our example of the box of strawberries, most ultimate consumers are not equipped to be able to inspect or check the complex devices and processes they use in daily living. In an agrarian economy, a farmer could examine a spade produced for him by the local blacksmith (e.g., Jones, 1981) with enough skill and visual/haptic information to reach a reasonable conclusion about whether the design and construction quality met his requirements. In our more specialized economy, consumers cannot make valid quality judgments on automobiles, computers, or even the safety of a local chemical plant because they lack both the specialized knowledge required and access to the inner workings of the product or system.

In such cases, customers rely on the judgment of professional inspectors, checkers, and auditors to make informed decisions. This reliance raises questions of honesty, trust, competence, and human–machine system design. From a sociotechnical systems perspective, inspectors must be seen as independent of producers of goods and services or their findings will not be accepted. For example, in civil aviation the U.S. Federal Aviation Administration (FAA) decrees that airline inspectors charged with checking airworthiness are kept organizationally independent of aviation maintenance technicians, who perform repairs, adjustments, and replacements. This independence can lead to role ambiguity and conflict in their job. For example, McKenzie (1958) noted that inspection is always of people: The inspector is judging the work of others by examining the outputs. Early work by McKenzie (1958), Thomas and Seaborne (1961), and Jamieson (1966) established that social pressures are an important part of the inspector's job and inspectors can at times change their behavior and performance in response to such pressures. The author worked in one factory where the customer returned shipments of product when they could not be used right away (e.g., during a strike) by finding a defect in the shipment. Later, when the customer needed the product, the factory repackaged the same shipments, often receiving complements on their improved quality!

This chapter covers both inspection and auditing, so that we need to establish that auditing and inspection do have commonalities or are indeed both instances of the same systems function and human behavior. Both clearly involve making decisions about the fitness of a product/service (inspection) or a system (auditing) for its intended use, with heavy overtones of protecting the public. However, a more detailed proof of congruence must be postponed until we have considered each process in more analytic detail (Section 4).

## 3  INSPECTION AND HUMAN FACTORS ERGONOMICS

As noted above, the study of inspection and inspectors is at least 50 years old, although most concentrated on inspection of products in a manufacturing setting. There are many other types, as noted by Drury (2002, 2009):

- *Regulatory inspection*—to ensure that regulated industries meet or exceed regulatory norms. Examples are review of restaurants against local service codes, fire safety inspection of buildings, and safety inspection of workplaces.

- *Medical inspection*—to ensure that a patient receives correct diagnosis of medical conditions. An example is inspection of mammograms (Nodine et al., 2002; Chen et al., 2008).

- *Maintenance*—to detect failure arising during the service life of a product. This failure detection function can be seen in inspection of road and rail bridges for structural determination or of civil airliners for stress cracks or corrosion.

- *Security*—to detect items deliberately concealed. These may be firearms or bombs carried onto aircraft, drugs smuggled across borders, or camouflaged targets in aerial photographs. Examples are X-ray inspection of airline baggage (e.g., Gale et al., 2000: Hsiao et al., 2008; Ghylin et al., 2007). They can also be suspicious happenings on a real-time video monitor at a security station. Law enforcement has many examples of searching crime sites for evidence.

- *Design review*—to detect discrepancies or problems with new designs. Examples are the checking of building drawings for building code violations, of chemical plant blueprints for possible safety problems, or of new restaurant designs for health code violations.

- *Functionality testing*—to detect lack of functionality in a completed system. This functional inspection can often include problem diagnosis, as with checks of avionics equipment in aircraft. Often functional inspection is particularly dangerous and costly, as in test flying aircraft or checking out procedures for a chemical process.

All of these inspection applications have much in common. Indeed, Drury (2003) has proposed a unified model of inspection in the security domain and shows how it can apply to all security inspection systems. This model was hardly new; it was based

**Table 1  Generic Function, Outcome, and Error Analysis of Test and Inspection**

| Function | Outcome | Errors | |
|---|---|---|---|
| **Setup** | Inspection system functional, calibrated correctly, and capable | 1.1. | Incorrect equipment |
| | | 1.2. | Nonworking equipment |
| | | 1.3. | Incorrect calibration |
| | | 1.4. | Incorrect or inadequate system knowledge |
| **Present** | Item (or process) presented to inspection system | 2.1. | Wrong item presented |
| | | 2.2. | Item mispresented |
| | | 2.3. | Item damaged by presentation |
| **Search** | Indications of all possible nonconformities detected, located | 3.1. | Indication missed |
| | | 3.2. | False indication detected |
| | | 3.3. | Indication mislocated |
| | | 3.4. | Indication forgotten before decision |
| **Decision** | All indications located by search measured correctly and classified correct outcome decision reached | 4.1. | Indication measured incorrectly |
| | | 4.2. | Indication classified incorrectly |
| | | 4.3. | Wrong outcome decision |
| | | 4.4. | Indication not processed |
| **Respond** | Action specified by outcome taken correctly | 5.1. | Nonconforming action taken on conforming item |
| | | 5.2. | Conforming action taken on nonconforming item |

*Source*: Drury (2002).

on function analytical models developed earlier by Drury (1978), Sinclair (1984), and Wang and Drury (1989). A recent incarnation can be seen in Jiang et al. (2003). Table 1 gives a generic functional breakdown of inspection, showing the major functions of inspection with the correct outcomes and errors arising from each function.

The reader is referred directly to Drury (2002) for a detailed consideration of inspection, including automated inspection and test, and a design methodology for "design for inspectability." In the current chapter, only an overview is provided to help understand the context for both checklists and audits. Each function is considered in the order given in Table 1. A single example of safety inspection of a workplace will be used to illustrate each function:

1. *Setup.* In this function, the inspection system is prepared for use. Needed tools, equipment, and supplies are procured, procedures are available to aid the inspector, and the inspector has been trained to perform the task correctly. For a workplace safety inspection, there will be some equipment needing calibration (e.g., psychrometer, air-sampling systems), a written procedure in the form of a checklist or computer program (e.g., Wilkins et al., 1997), and safety inspectors who have undertaken training and often certification. Certification is one way in which the competence and independence of inspectors are maintained, leading presumably to a higher degree of public trust in the inspection process. The SETUP function places demands on the regulatory system to provide the needed antecedents of effective inspection (i.e., sufficient resources).

2. *Present.* Here the inspector (suitably equipped) and the entity to be inspected come together so

that inspection can take place. The narrator of *Gilgamesh* urges the reader to "...go up to the wall of Uruk and walk around." Often, this function is purely mechanical: The manufacturing inspector has products arrive and depart on a conveyor, the safety inspector accesses all areas of a factory that could contain indications of an unsafe condition, and the FAA inspector goes to the file cabinets where maintenance records are kept to check that maintenance was performed and signed off correctly. The managerial implications for PRESENT are that inspectors must know the places they need to examine, and the organization being inspected must provide open and timely access to such sites. In safety inspection by a regulatory agency, there is often special legal provision for sites to be made available with little or no prior notice to prevent concealment of safety concerns known to management.

3. *Search.* Here we arrive at the first of the two most important and error-prone functions of inspection. Search is typically a sequential serial process during which the entire item to be inspected is brought under scrutiny piece by piece. The most obvious form of search is visual, and this has a long history of study, going back to the earliest days of human factors (Blackwell, 1946; Lamar, 1960). People (i.e., inspectors) search an area by successive visual fixations where the eye remains essentially stationary. What can be detected during a single fixation is a function of target and background characteristics (e.g., Overington, 1973) with considerable research (e.g., Treisman, 1986) on combinations of target and background conditions favoring rapid, parallel ("preattentive") search. Mathematical models (e.g., Morawski

et al., 1980; Wolfe, 1994) of the visual search process emphasize two features:

a. Over what area around the fixation point is the target detectable in a single fixation ("visual lobe") (e.g., Chan and Chiu, 2010)?

b. How are successive fixations sequenced to achieve coverage of the entire area?

Visual lobe models (e.g., Engel, 1971; Eriksen, 1990) determine how much area can be covered in a single fixation and hence the number of fixations required for coverage. The time to search an item completely varies directly with the number of fixations required and hence the reciprocal of lobe area (Morawski et al., 1980). Successive fixations are determined partly by top-down strategy and partly by bottom-up features of the currently fixated area (Wolfe, 1994). Top-down strategy has been modeled (e.g., Hong and Drury, 2002) as sequential, random, or a mixture (e.g., Arani et al., 1984). It is determined in part by the inspector's knowledge and expectations of where targets are likely. In an inspection context, a key derivation from search models is the *stopping time*, when the inspector decides that enough time has been spent on one item and moves to the next item. Stopping time chosen by inspectors accords quite well with the predictions of optimum stopping models (e.g., Chi and Drury, 1995; Baveja et al., 1996). Stopping time is a physical manifestation of how many resources the inspector (or the system giving inspection instructions) is willing to devote to each item inspected.

Visual search is not the only form of search important in inspection; there is also procedural search, where an inspector goes through a list of places that require examination. Procedural search is used extensively in aviation checklists (see later) where, for example, a preflight inspection of a general aviation aircraft follows a written procedure requiring examination of control surfaces, tires, fuel, structural joints, and so on. For each item on the checklist, the inspector is trained on what defects to look for. An example is fuel, where a small sample of fuel is drawn from a low point in the fuel line to check for water contamination, with water drops appearing as spheres in the fuel sample.

In a safety inspection, the inspector will have a list of key items/areas to search for indications of lack of safety. Inspectors will use their senses to examine each item in this procedural search, often requiring visual search within the procedural search. For example, inspectors must check that guarding is present on moving machinery, a largely procedural task. When they check safety records, such as the OSHA log in the United States, a visual search is required to determine whether all fields have been filled in and signed correctly. Note that

in both these examples considerable knowledge and skill are required to understand what would be an indication of a safety violation.

As noted in Table 1, the successful outcome of search is something detected that *could* be a defect. This is known in the nondestructive inspection (NDI) community as an *indication*. Subsequent inspection functions are concerned with how to deal with each indication. Note that if search fails, the indication is missed and subsequent functions cannot proceed. At least in visual inspection there is considerable evidence (Drury and Sinclair, 1983; Drury et al., 1997) that the search function is quite error prone, with only about 50% of defects ever being located as indications.

4. *Decision.* This is the function in which the indication is judged against a standard to determine whether it is a true defect. If inspection is about decision, this function represents the essence of inspection. Decision requires human (or machine-aided) judgment against a standard, so a standard must be prespecified. Standards in manufacturing inspection can come from physical properties (hardness, conductivity, surface finish) that can be measured with appropriate gauging. The decision in such cases of what the statistical quality control (SQC) community calls *variables inspection* can be automated quite simply and is thus rarely an appropriate human task. Not all measurements and standards can be implemented so simply. How do we quantify blemishes in the surface finish of automobile paint work (Lloyd et al., 2000) or corrosion areas on an aircraft fuselage (Wenner and Drury, 1996). These examples of *attributes inspection* require a complex, typically human judgment. Often, signal detection theory (SDT) has been used as a model of this part of the inspection process (e.g., Drury and Sinclair, 1983; Chi and Drury, 1995) although at times it has been misapplied to the overall inspection process, hence lumping search errors with wrong decisions to accept a true defect (e.g., Drury and Addison, 1973). SDT suggests a separation of decision difficulty (discriminability) from bias in reporting/not reporting defects (criteria), thus providing a useful link to different remedial actions, depending on whether the discriminability or criterion needs changing. For example, Drury et al. (1997) found that the decision function of inspection was extremely inconsistent between inspectors, implying the need for better training and job aids in aircraft inspection.

For safety inspection, discriminability represents the decision difficulty. This can be very easy when the implied standard is zero (e.g., *any* missing machine guard is a violation) or more difficult (e.g., how much untidiness represents "poor housekeeping"). The decision criterion reflects the willingness to report. From SDT

this is a function of the a priori probability of a defect and the relative costs of the two errors:

- *Miss*: not reporting a true defect
- *False alarm*: reporting an indication that was not a true defect

In safety inspection, the pressures on the inspector can be high. A false alarm can be used by the factory being inspected to bring disrepute on a regulatory agency and on the actual inspector. A miss can lead to an accident, injury, or even a Bhopal-like disaster. Similar pressures exist for aircraft inspectors, security operators, and even the intelligence community. The decision to report becomes even more difficult (from SDT) when the defect found is extremely rare. A recent example is the failure to find a crack in the titanium hub of a jet engine that caused the accident in 1997 at Pensacola, Florida. The inspector, despite years of experience, had never encountered a crack in a titanium hub before. More details on mathematical approaches to the decision function may be found in Drury (2002). An example of applying a mathematical model of the search plus decision functions to security inspection can be found in Ghylin et al. (2007).

5. *Response.* When the decision has been made, the action chosen must be taken. In a manufacturing context, this can be as simple as removing a defective item from the production process or as complex as stopping the process to diagnose the "root cause" of the defect being produced. In more general contexts, the action is often written (e.g., a repair order for a crack in an aircraft structure, written warning of unsanitary conditions in a restaurant, or a safety citation to company management for a missing machine guard).

Although response is a relatively mechanical function, it can be subject to errors. Aircraft inspectors who intend to write up all defects at the end of inspection can forget some defects, surgeons can mark the wrong leg for amputation, and the safety citation can be incomplete. This is one function where computer-based automation can help by making response simple and immediate. For example, Drury et al. (2000) developed a computer-based task card system for aircraft inspection that allowed easy generation of repair orders. Even more could have been done with drop-down menus for fault type (crack, corrosion, etc.) or a search function for the appropriate reference in the structural repair manual.

Throughout this short treatment of inspection, we have seen where and why good human factors/ergonomics practices can reduce error potential. There are also overarching considerations of job design and automation that can have a great impact on errors [e.g., the hybrid automation studies of Hou et al. (1993) and Jiang et al. (2003)]. Again, details may be found in Drury (2002).

The audit and checking activities associated with nonmanufacturing applications can now be placed in a suitable context.

## 4 CHECKING AND CHECKLISTS

When inspection is too complex to be carried out by an inspector unaided by procedural notes, a job aid is required to lead the inspector through the task. The nonmanufacturing examples given already (e.g., aircraft maintenance, safety inspectors) are typical of those requiring and using job aids. The simplest job aid for any procedural task (e.g., preparation for landing an aircraft) is the checklist. All pilots carry checklists for many complex procedures when a sequence of actions must be performed in a standard order. In addition to the landing preparation noted above, there are checklists for preflight inspection, startup/taxi, pre-takeoff, climb, cruise, postlanding, and engine shutdown. These are typically short laminated paper lists in general aviation or computer-based lists for corporate and passenger jets. Glider pilots use laminated checklists but also use mnemonics, such as "STALLS" for prelanding, where they might not have time to consult a written checklist. Safety inspectors in industry typically use a written checklist of several pages.

If the form of a checklist (paper, computer, mnemonic) can vary, so can the content and structure. Most checklists are used as memory aids for well-practiced tasks, so that they are structured as lists of commands, each of which is relatively tense: "switch both magnetos on: open fuel cock: prime engine for 5 seconds." The user is expected to know which are the magneto switches and which way they move for "on." Users are also expected to understand *why* each action is required so that they have some strategy for recovering from malfunctions (e.g., one magneto not working correctly).

In contrast, more detailed procedures are used for inspection and maintenance of aircraft and spacecraft. These procedures will spell out each step in detail, often with part numbers and numerical settings (e.g., tightening torque), and include warnings and cautions as well as a rationale for the overall procedure. With a computer-based system, detailed procedures can also be viewed as checklists: for example, when the procedure is being repeated after a short interval. Drury et al. (2000) used simple hypertext links to move between the checklist steps and the more detailed procedures in their program for inspection workcards. Much human factors design and evaluation has gone into the physical design of such procedures (e.g., Patel et al., 1994; Chervak et al., 1996; Drury et al., 2000), so in the remainder of this section we concentrate on classic checklists, as they are most often encountered in nonmanufacturing inspection and audit.

Checklists have their limitations, though. The cogent arguments put forward by Easterby (1967) provide a good early summary of these limitations in the context of design checklists, and most are still valid today. Checklists are only of use as an aid to designers of systems at the earliest stages of the process. By concentrating

on simple questions, often requiring yes or no answers, some checklists may reduce human factors to a simple stimulus–response system rather than encouraging conceptual thinking. Easterby quotes Miller (1967): "I still find that many people who should know better seem to expect magic from analytic and descriptive procedures. They expect that formats can be filled in by dunces and lead to inspired insights.... We should find opportunity to exorcise this nonsense" Easterby, 1967, p. 554).

Easterby finds that checklists can have a helpful structure but often have vague questions, make nonspecified assumptions, and lack quantitative detail. Checklists are seen as appropriate for some parts of ergonomics analysis (as opposed to synthesis) and are even more appropriate to aid operators (not ergonomists) in following procedural steps. Clearly, we should be careful, even 30 years on, to heed these warnings. Many checklists are developed, and many of these published, that contain design elements fully justifying such criticisms.

Most formal studies of checklist use have been in an aviation context, both in maintenance (Pearl and Drury, 1995) and in preflight inspection (Ockerman and Pritchett, 1998, 2000, 2004). They have also found widespread use in the flight operations side of aviation, with detailed analysis by Degani and Wiener (1990). The Degani and Wiener (1990) study laid the basis for much subsequent work on checklists. They analyzed incident reports from the National Transportation Safety Board (NTSB) and ASRS (NASA's Aviation Safety Reporting System), finding that the main checklist errors resulted from overlooking items following interruptions or distractions, particularly when working under time pressure or toward the end of the working day. Their recommended countermeasures were use of a "challenge and response" operating philosophy, grouping several items together and using a logical flow pattern. In particular, they advocated a "geographical" sequence of steps, good formatting/typography, and that "operators should keep checklists as short as possible to minimize interruptions." They also reviewed then-current technologies that could assist checklist use. An earlier study of checklists for circuit board inspection (Goldberg and Gibson, 1986) also found that a logically organized checklist outperformed a randomly organized one.

Patel et al. (1993) found that during the initial inspection of an aircraft on arrival at maintenance the sequence of tasks in the checklist or workcard did not match the sequence of tasks that aircraft maintenance technicians typically followed. In a related study by Pearl and Drury (1995), questionnaires and videotapes showed that mechanics tended to sequence their tasks using spatial cues on the airplane rather than the order specified on their workcard. The study also revealed that aviation maintenance technicians who performed low-level inspections used spatial locations of tasks to sequence them. In addition, many aircraft mechanics rarely used the checklist and viewed it as an only guide for inexperienced mechanics. Experienced inspectors felt that they had acquired sufficient skill to perform the inspection task using their memory and referred to the checklist only occasionally.

A more recent series of investigations (Ockerman and Pritchett, 1998, 2000, 2004) have examined the relationship between the medium (paper vs. wearable computers) on which the procedure was displayed, the presentations of procedure context, overreliance, and inspection performance for a preflight inspection task. The studies found that inspection performance could be influenced by the presence of procedure context information presented with procedures. The 1998 study also observed that one-third of the participants used their memory and not the task guidance system to perform the preflight inspection. They observed that in some sessions the subjects performed the task from memory and consulted the checklist only to see if anything was forgotten, echoing the Pearl and Drury (1995) findings from maintenance.

Computer applications for checklists were also advocated by Degani and Wiener (1990) and tested in an aviation maintenance/inspection environment by Drury et al. (2000). The latter study measured the impact of a hypertext-based computer program on the usability of work documentation in maintenance and inspection. Based on data collected in 1992–1993 at an airline partner, they concluded that computer-based inspection job aids were effective, although much of their effectiveness was attributed to good job aid design rather than computerization per se. Their task was one of detailed inspection of aircraft structures and used a checklist only as a top-level job aid, with more detailed instructions and data available via hyperlinks.

Major findings of all of these studies should be applicable to audit checklists, despite their somewhat different domains within aviation. Checklists are good job performance aids for repetitive tasks. They involve little explanation of detail or rationale for the sequence of operations, being mainly reminders of the correct sequence, often with facilities for marking (the "check" in "checklist") each item as it is performed to minimize the effect of interruptions or distractions (Degani and Wiener, 1990). The findings include (1) a geographical sequence is probably best; (2) good design principles should be followed; (3) technology can improve checklists; and (4) checklists are not always used, with reliance often placed on memory. The latter finding was reinforced by Wenner and Drury (2000), who note that some people did not read or follow very explicit instructions for performing a task.

Recently, two closely related studies of checklists were performed using a simulated repetitive aircraft inspection task with engineering student participants. The first (Larock, 2000; Larock and Drury, 2003) measured the effects of checklist layout and the number of sign-offs when a task was repeated eight times on eight days. The second (Pai, 2003) examined the use of computer-based checklists under the best design conditions found by Larock and Drury (2003) using the same task repeated over six days.

The first study compared functionally ordered and spatially ordered checklists and also whether each of the 108 items had to be signed off individually or whether they were signed off in 37 logically related subsets. As expected, spatial ordering was better than

functional ordering for both accuracy and speed. The number of sign-offs and the checklist layout interacted for sequence errors, where the best combination was spatial ordering and signing off in 37 groups. Over the course of eight daily trials, participants became faster at the task but tended to develop a spatial strategy for either checklist. The second study used this combination to test the efficacy of various computer implementations of the original paper checklist. A personal digital assistant (Palm-Pilot) was used with its built-in application of the "to-do list." A more user-friendly program was written specifically for the task studied and was implemented on the PDA and on a laptop computer. The conclusion was that the three computer implementations did not differ from each other, and all gave better speed and accuracy than those for the paper-based checklist.

These studies reinforce conclusions 1–4 noted above and showed that checklist behavior is not merely an artifact of using aviation professionals as subjects. Checklists emerge as a powerful tool, but one that needs careful human factors design to reach its maximum performance. Outside of aviation operations, there is little evidence that checklists are designed with these human factors findings in mind.

To develop checklists for auditing safety, ergonomics, or human factors, the design principles above should be followed. In addition, checklists need to be validated with actual users to ensure that their content, structure, and format do indeed lead to reliable performance.

## 5  AUDITING WITH SPECIFIC APPLICATION TO HUMAN FACTORS

When we audit an entity, we perform an examination of it. Dictionaries typically emphasize official examinations of (financial) accounts, reflecting the accounting origin of the term. Accounting texts go further: for example, "testing and checking the records of an enterprise to be certain that acceptable policies and practices have been consistently followed" (Carson and Carlson, 1977, p. 2). In the human factors field, the term is broadened to include nonfinancial entities but remains faithful to the concepts of checking, acceptable policies/practices, and consistency.

As with inspecting, auditing is mentioned in antiquity, at least in current translations: "[H]e who does not pay the fine annually shall owe ten times the sum, which the treasurer of the goddess shall exact; and if he fails in doing so, let him be answerable and give an account of the money at his audit" (Plato, *Laws*, Book VI).

Human factors audits can be applied, as can human factors itself, to both products and processes. Both applications have much in common, as any *process* can be considered as a *product* of a design procedure, but in this section we emphasize process audits because product evaluation is covered in detail in Chapter 50. Product usability audits have their own history (e.g., Malde, 1992), which is best accessed through the product design and evaluation literature (e.g., McClelland, 1990).

Auditing, like inspection, proceeds through a series of functional steps. For example, an audit by a certified public accountant would comprise the following steps (adapted from Koli, 1994):

1. *Diagnostic Investigation*. Describe the business and highlight areas requiring increased care and high risk.
2. *Test for Transaction*. Trace samples of transactions grouped by major area and evaluate.
3. *Test of Balances*. Analyze content.
4. *Formation of Opinion*. Communicate judgment in an audit report.

There are obvious direct parallels with the functions of inspection (Table 1), as noted by Drury (2009): *Diagnostic Investigation* comprises the Setup task, *Test for Transaction* comprises the Present and Search tasks, *Test of Balances* is the Decision task while *Formation of Opinion* is the Response task.

### 5.1  Need for Auditing Human Factors

Human factors or ergonomics programs have become a permanent feature of many companies, with typical examples shown in Alexander and Pulat (1985). As with any other function, human factors/ergonomics needs tools to measure its effectiveness. Earlier, when human factors operated through individual projects, evaluation could take place on a project-by-project basis. Thus, the interventions to improve apparel sewing workplaces described by Drury and Wick (1984) could be evaluated to show changes in productivity and reductions in cumulative trauma disorder causal factors. Similarly, Hasslequist (1981) showed productivity, quality, safety, and job satisfaction following human factors interventions in a computer component assembly line. In both cases, the objectives of the intervention were used to establish appropriate measures for the evaluation.

Ergonomics/human factors, however, is no longer confined to operating in a project mode. Increasingly, the establishment of a permanent function within an industry has meant that ergonomics is more closely related to the strategic objectives of the company. As Drury et al. (1989) have observed, this development requires measurement methodologies that also operate at the strategic level. For example, as a human factors group becomes more involved in strategic decisions about identifying and choosing the projects it performs, evaluation of the individual projects is less revealing. All projects performed could have a positive impact, but the group could still have achieved more with a more astute choice of projects. It could conceivably have had a more beneficial impact on the company's strategic objectives by stopping all projects for a period to concentrate on training the management, workforce, and engineering staff to make more use of ergonomics.

Such changes in the structure of the ergonomics/human factors profession indeed demand different evaluation methodologies. A powerful network of individuals, for example, who can, and do, call for human factors input in a timely manner can help an enterprise more than a number of individually successful project outcomes. Audit programs are one of the ways in which

such evaluations can be made, allowing a company to focus its human factors resources most effectively. They can also be used in a prospective, rather than retrospective, manner to help quantify the needs of the company for ergonomics/human factors. Finally, they can be used to determine which divisions, plants, departments, or even product lines are in most need of ergonomics input.

## 5.2 Design Requirements for Audit Systems

Returning to the definition of an audit, the emphasis is on checking, acceptable policies, and consistency. The aim is to provide a fair representation of the business for use by third parties. A typical audit by a certified public accountant follows the steps outlined in the previous section (diagnostic investigation, transaction test, balances test, opinion formation).

Such a procedure can also form a logical basis for human factors audits. The first step chooses the areas of study, the second samples the system, the third analyzes these samples, and the final step produces an audit report. These define the broad issues in human factors audit design:

1. *How to sample the system.* How many samples are to be used, and how are they distributed across the system?

2. *What to sample.* What specific factors are to be measured, from biomechanical to organizational?

3. *How to evaluate the sample.* What standards, good practices, or ergonomic principles are to be used for comparison?

4. *How to communicate the results.* What techniques are to be used for summarizing the findings, and how far can separate findings be combined?

A suitable audit system needs to address all of these issues, but some overriding design requirements must first be specified.

### 5.2.1 Breadth, Depth, and Application Time

Ideally, an audit system would be broad enough to cover any task in any industry, would provide highly detailed analysis and recommendations, and would be applied rapidly. Unfortunately, the three variables of breadth, depth, and application time are likely to trade off in a practical system. Thus, a thermal audit (Parsons, 1992) sacrifices breadth to provide considerable depth based on the heat balance equation but requires measurement of seven variables. Some can be obtained rapidly (air temperature, relative humidity), but some take longer (clothing insulation value, metabolic rate). Conversely, structured interviews with participants in an ergonomics program (Drury, 1990a) can be broad and rapid but quite deficient in depth.

At the level of audit instruments such as questionnaires or checklists, there are comprehensive surveys such as the Position Analysis Questionnaire (McCormick, 1979); the Arbeitswissenschaftliche Erhebungsverfahren zur Tätikgkeitsanalyse (AET) (Rohmert

and Landau, 1989), which takes 2–3 h to complete; or the simpler Work Analysis Checklist (Pulat, 1992). Alternatively, there are simple single-page checklists such as the Ergonomics-Working Position-Sitting Checklist (SHARE, 1990), which can be completed in a few minutes. Analysis and reporting can range in depth from merely tabulating the number of ergonomic standards violated to expert systems that provide prescriptive interventions (Ayoub and Mital, 1989).

Most methodologies fall between the various extremes given above, but the goal of an audit system with an optimum trade-off between breadth, depth, and time is probably not realizable. A better practical course would be to select several instruments and use them together to provide the specific breadth and depth required for a particular application.

### 5.2.2 Use of Standards

The human factors/ergonomics profession has many standards and good practice recommendations. These differ by country [American National Standards Institute (ANSI), British Standards Institution (BSI), German Institute for Standardization (DIN)], although commonality is increasing through joint standards such as those of the International Organization for Standardization (ISO). Some standards are quantitative, such as heights for school furniture (BSI, 1980), sizes of characters or a video terminal display (VDT) screen (ANSI/HFES-200), and occupational exposure to noise. Other standards are more general in nature, particularly those which involve management actions to prevent or alleviate problems, such as the Occupational Safety and Health Administration (OSHA, 1990) guidelines for meatpacking plants. Generally, standards are more likely to exist for simple tasks and environmental stressors and are hardly to be expected for the complex cognitive activities with which human factors predictions increasingly deal. Where standards exist, they can represent unequivocal elements of audit procedures as a workplace that does not meet these standards is in a position of legal violation. A human factors program that tolerates such legal exposure should clearly be held accountable in any audit. A comprehensive listing of standards pertaining to human factors and ergonomics can be found in the appropriate handbook (Karwowski, 2005).

Merely meeting legal requirements, however, is an insufficient test of the quality of ergonomics/human factors efforts. Many legal requirements are arbitrary or outdated: for example, weight limits for manual materials handing in some countries. Additionally, other aspects of a job with high ergonomic importance may not be covered by standards: for example, the presence of multiple stressors, work in restricted spaces resulting in awkward postures, or highly repetitive upper extremity motions. Finally, there are many "human factors good practices" that are not the subject of legal standards. Examples are the National Institute for Occupational Safety and Health (NIOSH) lifting equation (Waters et al., 1993), the Illuminating Engineering Society (IES, 1993) codes, or the zones of thermal comfort defined by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE, 1989)

or Fanger (1970). In some cases, standards are available in a different jurisdiction from that being audited. As an example, the military standard MIL-1472D (U.S. DoD, 1989) provides detailed standards for control and display design that are equally appropriate to process controls in manufacturing industry but have no legal weight there.

Despite the lack of legislation covering many human factors concerns, standards and other instantiations of good practice do have a place in ergonomics audits. Where they exist, they can be incorporated into an audit system without becoming the only criterion. Thus, noise levels in the United States have a legal limit of 90 dBA for hearing protection purposes. But at levels far below this, noise can disrupt communications (Jones and Broadbent, 1987) and distract from task performance. An audit procedure can assess the noise on multiple criteria (i.e., on hearing protection and on communication interruptions), with the former criterion used on all jobs and the latter only where verbal communication is an issue.

If standards and other good practices are used in a human factors audit, they provide a quantitative basis for decision making. Measurement reliability can be high and validity self-evident for legal standards. However, it is good practice in auditing to record only the measurement used, and not its relationship to the standard, which can be established later. This removes any temptation by the analyst to "bend" the measurement to reach a predetermined conclusion or to become complacent when the measurement is somewhat below the standard yet still potentially a detriment to human performance. Illumination measurements, for example, can vary considerably over a workspace, so that the audit question.

Is the work surface illumination > 750 lux?

☐    yes    ☐    no

could be answered legitimately either way for some workspaces by choice of sampling point. Such temptation can be removed, for example, by the following audit question:

What is the illumination at four points on the workstation?

☐    ☐    ☐    ☐    lux

Later analysis can establish whether, for example, the mean exceeds 750 lux or whether any of the four points fall below this level.

It is also possible to provide later analyses that combine the effects of several simple checklist responses, as in Parsons's (1992) thermal audit, where no single measure would exceed good practice even though the overall result would be cumulative heat stress.

### 5.2.3 Evaluation of an Audit System

For a methodology to be of value, it must demonstrate validity, reliability, sensitivity, and usability. Most texts that cover measurement theory treat these aspects in detail (e.g., Kerlinger, 1964). Shorter treatments are found within human factors methodology texts (e.g., Drury, 1990b; Osburn, 1987).

*Validity* is the extent to which a methodology measures the phenomenon of interest. Does our ergonomics audit program indeed measure the quality of ergonomics in the plant? It is possible to measure validity in a number of ways, but ultimately all are open to argument. For example, if we do not know the "true" value of the "quality of ergonomics" in a plant, how can we validate our ergonomics audit program? Broadly, there are three ways in which validation can be tested.

*Content validity* is perhaps the simplest but least convincing measure. If each item of our measurement device displays the correct content, validity is established. Theoretically, if we could list all of the possible measures of a phenomenon, content validity would describe how well our measurement device samples these possible measures. In practice, it is assessed by having experts in the field judge each item for how well its content represents the phenomenon studied. Thus, the heat balance equation would be judged by most thermal physiologists to have a content that well represents the thermal load on an operator. Not all aspects are as easily validated!

A recent investigation of the content validity of five occupational health and safety management audits (Robson et al., 2010) against a published Canadian standard on occupational safety and health management found that 74% of the standard's content was partially (40%) or fully (34%) represented across all audits. In some cases, particular management elements audited were not covered well with considerable variability across program elements. Thus, even seemingly straightforward content validity of following a prescriptive standard may not be realized in practice if careful attention is not paid during the development and testing of the audit prior to implementation.

*Concurrent* (or *prediction*) *validity* has the most immediate practical impact. It measures empirically how well the output of the measurement device correlates with the phenomenon of interest. Of course, we must have an independent measure of the phenomenon of interest, which raises difficulties. To continue our example, if we used the heat balance equation to assess the thermal load on operators, there should be a high correlation between this and other measures of the effects of thermal load. Perhaps measures such as frequency of temperature complaints or of heat disorders: heat stroke, hyperthermia, hypothermia, and so on. In practice, however, measuring such correlations would be contaminated by, for example, the propensity to report temperature problems or individual acclimatization to heat. Overall outputs from a human factors audit (if such overall outputs have any useful meaning) should correlate with other measures of ergonomic inadequacy, such as injuries, turnover, quality measures, or productivity. Alternatively, we can ask how well the audit findings agree with independent assessments of qualified human factors engineers (Keyserling et al., 1992; Koli et al., 1993) and thus validate against one interpretation of current good practice.

Finally, there is *construct validity*. This is concerned with inferences made from scores, evaluated by considering all empirical evidence and models. Thus, a model

may predict that one of the variables being measured should have a particular relationship to another variable not in the measurement device. Confirming this relationship empirically would help validate the particular construct underlying our measured variable. Note that different parts of an overall measurement device can have their construct validity tested in different ways. Thus, in a broad human factors audit, the thermal load could differentiate between groups of operators who do and do not suffer from thermal complaints. In the same audit a measure of difficulty in a target aiming task could be validated against Fitts's law. Other ways to assess construct validity are those that analyze clusters or factors within a group of measures. Different workplaces audited on a variety of measures and the scores, which are then subjected to factor analysis, should show an interpretable, logical structure in the factors derived. This method has been used on large databases for job-evaluation-oriented systems such as McCormick's position analysis questionnaire (PAQ) (McCormick, 1979).

*Reliability* refers to how well a measurement device can repeat a measurement on the same sample unit. Classically, if a measurement $X$ is assumed to be composed of a true value $X_t$ and a random measurement error $X_e$, then

$$X = X_t + X_e$$

For uncorrelated $X_t$ and $X_e$, taking variances gives

$$\text{Variance}(X) = \text{Variance}(X_t) + \text{Variance}(X_e)$$

or

$$V(X) = V(X_t) + V(X_e)$$

We can define the reliability of the measurement as the fraction of measurement variance accounted for by true measurement variance:

$$\text{reliability} = \frac{V(X_t)}{V(X_t) + V(X_e)}$$

Typically, reliability is measured by correlating the scores obtained through repeated measurements. In an audit instrument, this is often done by having two (or more) auditors use the instrument on the same set of workplaces. The square of the correlation coefficient between the scores (either overall scores or separately for each logical construct) is then the reliability. Thus, PAQ was found to have an overall reliability of 0.79, tested using 62 jobs and two trained analysts (McCormick, 1979).

In the absence of direct measurement capabilities, many checklists rely on observation of workers and subsequent categorization (i.e., rating) of parameters of interest. Postures are an excellent example since most checklists utilize posture categories rather than relying on the rater to estimate angles. This introduces the issues of inter- and intrarater reliability. Inter- and intrarater reliability can be used during the development process to optimize reliability by revising categories to achieve higher reliability. Assessments of interrater reliability are more common, exemplified by the recent investigation of Park et al. (2009) examining interrater reliabilities for postures, materials handling, and noise and vibration exposure among hospital employees. Village et al. (2009) reported interrater reliabilities (kappa values) ranging from 0.21 to 1.0 for categorization of gross postures, trunk angles, and several materials-handling parameters.

*Sensitivity* defines how well a measurement device differentiates between entities. Does an audit system for human–computer interaction find a difference between software generally acknowledged to be "good" and "bad"? If not, perhaps the audit system lacks sensitivity, although of course there may truly be no difference between the systems except blind prejudice. Sensitivity can be affected adversely by poor reliability, which increases the variability in a measurement relative to a fixed difference between entities (i.e., gives a poor signal-to-noise ratio). Low sensitivity can also come from a floor or ceiling effect. These arise where almost all of the measurements cluster at a high or low limit. For example, if an audit question on the visual environment was

Does illumination exceed 10 lux?

☐     yes     ☐     no

almost all workplaces could answer "yes" (although the author has found a number that could not meet even this low criterion). Conversely, a floor effect would be a very high threshold for illuminance. Sensitivity can arise too when validity is in question. Thus, heart rate is a valid indicator of heat stress but not of cold stress. Hence, exposure to various degrees of cold stress would be measured only insensitively by heart rate.

*Usability* refers to the auditor's ease of use of the audit system. Good human factors principles should be followed: for example, document design guidelines in constructing checklists (Wright and Barnard, 1975; Patel et al., 1993). If the instrument does not have good usability, it will be used less often and may even show reduced reliability due to auditors' errors.

## 5.3  Audit System Design

As outlined in Section 2, the audit system must choose a sample, measure the sample, evaluate it, and communicate the results. In this section we approach these issues systematically.

An audit system is not just a checklist; it is a methodology that often includes the technique of a checklist. The distinction needs to be made between methodology and techniques. Almost three decades ago, Easterby (1967) used Bainbridge and Beishon's (1964) definitions:

- *Methodology*: a principle for defining the necessary procedures
- *Technique*: a means to execute a procedural step

Easterby notes that a technique may be applicable in more than one methodology.

### 5.3.1  Sampling Scheme

In any sampling, we must define the unit of sampling, the sampling frame, and the sample choice technique.

For a human factors audit the unit of sampling is not as self-evident as it appears. From a job evaluation viewpoint (e.g., McCormick, 1979), the natural unit is the job that is composed of a number of tasks. From a medical viewpoint the unit would be the individual. Human factors studies focus on the task/operator/ machine/environment (TOME) system (Drury, 1992a,b) or, equivalently, the software/hardware/environment/ liveware (SHEL) system [International Civil Aviation Organization (ICAO), 1989]. Thus, from a strictly human factors viewpoint, the specific combination of TOME can become the sampling unit for an audit program.

Unfortunately, this simple view does not cover all the situations for which an audit program may be needed. Although it works well for the rather repetitive tasks performed at a single workplace typical of much manufacturing and service industry, it cannot suffice when these conditions do not hold. One relaxation is to remove the stipulation of a particular incumbent, allowing for jobs that require frequent rotation of tasks. This means that the results for one task will depend on the incumbent chosen or that several tasks will need to be combined if an individual operator is of interest. A second relaxation is that the same operator may move to different workplaces, thus changing the environment as well as the task. This is typical of maintenance activities, where a mechanic may perform any one of a repertory of hundreds of tasks, rarely repeating the same task. Here, the rational sampling unit is the task, which is observed for a particular operator at a particular machine in a particular environment. Examples of audits of repetitive tasks (Mir, 1982; Drury, 1990a) and maintenance tasks (Chervak and Drury, 1995) are given later to illustrate these different approaches.

Definition of the sampling frame, once the sampling unit is settled, is more straightforward. Whether the frame covers a department, a plant, a division, or an entire company, enumeration of all sampling units is possible at least theoretically. All workplaces, or jobs, or individuals can in principle be listed, although in practice the list may never be up to date in an agile industry where change is the normal state of affairs. Individuals can be listed from personnel records, tasks from work orders or planning documents, and workplaces from plant layout plans. A greater challenge, perhaps, is to decide whether indeed the entire plant really is the focus of the audit. Do we include office jobs or just production? What about managers, foremen, part-time janitors, and so on? A good human factors program would see all of these tasks or people as worthy of study, but in practice they may have had different levels of ergonomic effort expended upon them. Should some tasks or groups be excluded from the audit merely because most participants agree that they have few pressing human factors problems? These are issues that need to be decided explicitly before the audit sampling begins.

Choice of the sample from the sampling frame is well covered in sociology texts. Within human factors it typically arises in the context of survey design (Sinclair, 1990). To make statistical inferences from the sample to the population (specifically to the sampling frame), our sampling procedure must allow the laws of probability to be applied. The sampling methods used most often are described here.

***Random Sampling***    Each unit within the sampling frame is equally likely to be chosen for the sample. This is the simplest and most robust method, but it may not be the most efficient. Where subgroups of interest (strata) exist and these subgroups are not equally represented in the sampling frame, one collects unnecessary information on the most populous subgroups and insufficient information on the least populous. This is because our ability to estimate a population statistic from a sample depends on the absolute sample size and not, in most practical cases, on the population size. As a corollary, if subgroups are of no interest, random sampling loses nothing in efficiency.

***Stratified Random Sampling***    Each unit within a particular stratum of the sampling frame is equally likely to be chosen for the sample. With stratified random sampling we can make valid inferences about each of the strata. By weighting the statistics to reflect the size of the strata within the sampling frame, we can also obtain population inferences. This is often the preferred auditing sampling method, as, for example, we would wish to distinguish between different classes of tasks in our audits: production, warehouse, office, management, maintenance, security, and so on. In this way our audit interpretation could give more useful information concerning where ergonomics is being used appropriately.

***Cluster Sampling***    Clusters of units within the sampling frame are selected, followed by random or nonrandom selection within clusters. Examples of clusters would be the selection of particular production lines within a plant (Drury, 1990a) or selection of "representative" plants within a company or division. The difference between cluster and stratified sampling is that in cluster sampling only a subset of possible units within the sampling frame is selected, whereas in stratified sampling all of the sampling frame is used, as each unit must belong to one stratum. Because clusters are not randomly selected, the overall sample results will not reflect population values, so that statistical inference is not possible. If units are chosen randomly within each cluster, statistical inference within each cluster is possible. For example, if three production lines are chosen as clusters and workplaces sampled randomly within each, the clusters can be regarded as fixed levels of a factor and the data subjected to analysis of variance to determine whether there are significant differences between levels of that factor. What is sacrificed in cluster sampling is the ability to make *population* statements. Continuing this example, we could state that the lighting in line *A* is better than in line *B* or *C* but still not be able to make statistically valid statements about the plant as a whole.

### 5.3.2 Data Collection Instrument

So far we have assumed that the instrument used to collect the data from the sample is based on measured

data where appropriate. Although this is true of many audit instruments, this is not the only way to collect audit data. There have been interviews with participants (Drury, 1990a), interviews and group meetings to locate potential errors (Fox, 1992), and use of archival data such as injury of quality records (Mir, 1982). All have potential uses with, as remarked earlier, a judicious range of methods often providing the appropriate composite audit system.

One consideration regarding audit technique design and use is the extent of computer involvement. Computers are now inexpensive, portable, and powerful, so that they can be used to assist data collection, data verification, data reduction, and data analysis (Drury, 1990a). With the advent of more intelligent interfaces, checklist questions can be answered from mouse clicks on buttons, or selection from menus, as well as the more usual keyboard entry. Data verification can take place at entry time by checking for out-of-limits data, or odd data, such as the ratio of luminance to illuminance implying a reflectivity greater than 100%. In addition, branching in checklists can be made easier, with only valid follow-on questions highlighted. The "checklist user's manual" can be built into the checklist software using context-sensitive help facilities, as in the ergonomics evaluation analysis methodology (EEAM) checklist (Chervak and Drury, 1995). Computers can, of course, be used for data reduction (e.g., finding the insulation value of clothing from a clothing inventory), data analysis, and results presentation.

Having made the case for computer use, some precautions are in order. Computers are still bulkier than simple pencil-and-paper checklists. Computer reliability is not perfect, so that inadvertent data loss is still a real possibility. Finally, software and hardware date much more rapidly than hard copy, so that results stored safely on the latest media may be unreadable 10 years later. How many of us can still read punched cards or 8-in. floppy disks? In contrast, hard-copy records are still available from before the start of the common era.

### Checklists and Surveys as Audit Tools

For many practitioners the proof of the effectiveness of an ergonomics effort lies in the ergonomic quality of the work systems it produces. A plant or office with appropriate human–machine function allocation, well-designed workplaces, comfortable environment, adequate placement/training, and inherently satisfying jobs almost by definition has been well served by human factors. Such a facility may not have human factors specialists, just good designers of environment, training, organization, and so on, working independently, but this would generally be a rare occurrence. Thus, a checklist to measure such inherently ergonomic qualities has great appeal as part of an audit system. We have covered the design aspects of checklists in general, so we concentrate here on their use in the context of human factors/ergonomics audits.

Such checklists are almost as old as the discipline. An early paper by Burger and deJong (1964) lists four earlier checklists for ergonomic job analysis before going on to develop their own. Theirs was commissioned by the International Ergonomics Association

(IEA) in 1961 and is usually known as the IEA checklist. It was based in part on one developed at the Philips Health Centre by G. J. Fortuin and provided in detail in Burger and deJong's paper.

Like any other questionnaire, a checklist needs to have both a helpful overall structure and well-constructed questions. It should also be proven reliable, valid, sensitive, and usable, although precious few meet all these criteria. A recent survey of Certified Professional Ergonomists in the United States (Dempsey et al. 2005) revealed that 70.5% of respondents used checklists, with 67 of 301 respondents that reported using checklists indicating the the checklist was developed on their own or by their employer. It is unlikely these were subjected to tests of reliability or validity, although the usability should be high for those developed by the actual users. The most commonly identified single checklist was referred to as the OSHA checklist, with only 27 responses indicating that there are many checklists used by practicing ergonomists with seemingly few highly popular checklists.

In the remainder of this section, a selection of checklists is presented as typical of (reasonably) good practice. Emphasis will be on objective, structure, and question design. Note that checklists are not the only approach possible. Westwater and Johnson (1995) compared them with expert evaluation and empirical user testing in evaluating PDA design. They concluded that user-based evaluations led to more insights for this evaluation.

1. *IEA Checklist*. The IEA checklist (Burger and deJong, 1964) was designed for ergonomic job analysis over a wide range of jobs. It uses the concept of functional load to give a logical framework relating physical load, perceptual load, and mental load to the worker, the environment, and working methods/tools/machines. Within each cell (or subcell, e.g., physical load could be static or dynamic) the load was assessed on different criteria, such as force, time, distance, occupational medical, and psychological criteria. Table 2 shows the structure and typical questions. Dirken (1969) modified the IEA checklist to improve the questions and methods of recording. He found that it could be applied in a median time of 60 min per workstation. No data are given on evaluation of the IEA checklist, but its structure has been so influential that it is included here for more than historical interest.

2. *Position Analysis Questionnaire*. The PAQ is a structured job analysis questionnaire using 187 worker-oriented elements to characterize the human behaviors involved in jobs (McCormick et al., 1969). The PAQ is structured into six divisions, with the first three representing the classic experimental psychology approach (information input, mental process, work output) and the next a broader sociotechnical view (relationships with other persons, job context, other job characteristics). Table 3 shows these major divisions, examples of job elements in each, and the rating scales employed for response.

**Table 2  IEA Checklist Structure and Typical Questions**
**Structure**

|  |  | A | B | C |
|---|---|---|---|---|
| Load: 1.  Mean<br>      2.  Peaks<br>          (intensity,<br>          frequency,<br>          duration) |  | Worker | Environment | Working<br>Method,<br>Tools,<br>Machines |
| I. Physical load | 1.  Dynamic<br>2.  Static |  |  |  |
| II. Perceptual load | 1.  Perception<br>2.  Selection, decision<br>3.  Control of movement |  |  |  |
| III. Mental load | 1.  Individual<br>2.  Group |  |  |  |

**Typical Question**

| I/B.  Physical<br>Load/Environment |  | 2.1.  Physiological Criteria |
|---|---|---|
|  | 1.  Climate: high and low temperatures |  |
|  | 1.  Are these extreme enough to affect comfort or efficiency? |  |
|  | 2.  If so, is there any remedy? |  |
|  | 3.  To what extent is working capacity adversely affected? |  |
|  | 4.  Do personnel have to be specially selected for work in this particular environment? |  |

**Table 3  PAQ Structure and Scales**
**Structure**

| Division | Definition | Examples of Questions |
|---|---|---|
| 1.  Information input | Where and how does the worker get the information he uses in performing his job? | 1.  Use of written materials<br>2.  Near-visual differentiation |
| 2.  Mental processes | What reasoning, decision making, planning, and information-processing activities are involved in performing the job? | 1.  Level of reasoning in problem solving<br>2.  Coding–decoding |
| 3.  Work output | What physical activities does the worker perform, and what tools or devices does he use? | 1.  Use of keyboard devices<br>2.  Assembling–unassembling |
| 4.  Relationships with other persons | What relationships with other people are required in performing the job? | 1.  Instructing<br>2.  Contacts with public or customers |
| 5.  Job context | In what physical or social contexts is the work performed? | 1.  High temperature<br>2.  Interpersonal; conflict situations |
| 6.  Other job characteristics | What activities, conditions, or characteristics other than those described above are relevant to the job? | 1.  Specified work pace<br>2.  Amount of job structure |

**Scales**

| Types of Scales | | Scales Values | |
|---|---|---|---|
| Code | Type of Rating | Rating | Definition |
| U | Extent of use | N | Does not apply |
| I | Importance of the job | 1 | Very minor |
| T | Amount of time | 2 | Low |
| P | Possibility of occurrence | 3 | Average |
| A | Applicability (yes/no only) | 4 | High |
| S | Special code | 5 | Extreme |

*Source*: McCormick (1979).

Construct validity was tested by factor analyses of databases containing 3700 and 2200 jobs, which established 45 factors. Thirty-two of these fit neatly into the original six-division framework, with the remaining 13 being classified as "overall dimensions." Further proof of construct validity was based on 76 human attributes derived from the PAQ, rated by industrial psychologists and the ratings subjected to principal-component analysis to develop dimensions "which had reasonably similar attribute profiles" (McCormick, 1979, p. 204). As noted earlier, interreliability was 0.79 based on another sample of 62 jobs.

The PAQ covers many of the elements of concern to human factors engineers and has indeed much influenced subsequent instruments, such as AET. With good reliability and useful (although perhaps dated) construct validity, it is still a useful instrument if the natural unit of sampling is the job. The exclusive reliance on rating scales applied by the analyst goes rather against current practice of comparison of measurements against standards or good practices.

3. *AET* (*Arbeitswissenschaftliche Erhebungsverfahren zur Tätikgkeitsanalyse*). The AET has been published in German (Landau and Rohmert, 1981) and later in English (Rohmert and Landau, 1983). It is the job analysis subsystem of a comprehensive system of work studies. It covers "the analysis of individual components of man-at-work systems as well as the description and scaling of their interdependencies" (Rohmert and Landau, 1983, pp. 9–10). As with all good techniques, it starts from a model of the system (Verband für Arbeitsgestaltung, Betriebsorganisation und Unternehmensentwicklung, REFA, 1971; referenced in Wagner, 1989), to which is added Rohmert's stress–strain concept. The latter sees strain as being caused by the intensity and duration of stresses impinging on an operator's individual characteristics. It is seen as useful in the analysis of requirements and work design, organization in industry, personnel management, and vocational counseling and research.

AET itself was developed over many years using PAQ as an initial starting point. Table 4 shows the structure of the survey instrument with typical questions and rating scales. Note the similarity between AET's job demands analysis and the first three categories of the PAQ and between the scales used in AET and PAQ (Table 3).

Measurements of validity and reliability of AET are discussed by H. Luczak in an appendix to Landau and Rohmert (1981), although no numerical values are given. Cluster analysis of 99 AET records produced groupings that supported the AET constructs. Seeber et al. (1989) used AET along with two other work analysis methods in 170 workplaces. They found that AET provided the most differentiating aspects (suggesting sensitivity). They also measured postural complaints and showed that only the AET groupings for 152 female workers found significant differences between complaint levels, thus helping establish construct validity.

Like PAQ before it, AET has been used on many thousands of jobs, mainly in Europe. A sizable database is maintained that can be used for both norming of new jobs analyzed and analysis to test research hypotheses. It remains a most useful instrument for work analysis.

4. *Ergonomics Audit Program* (Mir, 1982; Drury, 1990a). This program was developed at the request of a multinational corporation to be able to audit its various divisions and plants as ergonomics programs were being instituted. The system developed was a methodology of which the workplace survey was one technique. Overall, the methodology used archival data or outcome measures (injury reports, personnel records, productivity) and critical incidents to rank order departments within a plant. A cluster sampling of these departments gives either the ones with the highest need (if the aim is to focus ergonomic effort) or a sample representative of the plant (if the objective is an audit). The workplace survey is then performed on the sampled departments.

The workplace survey was designed based on ergonomic aspects derived from a task/operator/machine/environment model of the person at work. Each aspect formed a section of the audit, and sections could be omitted if they were clearly not relevant (e.g., manual materials-handling aspects for data entry clerks). Questions within each section were based on standards, guidelines, and models, such as the NIOSH (1981) lifting equation, ASHRAE's (1990) *Handbook of Fundamentals* for thermal aspects, and Givoni and Goldman's (1972) model for predicting heart rate. Table 5 shows the major sections and typical questions.

Data were entered into the computer program and a rule-based logic evaluated each section to provide messages to the user in the form of either a "section shows no ergonomic problems" message:

MESSAGE

Results from analysis of auditory aspects:
Everything OK in this section.

or discrepancies from a single input:

MESSAGE

Seats should be padded, covered with nonslip materials, and have the front edge rounded.

**Table 4  AET Structure and Scales**

**Structure**

| Part | Major Divisions | Sections |
|------|-----------------|----------|
| A. Work systems analysis | 1. Work objects | 1.1. Material work objects<br>1.2. Energy as work object<br>1.3. Information as work object<br>1.4. Humans, animals; plants as work objects |
| | 2. Equipment | 2.1. Working equipment<br>2.2. Other equipment |
| | 3. Work environment | 3.1. Physical environment<br>3.2. Organizational and social environment<br>3.3. Principles and methods of remuneration |
| B. Task analysis | 1. Tasks relating to material work objects<br>2. Tasks relating to abstract work objects<br>3. Human-related tasks<br>4. Number and repetitiveness of tasks | |
| C. Job demand analysis | 1. Demands on perception | 1.1. Mode of perception<br>1.2. Absolute/relative evaluation of perceived information<br>1.3. Accuracy of perception |
| | 2. Demands for decision | 2.1. Complexity of decisions<br>2.2. Pressure of time<br>2.3. Required knowledge |
| | 3. Demands for response/activity | 3.1. Body postures<br>3.2. Static work<br>3.3. Heavy muscular work<br>3.4. Light muscular work, active light work<br>3.5. Strenuousness and frequency of movements |

**Scales**

| Types of Scales | | Scales Values | |
|-----------------|--|---------------|--|
| Code | Type of Rating | Duration Value | Definition |
| A | Does this apply? | 0 | Very infrequent |
| F | Frequency | 1 | Less than 10% of shift time |
| S | Significance | 2 | Less than 30% of shift time |
| D | Duration | 3 | 30–60% of shift time |
| | | 4 | More than 60% of shift time |
| | | 5 | Almost continuously during whole shift |

or discrepancies based on the integration of several inputs:

MESSAGE
The total metabolic workload is 174 watts.
Intrinsic clothing insulation is 0.56 clo.
Initial rectal temperature is predicted to be 36.0°C.
Final rectal temperature is predicted to be 37.1°C.

Counts of discrepancies were used to evaluate departments by ergonomics aspect, while the messages were used to alert company personnel to potential design changes. The latter use of the output as a training device for nonergonomic personnel was seen as desirable in a multinational company rapidly expanding its ergonomics program.

Reliability and validity have not been assessed, although the checklist has been used in a number of industries (Drury, 1990a). The workplace survey has been included here because, despite its lack of measured reliability and validity, it shows the relationship between audit as methodology and checklist as technique.

5. *ERGO, EEAM, and ERNAP* (Koli et al., 1993; Chervak and Drury, 1995). These checklists are both part of complete audit systems for different aspects of civil aircraft hangar activities. They were developed for the FAA to provide tools for assessing human factors in aircraft inspection (ERGO) and maintenance (EEAM)

**Table 5  Workplace Survey Structure and Typical Questions**

| Section | Major Classification | Examples of Questions |
|---|---|---|
| 1. Visual aspects | | Nature of task? |
| | | Illuminance at task (midfield, outer field)? |
| 2. Auditory aspects | | Noise level (dBA)? |
| | | Main source of noise? |
| 3. Thermal aspects | | Strong radiant sources present? |
| | | Wet bulb temperature? |
| | | (Clothing inventory) |
| 4. Instruments, controls, displays | Standing vs. seated | Are controls mounted between 30 and 70 in.? |
| | Displays | Signals for crucial visual checks? |
| | Labeling | Are trade names deleted? |
| | Coding | Color codes same for control and display? |
| | Scales, dials, counters | All numbers upright on fixed scales? |
| | Control–display relationships | Grouping by sequence or subsystem? |
| | Controls | Emergency button diameter > 0.75 in.? |
| 5. Design of workplaces | Desks | Seat to underside of desk > 6.7 in.? |
| | Chairs | Height easily adjustable to 15–21 in.? |
| | Posture | Upper arms vertical? |
| 6. Manual materials handling | NIOSH (1981) lifting guide | Task, H, V, D, F |
| 7. Energy expenditure | | Cycle time? |
| | | Object weight? |
| | | Type of work? |
| 8. Assembly/ repetitive aspects | | Seated, standing, or both? |
| | | If heavy work, is bench 6–16 in. below elbow height? |
| 9. Inspection aspects | | Number of fault types? |
| | | Training time until unsupervised? |

activities, respectively. Inspection and maintenance activities are nonrepetitive in nature, controlled by task cards issued to technicians at the start of each shift. Thus, the sampling unit is the task card, not the workplace, which is highly variable between task cards. Their structure was based on extensive task analyses of inspection and maintenance tasks, which led to generic function descriptions of both types of work (Drury et al., 1990). Both systems have sampling schemes and checklists. Both are computer based with initial data collection on either hard copy or direct into a portable computer. Recently, both have been combined into a single program (ERNAP) distributed by the FAA's Office of Aviation Medicine. The structure of ERNAP and typical questions are given in Table 6.

As in Mir's ergonomics audit program, the ERNAP, the checklist is again modular, and the software allows formation of data files, selection of required modules, analysis after data entry is completed, and printing of audit reports. Similarly, the ERGO, EEAM, and ERNAP instruments use quantitative or yes/no questions comparing the value entered with standards and good-practice guides. Each takes about 30 min per task. Output is in the form of an audit report for each workplace, similar

to the messages given by Mir's workplace survey, but in narrative form. Output in this form was chosen for compatibility with existing performance and compliance audits used by the aviation maintenance community.

Reliability of a first version of ERGO was measured by comparing the output of two auditors on three tasks. Significant differences were found at $p < 0.05$ on all three tasks, showing a lack of interrater reliability. Analysis of these differences showed them to be due largely to errors on questions requiring auditor judgment. When such questions were replaced with more quantitative questions, the two auditors had no significant disagreements on a later test. Validity was measured using concurrent validation against six Ph.D. human factors engineers who were asked to list all ergonomic issues on a power plant inspection task. The checklist found more ergonomic issues than the human factors engineers. Only a small number of issues were raised by the engineers that were missed by the checklist. For the EEAM checklist, again an initial version was tested for reliability with two auditors and achieved the same outcome for only 85% of the questions. A modified version was tested and the reliability was considered satisfactory with 93% agreement. Validity was again tested against four human factors engineers;

**Table 6  ERNAP Structure and Typical Questions**

| Audit Phase | Major Classification | Examples of Questions |
|---|---|---|
| I.   Premaintenance | Documentation | Is feedforward information on faults given? |
| | Communication | Is shift change documented? |
| | Visual characteristics | If fluorescent bulbs are used, does flicker exist? |
| | Electric/pneumatic equipment | Do pushbuttons prevent slipping of fingers? |
| | Access equipment | Do ladders lave nonskid surfaces on landings? |
| II.  Maintenance | Documentation | Does inspector sign off workcard after each task? |
| | Communication | Explicit verbal instructions from supervisor? |
| | Task lighting | Light levels in four zones during task (fc)? |
| | Thermal issues | Wet-bulb temperature in hanger bay (°C)? |
| | Operator perception | Satisfied with summer thermal environment? |
| | Auditory issues | Noise levels at five times during task (dBA)? |
| | Electrical and pneumatic | Are controls easily differentiated by touch? |
| | Access equipment | Is correct access equipment available? |
| | Hand tools | Does the tool handle end in the palm? |
| | Force measurements | What force is being applied (kg)? |
| | Manual material handling | Does task require pushing or pulling forces? |
| | Vibration | What is total duration of exposure on this shift? |
| | Repetitive motion | Does the task require flexion of the wrist? |
| | Access | How often was access equipment repositioned? |
| | Posture | How often were following postures adopted? |
| | Safety | Is inspection area cleaned adequately for inspection? |
| | Hazardous material | Were hazardous materials signed out and in? |
| III. Postmaintenance | Buyback | Are discrepancy worksheets readable? |

this time the checklist found significantly more ergonomic issues than the engineers without missing any of the issues they raised.

The ERNAP audits have been included here to provide examples of a checklist embedded in an audit system where the workplace is *not* the sampling unit. They show that nonrepetitive tasks can be audited in a valid and reliable manner. In addition, they demonstrate how domain-specific audits can be designed to take advantage of human factors analyses already made in the domain.

6. *Upper Extremity Checklist* (Keyserling et al., 1993). As its name suggests, this checklist is narrowly focused on biomechanical stresses to the upper extremities that could lead to cumulative trauma disorders (CTDs). It does not claim to be a full-spectrum analysis tool but is included here as a good example of a special-purpose checklist that has been carefully constructed and validated. The checklist (Table 7) was designed for use by management and labor to fulfill a requirement in the OSHA guidelines for meatpacking plants. The aim is to screen jobs rapidly for harmful exposures rather than to provide a diagnostic tool. Questions were designed based on the biomechanical literature, structured into six sections. Scoring was based on simple presence or absence of

a condition or on a three-level duration score. As shown in Table 7, the two or three levels were scored as 0, √, or *, depending on the stress rating built into the questionnaire. These symbols represented insignificant, moderate, or substantial exposures. A total score could be obtained by summing moderate and substantial exposures.

The upper extremity checklist was designed to be biased toward false positives (i.e., to be very sensitive). It was validated against detailed analyses of 51 jobs by an ergonomics expert. Each section (except the first, which recorded only the dominant hand) was considered as giving a positive screening if at least one * rating was recorded. Across the various sections, there was reasonable agreement between checklist users and the expert analysis, with the checklist being generally more sensitive, as was its aim. The original reference shows the findings of the checklist applied to 335 manufacturing and warehouse jobs.

As a special-purpose technique in an area of high current visibility for human factors, the upper extremity checklist has proven validity, can be used by those with minimal ergonomics training for screening jobs, and takes only a few minutes per workstation. The same team has also developed and validated a legs, trunk, and neck job screening procedure along similar lines (Keyserling et al., 1992).

**Table 7  Upper Extremity Checklist: Structure and Scoring**

**Structure**

| Major Section | Examples of Questions |
|---|---|
| Worker information | Which hand is dominant? |
| | Repetitive use of the hands and wrists? |
| | If ''yes,'' then: |
| | Is cycle < 30 s? |
| | Repeated for >50% cycle? |
| Mechanical stress | Do hard or sharp objects put localized pressure on: |
| | Back or side of fingers? |
| | Palm or base of hand? |
| Force | Lift, carry, push, or pull objects >4.5 kg? |
| | If gloves worn, do they hinder gripping? |
| Posture | Is pinch grip used? |
| | Is there wrist deviation? |
| Tools, hand-held objects and equipment | Is vibration transmitted to the operator's hand? |
| | Does cold exhaust air blow on the hand or wristz? |

**Scoring Scheme**

| Question | Scoring | | |
|---|---|---|---|
| Is there wrist deviation? | No | Some | > 33% cycle |
| | 0 | √ | * |
| Overall evaluation: | | | |

total score = number of √ + number of *

7. *Ergonomic Checkpoints.* The workplace improvement in small enterprises (WISE) methodology (Kogi, 1994) was developed by the IEA and the International Labour Office (ILO) to provide cost-effective solutions for smaller organizations. It consists of a training program and a checklist of potential low-cost improvements. This checklist, called *ergonomics checkpoints*, can be used both as an aid to discovery of solutions and as an audit tool for workplaces within an enterprise.

The 128-point checklist has now been published (Kogi and Kuorinka, 1995) and as a book by the ILO (1999). It covers the nine areas shown in Table 8. Each item is a statement rather than a question and is called a *checkpoint*. For each checkpoint there are four sections, also shown in Table 8. There is no scoring system as such; rather, each checkpoint becomes a point of evaluation of each workplace for which it is appropriate. Note that each checkpoint also covers why that improvement is important and a description of the core issues underlying it. Both of these help the move from rule-based reasoning to knowledge-based reasoning as nonergonomists continue to use the checklist. A similar idea was embodied in the Mir (1982) ergonomic checklist.

8. *Operational Demand Evaluation Checklist.* Public et al. (2010) developed this checklist to capture the operational demands on rail signalers. Rail signalers are responsible for directing rail traffic to attain timely performance as well as safety of the traffic as well as equipment and people that could be impacted by a mishap. Rail systems are complex dynamic

**Table 8  Ergonomic Checkpoints**

Structure of the Checklist

| Major Section | Typical Checkpoints |
|---|---|
| Materials handling | Clear and mark transport ways. |
| Handtools | Provide handholds, grips, or good holding points for all packages and containers. |
| Productive machine safety | Use jigs and fixtures to make machine operations stable, safe, and efficient. |
| Improving workstation design | Adjust working height for each worker at elbow level or slightly below it. |
| Lighting | Provide local lights for precision or inspection work. |
| Premises | Ensure safe wiring connections for equipment and lights. |
| Control of hazards | Use feeding and ejection devices to keep hands away from dangerous parts of machinery. |
| Welfare facilities | Provide and maintain good changing, washing, and sanitary facilities to keep good hygiene and tidiness. |
| Work organization | Inform workers frequently about the results of their work. |

**Structure of Each Checkpoint**

| | |
|---|---|
| Why? | Reasons why improvements are important |
| How? | Description of several actions each of which can contribute to improvement |
| Some more hints | Additional points which are useful for attaining the improvement |
| Points to remember | Brief description of the core element of the checkpoint |

*Source*: K. Kogi, private communication, November 13, 1995.

entities, and maintaining mental workload below levels that could lead to errors or inappropriate decisions is important.

Public et al. (2010) began the process of creating the checklist with extensive field data collection with signalers using a range of data collection methods, including interviews, observations, and verbal protocol analysis. A structured interview technique (repertory grid technique) was used to elicit knowledge from rail signalers about the most significant elements identified during initial data collection with respect to influencing signaler mental workload. The identified elements were grouped into categories of operational infrastructure, indicators, process, and service pattern. The repertory grid technique was used to understand which constructs were most meaningful to subject matter experts in describing the overall construct of mental workload and how the elements identified earlier were most able to reflect the presence or absence of the constructs.

The results of the repertory grid technique were then used to develop the checklist. The scoring of high, medium, and low for each element was determined from previously collected data or based upon subject matter experts' opinions where data were lacking. Concurrent validity was assessed by comparing the results of the checklist to a "grading system familiar to the rail industry." The comparison tool graded signal boxes on the "responsibilities and decision-making required as a consequence of the infrastructure controlled and the service operated." Interrater reliability was assessed, but no statistics were presented. Training was developed in an attempt to increase interrater reliability.

9. *Line-Oriented Safety Audit* (*LOSA*). Over 15 years the civil aviation industry has developed a safety audit program for cockpit crew. This was initially developed as a way to check whether the discipline of crew resource management (CRM: e.g., Helmreich et al., 2001) had taken hold in cockpit crews during line operations (Klinect et al., 2003). This was an in-cockpit observation method using trained observers (human factors engineers or experienced airline pilots). The methodology was later refined as a result of new research on threat error management (TEM) and is now an FAA Advisory Circular (FAA, 2006). The actual data collection methodology is quite different from the typical checklist, although it does have boxes to fill in. These are narrative boxes for each stage of flight: predeparture/ axi, take-off/climb, cruise, descent/approach/land/taxi. These raw data are verified by a data verification round table, which can take several days. From this verification comes a set of errors in each of several standard categories, finally being presented stripped of all identification material as error rates in each category. A formal reliability test of LOSA was conducted using the LOSA observer feedback form (LOFF) with two coding exercises using 116 trained observers. The Kudler–Richardson KR-20 coefficient was measured as 0.70, while the split-half Spearman–Brown coefficient was 0.88, both indications of high reliability (Klinect, 2005, pp. 70–71). Currently the LOSA is being extended to airline ground, ramp, and maintenance operations (Ma et al., 2011).

10. Smith (2001) described a production line audit designed to establish a baseline of current ergonomics activities and priorities. The approach used observational task analysis in conjunction with questionnaires and interviews. Significant musculoskeletal stressors were selected as the focus of the audit program, and thus this audit was not designed to audit the potential broad spectrum of ergonomics issues that could be present in an assembly environment. The audit relied on observational analyses of risk factors for each body part, supplemented by body part discomfort maps filled out by line employees, although no details of reliability or validity are given.

11. *Other Checklists.* The sample of successful audit checklists above has been presented in some detail to provide the reader with their philosophy, structure, and sample questions. Rather than continue in the same vein, other interesting checklists are outlined in Table 9. Each entry shows the domain, the types of issues addressed, the size or time taken in use, and whether validity and reliability have been measured. Most textbooks now provide checklists, and a few of these are cited. No claim is made that Table 9 is comprehensive; rather, it is a sampling with references so that readers can find a suitable match to their needs. The first nine entries in the table are conveniently colocated in Landau and Rohmert (1989). Many of their reliability and validity studies are reported in this publication. The next entries are results of the Commission of European Communities fifth ECSC program, reported in Berchem-Simon (1993). Others are from texts and original references. The author has not personally used all of these checklists and so cannot endorse them specifically. Also, omission of a checklist from this table implies nothing about its usefulness.

**Other Data Collection Methods.** Not all data come from checklists and questionnaires. We can audit a human factors program using outcome measures alone. However, outcome measures such as injuries, quality, and productivity are nonspecific to human factors: Many other external variables can affect them. An obvious example is changes in the reporting threshold for injuries, which can lead to sudden apparent increases and decreases in the safety of a department or plant.

**Table 9  Selection of Published Checklists**

| Name | Reference | Coverage | Reliability | Validity |
|---|---|---|---|---|
| TBS | Hacker et al. (1983) | Mainly mental work | | Vs. AET |
| VERA | Volpert et al. (1983) | Mainly mental work | | Vs. AET |
| RNUR | RNUR (1976) | Mainly physical work | | |
| LEST | Guélaud (1975) | Mainly physical work | | |
| AVISEM | AVISEM (1977) | Mainly physical work | | |
| GESIM | GESIM (1988) | Mainly physical work | | |

Additionally, injuries are (or should be) extremely rare events. Thus, to obtain enough data to perform meaningful statistical analysis may require aggregation over many disparate locations andz/or time periods. In ergonomics audits, such outcome measures are perhaps best left for long-term validation or for use in selecting cluster samples. An example is the "validation" of LOSA by using it to measure the improvements in error reduction after a CRM program was instituted. Ma et al. (2010) quote Croft (2001) showing a 59% decline in unstabilized approaches as measured by LOSA after a CRM program at Continental Airlines.

Besides outcome measures, interviews represent a possible data collection method. Whether directed or not (e.g., Sinclair, 1990), they can produce critical incidents, human factors examples, or networks of communication (e.g., Drury, 1990a) that have value as part of an audit procedure. Interviews are used routinely as part of design audit procedures in large-scale operations such as nuclear power plants (Kirwan, 1989) or naval systems (Malone et al., 1988).

A novel interview-based audit system was proposed by Fox (1992) based on methods developed by British Coal (reported by Simpson, 1994). Here an error-based approach was taken using interviews and archival records to obtain a sampling of actual and possible errors. These were then classified using Reason's (1990) active/latent failure scheme and orthogonally by Rasmussen's (1987) skill-, rule-, and knowledge-based framework. Each active error is thus a conjunction of skill/mistake/violation with skill/rule/knowledge. Within each conjunction, performance-shaping factors can be deduced and sources of management intervention listed. This methodology has been used in a number of mining-related studies (see Section 5.4.2).

It is worth mentioning that the term ergonomics audit is occasionally used by consultants in reference to assessing elements of ergonomics programs either corporatewide or at individual sites. The audits do not necessarily assess the ergonomics of tasks, machines/equipment, or environment but rather assess whether ergonomics processes such as individual workstations are carried out, whether surveillance for injuries is carried out, the nature of policies and procedures, and so on. These are typically carried out through interviews. Although these may be effective for increasing the quality of an ergonomics program, they do not necessarily measure effectiveness of the program.

### 5.3.3  Data Analysis and Presentation

Human factors as a discipline covers a wide range of topics from workbench height to function allocation in automated systems. An audit program can only hope to abstract and present a part of this range. With our consideration of sampling systems and data collection devices we have seen different ways in which an unbiased abstraction can be aided. At this stage the data consist of large numbers of responses to large numbers of checklist items or detailed interview findings. How can, or should, these data be treated for best interpretation?

Here there are two opposing viewpoints: One is that the data are best summarized across sample units but not across topics. This is typically the way the human factors professional community treats the data, giving summaries in published papers of the distribution of responses to individual items on the checklist. In this way, findings can be more explicit: for example, that the lighting is an area that needs ergonomics effort or that

the seating is generally poor. Adding together lighting and seating discrepancies is seen as perhaps obscuring the findings rather than assisting in their interpretation.

The opposite viewpoint, in many ways, is taken by the business community. For some, an overall figure of merit is a natural outcome of a human factors audit. With such a figure in hand, the relative needs of different divisions, plants, or departments can be assessed in terms of ergonomic and engineering effort required. Thus, resources can be distributed rationally from a management level. This view is heard by those in the manufacturing and service industries who after an audit ask "How did we do?" and expect a very brief answer. The proliferation of the spreadsheet, with its ability to sum and average rows and columns of data, has encouraged people to do just that with audit results. Repeated audits fit naturally into this view, as they can become the basis for monthly, quarterly, or annual graphs of ergonomic performance.

Neither view alone is entirely defensible. Of course, summing lighting and seating needs produces a result that is logically indefensible and that does not help diagnosis. But equally, decisions must be made concerning optimum use of limited resources. The human factors auditor, having chosen an unbiased sampling scheme and collected data on (presumably) the correct issues, is perhaps in an excellent position to assist in such management decisions. But so, too, are other stakeholders, primarily the workforce.

Audits are not, however, the only use of some of the data collection tools. For example, the Keyserling et al. (1993) upper extremity checklist was developed specifically as a screening tool. Its objective was to find which jobs/workplaces are in need of detailed ergonomic study. In such cases, summing across issues for a total score has an operational meaning (i.e., that a particular workplace needs ergonomic help).

Where interpretation is made at a deeper level than just a single number, a variety of presentation devices have been used. These must show scores (percent of workplaces, distribution of sound pressure levels, etc.) separately but so as to highlight broader patterns. Much is now known about separate versus integrated displays and emergent features (e.g., Wickens, 1992, pp. 121–122), but the traditional profiles and spider's web charts are still the most usual presentation forms. Thus, Wagner (1989) shows the AVISEM profile for a steel industry job before and after automation. The nine different issues ("rating factors") are connected by lines to show emergent shapes for the old and the new jobs. Landau and Rohmert's (1981) original book on AET shows many other examples of profiles. Klimer et al. (1989) present a spider web diagram to show how three work structures influenced 10 issues from the AET analysis. Mattila and Kivi (1989) present their data on the job load and hazard analysis system applied to the building industry in the form of a table. For six occupations, the rating on five different loads/hazards is presented as symbols of different sizes within the cells of the table.

There is little that is novel in the presentation of audit results: Practitioners tend to use the standard tabular or graphical tools. But audit results are inherently multidimensional, so that some thought is needed if the reader is to be helped toward an informed comprehension of the audit's outcome.

## 5.4   Audit Systems in Practice

Almost any of the audit programs and checklists referred to in previous sections give examples of their use in practice. Only two examples will be given here, as others are readily accessible. These examples were chosen as they represent quite different approaches to auditing.

### 5.4.1   Auditing a Decentralized Business

From 1992 to 1996, a major U.S.-based apparel manufacturer had run an ergonomics program aimed primarily at the reduction of workforce injuries in backs and upper extremities. As detailed in Drury et al. (1999), the company during that time comprised nine divisions and employed about 45,000 workers. Of particular interest was the fact that the divisions enjoyed great autonomy, with only a small corporate headquarters with a single executive responsible for all risk management activities. The company had grown through mergers and acquisitions, meaning that different divisions had different degrees of vertical integration. Hence, core functions such as sewing, pressing, and distribution were common to most divisions, while some also included weaving, dyeing, and embroidery. In addition, the products and fabrics presented quite different ergonomic challenges, from delicate undergarments, through heavy jeans, to knitted garments and even luggage.

The ergonomics program was similarly diverse. It started with a corporate launch by the highest level executives, then was rolled out to the divisions and to individual plants. The pace of change was widely variable. All divisions were given a standard set of workplace analysis and modification tools (based on Drury and Wick, 1984) but were encouraged to develop their own solutions to problems in a way appropriate to their specific needs.

Evaluation took place continuously, with regular meetings between representatives of plants and divisions to present results of before-and-after workplace studies. However, there was a need for a broader audit of the entire corporation aimed at understanding how much had been achieved for the multimillion-dollar investment, where the program was strong or weak, and what program needs were emerging for the future. During 1995, a team of auditors visited all nine divisions and a total of 12 plants spread across eight divisions. This was three years after the initial corporate launch and about two years after the start of shop-floor implementation.

A three-part audit methodology was used. First, a workplace survey was developed based on elements of the program itself, supplemented by direct comparisons to ergonomics standards and good practices. Table 10 shows this 50-item survey form, with data added for the percentage of "yes" answers where the responses were not measures or scale values. The workplace survey was given at a total of 157 workplaces across the 12 plants. Second, a user survey (Table 11) was used in an interview format with 66 consumers of ergonomics,

**Table 10 Ergonomics Audit: Workplace Survey with Overall Data**

| Number | | | Division | Plant | Job Type |
|--------|-----|-----|----------|-------|----------|
| | Yes | No | | Factor | |
| **1. Postural aspects** | | | | | |
| W1 | 68% | | Frequent extreme motions of back, neck, shoulders, wrists | | |
| W2 | 66% | | Elbows raised or unsupported more than 50% of time | | |
| W3 | 22% | | Upper limbs contact nonrounded edges | | |
| W4 | 73% | | Gripping with fingers | | |
| W5 | 36% | | Knee/foot controls | | |
| **1.1. Seated** | | | | | |
| W6 | 12% | | Leg clearance restricted | | |
| W7 | 21% | | Feet unsupported/legs slope down | | |
| W8 | 17% | | Chair/table restricts thighs | | |
| W9 | 22% | | Back unsupported | | |
| W10 | 37% | | Chair height not adjustable easily | | |
| **1.2. Standing** | | | | | |
| W11 | 3% | | Control requires weight on one foot more than 50% time | | |
| W12 | 37% | | Standing surface hard | | |
| W13 | 92% | | Work surface height not adjustable easily | | |
| **1.3. Hand tools** | | | | | |
| W14 | 77% | | Tools require hand/wrist bending | | |
| W15 | 9% | | Tools vibrate | | |
| W16 | 63% | | Restricted to one handed use | | |
| W17 | 39% | | Tool handle ends in palm | | |
| W18 | 20% | | Tool handle has nonrounded edges | | |
| W19 | 56% | | Tool uses only two or three fingers | | |
| W20 | 9% | | Requires continuous or high force | | |
| W21 | 41% | | Tool held continuously in one hand | | |
| **2. Vibration** | | | | | |
| W22 | 14% | | Vibration reaches body from any source | | |
| **3. Manual materials handling** | | | | | |
| W23 | 40% | | More than five moves per minute | | |
| W24 | 36% | | Loads unbalanced | | |
| W25 | 14% | | Lift above head | | |
| W26 | 28% | | Lift off floor | | |
| W27 | 83% | | Reach with arms | | |
| W28 | 78% | | Twisting | | |
| W29 | 60% | | Bending trunk | | |
| W30 | 3% | | Floor wet or slippery | | |
| W31 | 0% | | Floor in poor condition | | |
| W32 | 17% | | Area obstructs task | | |
| W33 | 4% | | Protective clothing unavailable | | |
| W34 | 2% | | Handles used | | |
| **4. Visual aspects** | | | | | |
| W35 | | | Task nature: 1, rough; 2, moderate; 3, fine; 4, very fine | | |
| W36 | | | Glare/reflection: 0, none; 1, noticeable; 2, severe | | |
| W37 | | | Color contrast: 0, none; 1, noticeable; 2, severe | | |
| W38 | | | Luminance contrast: 0, none; 1, noticeable; 2, severe | | |
| W39 | | | Task illuminance (foot candles) | | |
| W40 | 69% | | Luminance: task > midfield > outerfield = yes | | |
| **5. Thermal aspects** | | | | | |
| W41 | | | Dry-bulb temperature (°F) | | |
| W42 | | | Relative humidity (%) | | |

*(continues)*

**Table 10 (*Continued*)**

| Number | | | Division | Plant | Job Type |
|---|---|---|---|---|---|
| | Yes | No | | | Factor |
| W43 | | | | | Airspeed: 1, just perceptible; 2, noticeable; 3, severe |
| W44 | | | | | Metabolic cost |
| W45 | | | | | Clothing (clo value) |
| 6. Auditory aspects | | | | | |
| W46 | | | | | Maximum sound pressure level (dBA) |
| W47 | | | | | Noise sources: 1, m/c; 2, other m/c; 3, general; 4, other |
| 7. General factors | | | | | |
| W48 | | | | | Primary cycle time (seconds) |
| W49 | 62% | | | | Seen ergonomics video |
| W50 | 38% | | | | Any ergonomics changes to workplace or methods |

typically plant managers, production managers, human resource managers, or their equivalent at the division level, usually vice presidents. Finally, a total of 27 providers of ergonomics services were given a similar provider survey (Table 12) interview. Providers were mainly engineers, with three human resources specialists and one line supervisor. From these three audit methods the corporation wished to provide a time snapshot of how effectively the current ergonomics program was meeting their needs for reduction of injury costs. While the workplace survey measured how well ergonomics was being implemented at the workplace, the user and provider surveys provided data on the roles of the decision makers beyond the workplace.

Detailed audit results are provided in Drury et al. (1999), so only examples and overall conclusions are covered in this chapter. Workplaces showed some evidence of good ergonomic practice, with generally satisfactory thermal, visual, and auditory environments. There were some significant differences ($p < 0.05$) between workplace types rather than between divisions or plants; for example, better lighting ($>700$ lux) was associated with inspection and sewing. Also, higher thermal load was associated with laundries and machine load/unload. Overall, 83% of workplaces met the ASHRAE (1990) summer comfort zone criteria. As shown in Table 13, the main ergonomics problem areas were in poor posture and manual materials handling. Where operators were seated (only 33% of all workplaces), seating was relatively good. In fact, many

of the workforce had been supplied with well-designed chairs as part of the ergonomics program.

To obtain a broad perspective, the three general factors at the end of Table 10 were analyzed. Apart from cycle time (W48), the questions related to workers having seen the corporate ergonomics video (W49) and having experienced a workplace or methods change (W50). Both should have received a "yes" response if the ergonomics program were reaching the entire workforce. In fact, both showed highly significant differences between plants, $X_8^2 = 92.0$, $p < 0.001$ and $X_8^2 = 22.2$, $p < 0.02$, respectively). Some of these differences were due to two divisions lagging in ergonomics implementation, but even beyond this there were large between-plant differences. Overall, 62% of the workforce had seen the ergonomics video, a reasonable value but one with wide variance between plants and divisions. Also, 38% of workplaces had experienced some change, usually ergonomics related,

**Table 13 Responses to Ergonomics User**

| Question and Concern | Corporate | | Plant | |
|---|---|---|---|---|
| | Mgt. | Staff | Mgt. | Staff |
| 1.   What is ergonomics? | | | | |
| 1.1.   Fitting job to operator | 1 | 6 | 10 | 5 |

| 6.1.6.   The seniority/bumping problem | 0 | 3 | 1 | 0 |
| 6.2.   Ergonomics program concerns | | | | |
| 6.2.1.   Level of reporting of ergonomics | 0 | 1 | 7 | 0 |
| 6.2.2.   Communication/who does ergonomics | 7 | 1 | 4 | 0 |
| 6.2.3.   Stability/staffing of ergonomics | 0 | 0 | 10 | 4 |
| 6.2.4.   General evaluation of ergonomics | | | | |
| Positive | 1 | 3 | 3 | 4 |
| Negative | 4 | 10 | 10 | 3 |
| 6.2.5.   Lack of financial support for ergonomics | 0 | 0 | 1 | 0 |
| 6.2.6.   Lack of priority for ergonomics | 2 | 2 | 1 | 4 |
| 6.2.7.   Lack of awareness of ergonomics | 2 | 1 | 6 | 1 |

a respectable figure after only two to three years of the program.

From the user and provider surveys, an enhanced picture emerged. Again, there was variability between divisions and plants, but 94% of the users defined ergonomics as fitting the job to the operator rather than training or medical management of injuries. Most users had requested an ergonomic intervention within the past two months, but other "users" had never in fact used ergonomics.

The solutions employed ranged widely, with a predominance of job aids such as chairs or standing

pads. Other frequent categories were policy changes (e.g., rest breaks, rotation, box weight reduction) and workplace adjustment to the individual operator. There were few uses of personal aids (e.g., splints) or referrals to physicians as ergonomic solutions. Changes to the workplace clearly predominated over changes to the individual, although a strong medical management program was in place when required. When questioned about ergonomics results, all mentioned safety (or workplace comfort or ease of use), but some also mentioned others. Cost or productivity benefits were the next most common response, with a few additional ones relating to employee relations, absence/turnover, or job satisfaction. Significantly, only one respondent mentioned quality.

The major user concern at the plant level was time devoted to ergonomics by providers. At the corporate level, the need was seen for more rapid job analysis methods and corporate policies (e.g., on back belts or "good" chairs). Overall, 94% of users made positive comments about the ergonomics program.

Ergonomics providers were almost always trained in the corporate or division training seminars, usually near the start of the program. Providers' chief concern was for the amount of time and resources they could spend on ergonomics activities. Typically, ergonomics was only one job responsibility among many. Hence, broad programs, such as new chairs or back belts, were supported enthusiastically, as they gave the maximum perceived impact for the time devoted. Other solutions presented included job aids, workplace redesign (e.g., moving from seated to standing jobs for long-seam sewing), automation, rest breaks, job rotation, packaging changes, and medical management. Specific needs were seen in the area of corporate or supplier help in obtaining standard equipment solutions and of more division-specific training. As with users, the practitioners enjoyed their ergonomics activity and thought it worthwhile.

Recommendations arising from this audit were that the program was reasonably effective at present but had some long-term needs. The corporation sees itself as an industry leader and wants to move beyond a relatively superficial level of ergonomics application. To do this will require more time resources for job analysis and change implementation. Corporate help could also be provided in developing more rapid analysis methods, standardized video-based training programs, and more standardized solutions to recurring ergonomics problems. Many of these changes have since been implemented.

On another level, the audit was a useful reminder to the company of the fact that it had incurred most of the up-front costs of a corporate ergonomics program and was now beginning to reap the benefits. Indeed, by 1996, corporate injury costs and rates had decreased by about 20% per year after peaking in 1993. Clearly, the ergonomics program was not the only intervention during this period, but it was seen by management as the major contributor to improvement. Even on the narrow basis of cost savings, the ergonomics program was a success for the corporation.

## 5.4.2  Error Reduction at a Colliery

In a two-year project reported by Fox (1992) and Simpson (1994), the human error audit described in Section 5.3.2 was applied to two colliery haulage systems. The results of the first study are presented here. In both systems, data collection focused on potential errors and the performance-shaping factors (PSFs) that can influence these errors. Data were collected by "observation, discussion and measurement within the framework of the broader man–machine systems and checklist of PSFs," taking some 30–40 shifts at each site. The entire haulage system from surface operations to delivery at the coal face was covered.

The first study found 40 active failures (i.e., direct error precursors) and 9 latent failures (i.e., dormant states predisposing the system to later errors). Four broad classes of active failures were (1) errors associated with locomotive maintenance (7 errors) (e.g., fitting incorrect thermal cutoffs), (2) errors associated with locomotive operation (10 errors) (e.g., locomotives not returned to the service bay for a 24-h check), (3) errors associated with loads and load security (7 errors), (e.g., failure to use spacer wagons between overhanging loads), and (4) errors associated with the design/operation of the haulage route (10 errors), (e.g., continued use despite potentially unsafe track) plus a small miscellaneous category.

The latent failures were (Fox, 1992) (1) quality assurance in supplying companies, (2) supply-ordering procedures within the colliery, (3) locomotive design, (4) surface "makeup" of supplies, (5) lack of equipment at specific points, (6) training, (7) attitudes to safety, and (8) the safety inspection/reporting/action procedures. As an example of item 3, locomotive design, the control positions were not consistent across the locomotive fleet, despite all originating from the same manufacturer. Using the slip/mistake/violation categorization, each potential error could be classified so that the preferred source of action (intervention) could be specified.

This audit led to the formation of two teams, one to tackle locomotive design issues and the other for safety reporting and action. As a result of team activities, many ergonomic actions were implemented. These included management actions to ensure a uniform wagon fleet, autonomous inspection/repair teams for tracks, and multifunctional teams for safety initiatives.

The outcome was that the accident rate dropped from 35.40 per 100,000 person-shifts to 8.03 in one year. This brought the colliery from worst in the regional group of 15 collieries to best in the group and indeed in the United Kingdom. In addition, personnel indicators, such as industrial relations climate and absence rates, improved.

## 6  CONCLUSIONS

In this chapter we have arrived at human factors audits through a context of inspection and checklist design. It should be obvious by now that checklists are a subset of audits, which are in turn a subset of inspection. Within the context of inspection, we have seen that all inspections follow a short logical sequence of functions

and that each function has considerable scope for model-based and empirical design to improve the human factors and system performance. Nonmanufacturing applications have been emphasized, with the focus on processes and broader systems rather than on repetitively produced products. Audits have been shown to be functionally similar to inspections.

Inspecting, checking, and auditing are interesting, as they all have human factors design aspects but can all be applied to both the processes being audited and the auditing process itself. Whether inspecting nonmanufacturing items or checking items on a checklist or performing an audit, there is prescriptive advice on how to develop or choose a system that accords with human factors good practices.

**School of Industrial & Systems Engineering**
**Georgia Institute of Technology**
**Atlanta, Georgia**

## 1 INTRODUCTION

The past decade has been a period of very serious scrutiny of the activities of most enterprises. Business processes have been reengineered and enterprises have been downsized or, more popularly, rightsized. Every aspect of an enterprise now must provide value to customers, earn revenues based on this value, and pay its shares of costs. Aspects of an enterprise that do not satisfy these criteria are targeted for elimination.

This philosophy seems quite reasonable and straight-forward. However, implementation of this philosophy becomes rather difficult when the "value" provided is indirect and abstract. When anticipated benefits are not readily measurable in monetary units and only indirectly affect things amenable to monetary measurement, it can be very difficult to assess the worth of investments in such benefits.

There is a wealth of examples of such situations. With any reasonable annual discount rate, the tangible discounted cash flow of benefits from investments in libraries and education, for example, would be so small as to make it very difficult to justify societal investments in these institutions and activities. Of course, we feel quite justified arguing for such investments. Thus, there obviously must be more involved in such an analysis than just discounted cash flow.

This chapter addresses types of human factors and ergonomics investments that have these intangible characteristics in addition to more tangible attributes. One type is research and development (R&D). This type of investment is often made for the purpose of creating long-term value. It will certainly require years and may take decades before returns are fully realized. It is easy to see how R&D can be difficult to justify in terms of impacts on, for instance, this year's sales and profits or current operational readiness.

Another type of investment with these intangible characteristics involves products and services that enhance human effectiveness. This includes selection,

training, system design, job design, organizational development, health and safety, and, in general, the wide range of things done to assure and enhance the effectiveness of people in organizations ranging from businesses to military units. In particular, investments focused on increasing human potential, rather than direct job performance outputs, are much more difficult to justify than those with near-term financial returns (Rouse et al., 1997b).

This chapter also addresses the complex interaction of these two types of investments, namely, R&D investments in human effectiveness. This is done by building on previous efforts—by the authors and many others—addressing the two elements of this interaction. Investing in R&D to enhance human effectiveness presents a confluence of difficulties related to representing and quantifying benefits as well as attributing costs. Nevertheless, there is a widely shared sense that such investments are socially and economically important. It is difficult, however, to justify particular projects on the basis of such perceptions.

A primary difficulty involves the trade-off between the relatively short-term payoffs of direct improvements in job performance and the inherently long-term benefits of R&D efforts aimed at enhancing human effectiveness. Short-term investments usually involve less uncertainty and fewer risks. In contrast, revolutionary high-payoff innovations usually emerge from much earlier R&D investments. Thus, small, certain, near-term returns compete with large, uncertain, long-term, and potentially very substantial returns. The methodology presented in this chapter enables addressing both types of investments.

In general, several issues underlie the difficulties of justifying the aforementioned types of long-term investments. As just noted, a fundamental issue concerns the associated uncertainties. Not only are the magnitudes and timing of returns uncertain—the very nature and characteristics of returns are uncertain. With R&D investments, for instance, the eventual payoffs from investments are almost always greater for unanticipated applications than for the originally envisioned applications (Burke, 1996). Further, organizations that make the original investments are often unable to take advantage of the eventual returns from R&D (Christensen, 1997).

These findings raise concerns about whether or not the outcomes of R&D will actually be employed. Newly emerging technologies and competitors' initiatives may diminish the value of the outcomes. We assert that R&D should be viewed as the means for creating technology "options" that address the contingent needs of an enterprise (Rouse and Boff, 2001, 2003, 2004). The notion of options, which we formalize in the next section, implies that deployment of the outcome of R&D is contingent on the situation at hand when the decision to exercise an option must be made.

Another central issue relates to the preponderance of intangible outcomes for these types of investments. For example, investments in training may enhance leadership skills of managers or commanders. Investments in organizational development can improve the cohesiveness of "mental models" of management teams or command teams and enhance the shared nature of these models. However, it is difficult to capture fully such impacts in terms of tangible, "bottom-line" metrics.

It is important to differentiate between intangible outcomes and those that are tangible but difficult to translate into monetary benefits or costs. For example, an investment might decrease pollution, which is very tangible, but it may be difficult to translate this projected reduction to estimated economic gain. This is a mainstream issue in economics and not unique to cost/benefit analyses.

A further issue concerns cost/benefit analyses across multiple stakeholders. Most companies' stakeholders include customers, shareholders, employees, suppliers, and communities. Government agencies often have quite diverse sociopolitical constituencies who benefit—or stand to lose benefits—in a myriad of ways depending on investment decisions. For example, government-sponsored market research may be part of a regional economic development plan or may be part of a broader political agenda focused on creating jobs. In general, diverse constituencies are quite likely to attempt to influence decisions in a variety of ways. These situations raise many basic questions relative to the importance of benefits and costs for the different stakeholders.

Yet another issue concerns the difference between assessing cost/benefits and predicting cost/benefits. It is certainly valuable to know whether past investments were justified. However, it would be substantially more valuable to be able to predict whether anticipated investments will later provide benefits that justify the initial investments. Of course, limits of our abilities to predict outcomes are not unique to cost/benefit analysis.

The types of investment problems addressed in this chapter are rife with many uncertainties, intangibles, and stakeholders and associated unpredictability. These issues are explored in this chapter in the context of alternative frameworks for performing cost/benefit analyses. This leads to clear conclusions about how best to methodologically handle these types of investments. Application of the resulting methodology is then illustrated in the context of three investment problems involving technologies for aiding, training, and assuring the health and safety of personnel in military systems.

## 2 COST/BENEFIT FRAMEWORKS

There are a variety of frameworks for scrutinizing and justifying investments, including:

- *Cost/benefit analysis*: methods for estimating and evaluating time sequences of costs and benefits associated with alternative courses of action
- *Cost/effectiveness analysis*: methods for estimating and evaluating time sequences of costs and multiattribute benefits to assure that the greatest benefits accrue for given costs
- *Life-cycle costing*: methods for estimating and evaluating costs of acquisition, operation, and retirement of alternative solutions over their total life cycles

- *Affordability analysis*: methods for estimating and evaluating life-cycle costs compared to expected acquisition, operations, and maintenance budgets over the total life cycle of an alternative investments
- *Return-on-investment analysis*: methods for projecting the ratio, expressed as a percentage, of anticipated free cash flow to planned resource investments

This chapter focuses on cost/benefit in a broad sense that includes many aspects of the other approaches. For more traditional treatments of cost/benefit analysis, as well as worked examples, see Layard and Glaister (1994) and Gramlich (1997).

We should, at the outset, contrast approaches to analysis of investments with those for managing investments. R&D funnels, multistage decision processes, and so forth, are intended to assess progress and evaluate the attractiveness of continued investment. Reviews of these constructs can be found in Cooper et al. (1998b) and Rouse and Boff (2001).

Cost/benefit analyses are very straightforward when one considers fixed monetary investments made now to earn a known future stream of monetary returns over some time period. Things get much more complicated, however, when investments occur over time, some of which may be discretionary, and when returns are uncertain.

Further complications arise when one must consider multiple stakeholders' preferences regarding risks and rewards. Additional complexity is added when returns are indirect and intangible rather than purely monetary. These complications and complexity are more common than are situations where the straightforward cost/benefit analyses are applicable. This section discusses alternative frameworks for addressing cost/benefit analyses and compares these alternatives relative to their abilities to address the issues considered in the Introduction.

## 2.1 Traditional Economic Analysis

The time value of money is the central concept in this traditional approach. Resources invested now are worth more than the same amounts gained later. This is due to the costs of the investment capital that must be paid, or foregone, while waiting for subsequent returns on the investment. The time value of money is represented by discounting the cash flows produced by the investment to reflect the interest that would, in effect at least, have to be paid on the capital borrowed to finance the investment.

Equations (1)–(3) summarize the basic calculations of the discounted cash flow model. Given projections of costs, $c_i$, $i = 0, 1, \ldots, N$, and returns, $r_i$, $i = 0, 1, \ldots, N$, the calculations of net present value (NPV), internal rate of return (IRR), or cost/benefit ratio (CBR) are quite straightforward elements of financial management (Brigham and Gapenski, 1988). The only subtlety is choosing a discount rate, DR, to reflect the current

value of future returns decreasing as the time until those returns will be realized increases:

$$NPV = \sum_{i=0}^{N} \frac{r_i - c_i}{(1 + DR)^i} \tag{1}$$

$$IRR = DR \text{ such that } \sum_{i=0}^{N} \frac{r_i - c_i}{(1 + DR)^i} = 0 \tag{2}$$

$$CBR = \frac{\sum_{i=0}^{N} c_i/(1 + DR)^i}{\sum_{i=0}^{N} r_i/(1 + DR)^i} \tag{3}$$

It is quite possible for DR to change with time, possibly reflecting expected increases in interest rates in the future. Equations (1)–(3) must be modified appropriately for time-varying discount rates.

The metrics in equations (1)–(3) are interpreted as follows:

- NPV reflects the amount one should be willing to pay now for benefits received in the future. These future benefits are discounted by the interest paid now to receive these later benefits.
- IRR, in contrast, is the value of DR if NPV is zero. This metric enables comparing alternative investments by forcing the NPV of each investment to zero. Note that this assumes a fixed interest rate and reinvestment of intermediate returns at the internal rate of return.
- CBR simply reflects the discounted cash outflows divided by the discounted cash inflows, or benefits.

These types of metrics have been successfully applied to a variety of human systems integration investments in automotive, chemical, defense, and pharmaceutical industries (Rouse, 2010). The general conclusion is that, in situations where the investing entity is also the entity that receives the returns on the investment, there is often clear economic value of investing in people. In contrast, when the entity investing is not the entity receiving the returns, the tendency is to view such investments as operating costs and minimize them.

## 2.2 Multiattribute Utility Models

Cost/benefit calculations become more complicated when benefits are not readily transformable to economic terms. Benefits such as safety, quality of life, and aesthetic value are very difficult to translate into strictly monetary values. Multiattribute utility models provide a means for dealing with situations involving mixtures of economic and noneconomic attributes.

Let cost attribute $i$ at time $j$ be denoted by $c_{ij}$, $i = 1, 2, \ldots, L$ and $j = 0, 1, \ldots, N$, and benefit attribute $i$ and time $j$ be denoted by $b_{ij}$, $i = 1, 2, \ldots, M$ and $j = 0, 1, \ldots, N$. The values of these costs and benefits are

transformed to common utility scales using $u(\underline{c}_{ij})$ and $u(b_{ij})$. These utility functions serve as inputs to the overall utility calculation at time $j$ as shown in equation (4) (Keeney and Raiffa, 1976):

$$U(\underline{c}_j, \underline{b}_j) = U[u(c_{1j}), u(c_{2j}), \ldots, u(c_{Lj}),$$
$$u(b_{1j}), u(b_{2j}), \ldots, u(b_{Mj})] \qquad (4)$$

which provides the basis for an overall calculation across time using

$$U(\underline{C}, \underline{B}) = U[U(\underline{c}_1, \underline{b}_1), U(\underline{c}_2, \underline{b}_2), \ldots, U(\underline{c}_N, \underline{b}_N)]$$
$$(5)$$

Note that the time value of benefits depicted in equations (1)–(3) is included in equations (4) and (5) by dealing with the time value of costs and returns explicitly and separately from uncertainty.

An alternative approach involves assessing utility functions for discounted costs and benefits, possibly discounted as represented in equations (1)–(3). With this approach streams of costs and benefits are collapsed across time before the values are transformed to utility scales. The validity of this simpler approach depends on the extent to which people's preferences for discounted costs and benefits reflect their true preferences.

The mappings from $c_{ij}$ and $b_{ij}$ to $u(c_{ij})$ and $u(b_{ij})$, respectively, enable dealing with the subjectivity of preferences for noneconomic benefits. In other words, utility theory enables one to quantify and compare things that are often perceived as difficult to objectify. Unfortunately, models based on utility theory do not always reflect the ways in which human decision making actually works.

Subjective expected utility (SEU) theory reflects these human tendencies. Thus, to the extent that one accepts that perceptions are reality, one needs to consider the SEU point of view when one makes expected utility calculations. In fact, one should consider making these calculations using both objective and subjective probabilities to gain an understanding of the sensitivity of the results to perceptual differences.

Once one admits the subjective, one needs to address the issue of whose perceptions are considered. Most decisions involve multiple stakeholders—in other words, people who hold a stake in the outcome of a decision. It is, therefore, common for multiple stakeholders to influence a decision. Consequently, the cost/benefit calculation needs to take into account multiple sets of preferences. The result is a group utility model as shown in equation (6) (Keeney and Raiffa, 1976; Kirkwood, 1979):

$$U = U[U_1(\underline{C}, \underline{B}), U_2(\underline{C}, \underline{B}), \ldots, U_K(\underline{C}, \underline{B})] \qquad (6)$$

where K is the number of stakeholders.

Formulation of such a model requires that two important issues be resolved. First, mappings from attributes to utilities must enable comparisons across stakeholders. In other words, one has to assume that $u = 0.8$, for example, implies the same value gained or lost for all stakeholders, although the mapping from attribute to utility may vary for each stakeholder. Thus, all stakeholders may, for instance, have different needs or desires for safety and, hence, different utility functions. They also may have different time horizons within which they expect benefits—for example, stakeholders of different generations, some perhaps not yet born, have different time horizons within which they expect to receive benefits. However, once the mapping from attributes to utility is performed and utility metrics are determined, one has to assume that these metrics can be compared quantitatively.

The second important issue concerns the relative importance of stakeholders. Equation (6) implies that the overall utility attached to each stakeholder's utility can differ. For example, it is often the case that primary stakeholders' preferences receive more weight than the preferences of secondary stakeholders. The difficulty of this issue is obvious. Who decides? Is there a superstakeholder, for instance? Do the groups of stakeholders, or their representatives, simply vote on who gets how much weight? Such a procedure has its own theoretical problems that cannot be addressed here.

Beyond these two more-theoretical issues, there are substantial practical issues associated with determining the functional forms of $u(c_{ij})$ and $u(b_{ij})$ and the parameters within these functional relationships. This also is true for the higher level forms represented by equations (4)–(6). As the numbers of stakeholders ($K$), cost attributes ($L$), benefit attributes ($M$), and time periods ($N$) increase, these practical assessment problems can be quite daunting.

## 2.3 Option-Pricing Theory

Many investment decisions are not made all at once. Instead, initial investments are made to create the potential for possible future and usually larger investments involving much greater benefits than likely for the initial investments. For example, investments in R&D are often made to create the intellectual property and capabilities that will support or provide the opportunity to subsequently decide whether or not to invest in launching new products or services. These launch decisions are contingent on R&D reducing uncertainties and risks as well as further market information being gained in the interim between the R&D investment decision and possible launch decision. In this way, R&D investments amount to purchasing options to make future investments and earn subsequent returns. These options, of course, may or may not be exercised.

Amram and Kulatilaka (1999), Boer (1998, 1999), and Luehrman (1998) advocate using option-pricing theory to analyze investments involving such contingent downstream decisions. Option-pricing theory focuses on establishing the value of an option to make an investment decision in an uncertain environment at a later date. Developing option-based models begins with

consideration of the effects sought by the investment and the capabilities needed to provide these effects. In the private sector, desired effects are usually profits, perhaps expressed as earnings per share, and needed capabilities are typically competitive market offerings. Options can relate to which technologies are deployed and/or which market segments are targeted. Purchasing options may involve R&D investments, alliances, mergers, acquisitions, and so on. Exercising options involves deciding which technologies will be deployed in which markets and investing accordingly.

In the public sector, effects are usually couched in terms of provision of some public good such as defense. More specific effects might be expressed in terms of measures of surveillance and reconnaissance coverage, for instance. Capabilities would then be defined as alternative means for providing the desired effects. Options in this example might relate to technologies that could enable the capabilities for providing these effects. Attractive options would be those that could provide given effects at lower costs of development, acquisition, and/or operations.

Option-based valuations are economic valuations. Various financial projections are needed as input to option calculations. Projections needed include:

- Investment to "purchase" option, including timing
- Investment to "exercise" option, including timing
- Free cash flow—profits and/or cost savings—resulting from exercise
- Volatility of cash flow, typically expressed as a percentage

The analyses needed to create these projections are often substantial. For situations where cash flows are solely cost savings, it is particularly important to define credible baselines against which savings are estimated. Such baselines should be choices that would actually be made were the options of interest not available.

The models employed for option-based valuations were initially developed for valuation of financial instruments (Black and Scholes, 1973). For example, an option might provide the right to buy shares of stock at a predetermined price some time in the future. Valuation concerns what such an option is worth. This depends, obviously, on the likelihood that the stock price will be greater than the predetermined price associated with the option.

More specifically, the value of the option equals the discounted expected value of the stock at maturity, conditional on the stock price at maturity exceeding the exercise price, minus the discounted exercise price, all times the probability that, at maturity, the stock price is greater than the exercise price (Smithson, 1998). The net option value equals the option value calculated in this manner minus the cost of purchasing the option.

Thus, there are NPVs embedded in the determination of net option values. However, in addition, there is explicit representation of the fact that one will not exercise an option at maturity if the current market share price is less than or equal to the exercise price. As mentioned earlier, sources such as Amram and Kulatilaka (1999), Boer (1998, 1999), Luehrman (1998), Luenberger (1997), and Smithson (1998) provide a wealth of illustrations of how option values are calculated for a range of models.

It is important to note that the options addressed in this chapter are usually termed "real" options in the sense that the investments associated with these options are usually intended to create tangible assets rather than purely financial assets. Application of financially derived models to nonfinancial investments often raises the issue of the extent to which assumptions from financial markets are valid in the domains of nonfinancial investments. This concern is usually addressed with sensitivity analysis.

The assumptions underlying the option-pricing model and the estimates used as input data for the model are usually subject to much uncertainty. This uncertainty should be reflected in option valuations calculated. Therefore, what is needed is a probability distribution of valuations rather than solely a point estimate. This probability distribution can be generated using Monte Carlo simulation to systematically vary model and input variables using assumed distributions of parameter/data variations. The *Technology Investment Advisor* (Rouse et al., 2000) is an example of a tool available to support these types of sensitivity analyses.

These analyses enable consideration of options in terms of both returns and risks. Interesting "What if?" scenarios can be explored. A question that we have frequently encountered when performing these analyses is, "How bad can it get and have this decision still make sense?" This question reflects a desire to thoroughly understand the decision being entertained, not just get better numbers.

The option value resulting from the above formulation is totally premised on the assumption that waiting does not preempt deciding later. In other words, the assumption is that the decision to exercise an option cannot be preempted by somebody else deciding earlier. In typical situations where other actors (e.g., competitors) can affect possible returns, it is common to represent their impact in terms of changes of projected cash flows (Amram and Kulatilaka, 1999). In many cases, competitors acting first will decrease potential cash flows that will decrease the option value. It is often possible to construct alternative competitive scenarios and determine an optimal exercise date.

A central attraction of this model is the explicit recognition that the purpose of an investment now (i.e., purchasing an option) is to assure the option to make a subsequent investment later (i.e., exercise the option). Thus, for example, one invests in creating new technologies for the option of later incorporating these technologies in product and service lines. The significance of the contingent nature of this decision makes an option-pricing model a much better fit than a traditional discounted cash flow model.

Rouse (2010) includes several examples of human systems integration investments that were framed as real options and shown to have substantial economic value.

In several cases, the cash flow estimates needed for the option-pricing models reflected savings of downstream operating costs once systems were deployed.

However, not all long-term investment decisions have substantial contingent elements. For example, one may invest in training and development to later have the option of selecting among talented managers for elevation to executive positions. There are minimal investments associated with exercising such options—almost all of the investment occurs up front. Thus, option-pricing models are not useful for such decisions.

## 2.4 Knowledge Capital Approach

Tangible assets and financial assets usually yield returns that are important elements of a company's overall earnings. It is often the case, however, that earnings far exceed what might be expected from these "hard" assets. For example, companies in the software, biotechnology, and pharmaceutical industries typically have much higher earnings than companies with similar hard assets in the aerospace, appliance, and automobile industries, to name just a few. It can be argued that these higher earnings are due to, for example, greater knowledge capital among software companies. However, since knowledge capital does not appear on financial statements, it is very difficult to identify and, better yet, project knowledge earnings.

Mintz (1998) summarizes a method developed by Baruch Lev for estimating knowledge capital and earnings. This article in *CFO* drew sufficient attention to be discussed in *The Economist* (1999) and reviewed by Strassman (1999). In general, both reviews applauded the progress represented by Mintz's article but also noted the shortcomings of his proposed metrics.

The key, Mintz and Lev argue, is to partition earnings into knowledge earnings and hard asset earnings. Equation (7) accomplishes this by first projecting normalized annual earnings from an average of three past years and estimates for three future years using readily available information. Earnings from tangible and financial assets are calculated from reported asset values using industry averages of 7 and 4.5% for tangible and financial assets, respectively. Knowledge capital is then estimated by dividing knowledge earnings by a knowledge capital discount rate, as shown in equation (8). Based on an analysis of several knowledge-intensive industries, Mintz and Lev use 10.5% for this discount rate:

$$\text{Knowledge earnings} = \text{normalized annual earnings}$$
$$- \text{earnings from tangible assets}$$
$$- \text{earnings from financial assets} \quad (7)$$

$$\text{Knowledge capital} = \text{knowledge earnings}$$
$$/\text{knowledge capital discount rate} \quad (8)$$

Using this approach to calculate knowledge capital, Mintz compares 20 pharmaceutical companies to 27 chemical companies. He determines, for example, ratios of knowledge capital to book value of 2.45 for pharmaceutical companies and 1.42 for chemical companies.

Similarly, the market value–book value ratio is 8.85 for pharmaceutical companies and 3.53 for chemical companies. Considering this correlation between knowledge capital and market value, Strassman (1999) points out that Mintz's estimates do not fully explain the full excess of market values over book values.

The key issue within this overall approach is being able to partition earnings. While earnings from financial assets should be readily identifiable, the distinction between tangible and knowledge assets is problematic. Further, using industry average return rates to attribute earnings to tangible assets does not allow for the significant possibility of tangible assets having little or no earnings potential. Finally, of course, simply attributing all earnings "left over" to knowledge assets amounts to giving knowledge assets credit for everything that cannot be explained by traditional financial methods.

Nevertheless, the knowledge capital construct appears to have potential application to investments involving, for example, R&D or training and development. The purpose of these two types of investments seems to obviously be that of increasing knowledge capital. Further, companies that make investments for this purpose do seem to create more knowledge capital. The key for cost/benefit analyses is being able to project investment returns in terms of knowledge capital and, in turn, project earnings and separate these earnings into knowledge earnings and hard earnings. Further, one needs to be able to do this for specific investment opportunities, not just the company as a whole.

## 2.5 Comparison of Frameworks

Table 1 provides a comparison of the four frameworks just reviewed. It is important to note that this assessment is not really an apples-to-apples comparison. Multiattribute utility theory provides much more of a general framework than the other three approaches that emphasize financial metrics. Nevertheless, these four approaches represent the dominant alternatives.

Traditional economic analyses are clearly the most narrow. However, in situations where they apply, these analyses are powerful and useful. Most of the investment situations addressed in this chapter do not fit these narrow characteristics. For example, if R&D investments in human effectiveness are viewed within a traditional framework, with typical discount rates, no one would ever invest anything in such R&D. But people do make such investments and, thus, there must be more to it than just NPV, IRR, and CBR. [In fact, Cooper et al. (1998b) have found that companies relying solely on financial metrics for R&D investment decisions tend to be the poorest performers of R&D in terms of subsequent market success.]

One view is that R&D reduces uncertainty and buys time before committing very substantial resources to productization, process development, and so on. Option-pricing theory seems to be a natural extension of traditional methods to enable handling these complications. As noted earlier, several authors have advocated this approach for analyses of R&D investments, for example, Boer (1998, 1999) and Lint and Pennings (1998).

**Table 1  Comparison of Cost/Benefit Frameworks**

| Issue/Framework | Traditional Economic Analysis | Multiattribute Utility Models | Option-Pricing Theory | Knowledge Capital Approach |
|---|---|---|---|---|
| Representation of uncertainties | Focuses on expected revenues and costs without consideration of variances. | Probabilistic uncertainties and stakeholder preferences regarding uncertainties are central to models. | Volatility of returns is a central construct within this model. | Focuses on actual and expected earnings without consideration of variances. |
| Intangible vs. tangible outcomes | All outcomes must be converted to monetary units. | Preferences regarding intangible outcomes can be incorporated. | All outcomes must be converted to monetary units. | All outcomes must be converted to monetary units. |
| Multiple stakeholders in costs/benefits | One-dimensional nature of costs and benefits implies one stakeholder. | Formulations for multiple stakeholders are available and limitations are understood. | One-dimensional nature of costs and benefits implies one stakeholder. | One-dimensional nature of costs and benefits implies one stakeholder. |
| Assessing vs. projecting costs/benefits | Depends on abilities to project monetary costs and benefits. | Depends on abilities to project attributes of utility functions. | Depends on abilities to project monetary costs and benefits. | Difficult to project impact of particular investments. |

The knowledge capital approach provides another, less mathematical, way of capturing the impacts of R&D investments in human effectiveness. The difficulty of this approach, which is probably inherent to its origins in accounting and finance, is that it does not address the potential impacts of alternative investments. Instead, it serves to report the overall enterprise score after the game.

Multiattribute utility models can—in principle—address the full range of complications and complexity discussed thus far. Admittedly, the ability to create a rigorous multiattribute utility model depends on the availability of substantial amounts of information regarding stakeholders' preference spaces, probability density functions, and so on. However, in the absence of such information, a much more qualitative approach can be quite useful, as is discussed later in this chapter.

The value of the multiattribute utility approach also depends on being able to compare overall utilities of alternative investments that, in turn, depends on being able to compare different stakeholders' utilities of the alternatives. This ability to transform a complex, multidimensional comparison into a scalar comparison is laden with assumptions. The saving grace of the approach, in this regard, is that it makes these assumptions quite explicit and, hence, open to testing. This does not, of course, guarantee that they will be tested.

Expected utility calculations serve to show how one alternative is better than another, rather than providing absolute scores. Thus, differences of expected utilities among alternatives are usually more interesting than the absolute numbers. In fact, the dialog among stakeholders that is often associated with trying to understand the sources of expected utility differences can provide crucial insights into the true nature of differences among alternatives.

Overall, one must conclude that multiattribute utility models provide the most generalizable approach. This is supported by the fact that multiattribute

models can incorporate metrics such as NPV, option value, and knowledge capital as attributes within the overall model—indeed, the special case of one stakeholder, linear utility functions, and NPV as the sole attribute is equivalent to the traditional financial analysis. Different stakeholders' preferences for these metrics can then be assessed and appropriate weightings determined. Thus, use of multiattribute models does not preclude also taking advantage of the other approaches—the four approaches therefore can be viewed as complementary rather than competing. For these reasons, the multiattribute approach is carried forward in the remainder of this chapter.

## 3  COST/BENEFIT METHODOLOGY

Cost/benefit analysis should always be pursued in the context of particular decisions to be addressed. A valuable construct for facilitating an understanding of the context of an analysis is the value chain from investments to returns. More specifically, it is quite helpful to consider the value chain from investments (or costs), to products, to benefits, to stakeholders, to utility of benefits, to willingness to pay, and finally to returns on investments. This value chain can be depicted as:

| | | |
|---|---|---|
| investments (costs) | to | resulting products over time |
| products over time | to | benefits of products over time |
| benefits over time | to | range of stakeholders in benefits |
| range of stakeholders | to | utility of benefits to each stakeholder |
| utility to stakeholders | to | willingness to pay for utility gained |
| willingness to pay | to | returns to investors |

The process starts with investments that result—or will result—in particular products over time. Products need not be end products; they might be knowledge, skills, or technologies. These products yield benefits, also over time. A variety of people—or stakeholders—have a stake in these benefits. These benefits provide some level of utility to each stakeholder. The utility perceived—or anticipated—by each stakeholder affects their willingness to pay for these benefits. Their willingness to pay affects their "purchase" behaviors that result in returns for investors.

The central methodological question concerns how one can predict the inputs and outputs of each element of this value chain. This question is addressed elsewhere in some detail for R&D management (Rouse et al., 1997a; Rouse and Boff, 1998) and for human effectiveness (Rouse and Boff, 2003). Briefly, a variety of models have been developed for addressing this need for prediction. These models are very interesting and offer much potential. However, they suffer from a central shortcoming. With few exceptions, there is an almost overwhelming lack of data for estimating model parameters as well as a frequent lack of adequate input data. Use of data from baselines can help, but the validity of these baselines depends on new systems and products being very much like their predecessors. Overall, the paucity of data dictates development of a more qualitative methodology whose usefulness is not totally determined by availability of hard data. The remainder of this section outlines such a methodology.

As indicated in the earlier comparison of four frameworks for addressing cost/benefit analysis, the most broadly applicable of these alternatives are multiattribute utility models. The remainder of this section describes a seven-step methodology that includes the following steps:

- Identify stakeholders in alternative investments.
- Define benefits and costs of alternatives in terms of attributes.
- Determine utility functions for attributes (benefits and costs).
- Decide how utility functions should be combined across stakeholders.
- Assess parameters within utility models.
- Forecast levels of attributes (benefits and costs).
- Calculate expected utility of alternative investments.

It is important to note that this methodology is, by no means, novel and builds upon works by many others related to multiattribute analysis (e.g., Keeney and Raiffa, 1976; Sage, 1977; Hammond et al., 1998; Matheson and Matheson, 1998; Sage and Armstrong, 2000).

### 3.1 Step 1: Identify Stakeholders

The first step involves identifying the stakeholders who are of concern relative to the investments being entertained. Usually this includes all of the people in the value chain summarized earlier. This might include, for example, those who will provide the resources that will enable a solution, those who will create the solution, those who will implement the solution, and those who will benefit from the solution.

### 3.2 Step 2: Define Benefit and Cost Attributes

The next step involves defining the benefits and costs involved from the perspective of each stakeholder. These benefits and costs define the attributes of interest to the stakeholders. Usually, a hierarchy of benefits and costs emerges, with more abstract concepts at the top, for example, viability, acceptability, and validity (Rouse, 1991), and concrete measurable attributes at the bottom.

### 3.3 Step 3: Determine Stakeholders' Utility Functions

The value that stakeholders attach to these attributes are defined by stakeholders' utility functions. The utility functions enable mapping disparate benefits and costs to a common scale. A variety of techniques are available for assessing utility functions (Keeney and Raiffa, 1976).

### 3.4 Step 4: Determine Utility Functions Across Stakeholders

Next, one determines how utility functions should be combined across stakeholders. At the very least, this involves assigning relative weights to different stakeholders' utilities. Other considerations such as desires for parity can make the ways in which utilities are combined more complicated. For example, equation (5) may require interaction terms to assure all stakeholders gain some utility.

### 3.5 Step 5: Assess Parameters of Utility Functions

The next step focuses on assessing parameters within the utility models. For example, utility functions that include diminishing or accelerating increments of utility for each increment of benefit or cost involve rate parameters that must be estimated. As another instance, estimates of the weights for multistakeholder utility functions have to be estimated. Fortunately, there are a variety of standard methods for making such estimates.

### 3.6 Step 6: Forecast Levels of Attributes

With the cost/benefit model fully defined, one next must forecast levels of attributes or, in other words, benefits and costs. Thus, for each alternative investment, one must forecast the stream of benefits and costs that will result if this investment is made. Quite often, these forecasts involve probability density functions rather than point forecasts. Utility theory models can easily incorporate the impact of such uncertainties on stakeholders' risk aversions. On the other hand, information on probability density functions may not be available or may be prohibitively expensive. In these situations, beliefs of stakeholders and subject matter experts can be employed, perhaps coupled with sensitivity analysis (see step 7) to determine where additional data collection may be warranted.

### 3.7 Step 7: Calculate Expected Utilities

The final step involves calculating the expected utility of each alternative investment. These calculations are performed using specific forms of equations (4)–(6). This step also involves using sensitivity analysis to assess, for example, the extent to which the rank ordering of alternatives, by overall utility, changes as parameters and attribute levels of the model are varied.

### 3.8 Use of the Methodology

Some elements of the cost/benefit methodology just outlined are more difficult than others. The overall calculations are quite straightforward. The validity of the resulting numbers depends, of course, on stakeholders and attributes having been identified appropriately. It further depends on the quality of the inputs to the calculations.

These inputs include estimates of model parameters and forecasts of attribute levels. As indicated earlier, the quality of these estimates is often compromised by lack of available data. Perhaps the most difficult data collection problems relate to situations where the impacts of investments are both uncertain and very much delayed. In such situations, it is not clear which data should be collected and when they should be collected.

A recurring question concerns the importance that should be assigned to differences in expected utility results. If alternative $A$ yields $U(A) = 0.648$ and alternative $B$ yields $U(B) = 0.553$, is $A$ really that much better than $B$? In fact, are either utilities sufficiently great to justify an investment?

These questions are best addressed by considering past investments. For successful past investments, what would their expected utilities have been at the time of the investment decisions? Similarly, for unsuccessful past investments, what were their expected utilities at the time? Such comparisons often yield substantial insights.

Of course, the issue is not always $A$ versus $B$. Quite often the primary question concerns which alternatives belong in the portfolio of investments and which do not. Portfolio management is a fairly well-developed aspect of new product development (e.g., Cooper et al., 1998a; Gill et al., 1988). Well-known and recent books on R&D/technology strategy pay significant attention to portfolio selection and management (e.g., Roussel et al., 1991; Matheson and Matheson, 1998; Boer, 1999; Allen, 2000). In fact, the conceptual underpinnings of option-pricing theory are based on notions of market portfolios (Amram and Kulatilaka, 1999).

Most portfolio management methods rely on some scoring or ranking mechanism to decide which investments will be included in the portfolio. Expected utility is a quite reasonable approach to creating such scores or ranks. This is particularly useful if sensitivity analysis has been used to interactively explore the basis and validity of differences among alternatives.

A more sophisticated view of portfolio management considers interactions among alternatives in the sense that synergies between two alternatives may make both of them more attractive (Boer, 1999; Allen, 2000). Also, correlated risks between two alternatives may make both of them less attractive. A good portfolio has an appropriate balance of synergies and risks.

In principle, at least, the notions of portfolio synergy and risk can be handled within multiattribute utility models. This can be addressed by adding attributes that are characteristics of multiple rather than individual alternatives. In fact, such additional attributes might be used to characterize the whole portfolio. An important limitation of this approach is the likely significant increase in the complexity of the overall problem formulation. Indeed, this is an issue in general when multi-attribute utility models are elaborated to better represent problem complexities.

Beyond these technical issues, it is useful to consider how this cost/benefit methodology should affect decision making. To a very great extent, the purpose of this methodology is to get the right people to have the right types of discussions and debates on the right issues at the right time. If this happens, the value of people's insights from exploring the multiattribute model usually far outweighs the importance of any particular numbers.

The practical implications of this conclusion are quite simple. Very often, decision making happens within working groups who view computer-generated, large-screen displays of the investment problem formulation and results as they emerge. Such groups perform sensitivity analyses to determine the critical assumptions or attribute values that are causing some alternatives to be more highly rated or ranked than others. They use "What if ..?" analyses to explore new alternatives, especially hybrid alternatives.

This approach to investment decision making helps to substantially decrease the impact of limited data being available. Groups quickly determine which elements of the myriad of unknowns really matter—where more data are needed and where more data, regardless of results, would not affect decisions. A robust problem formulation that can be manipulated, redesigned, and tested for sanity provides a good way for decision-making groups to reach defensible conclusions with some level of confidence and comfort.

## 4  THREE EXAMPLES

Human effectiveness concerns enhancing people's direct performance (aiding), improving their potential to perform (training), and assuring their availability to perform (health and safety). These are central issues in human systems integration. Investments in human effectiveness also have the potential of increasing returns on other investments by, for example, enabling people to take full advantage of new technologies.

Three examples of aiding, training, and health and safety investments are discussed in this section: VCATS (aiding), DMT (training), and PTOX (health and safety). These examples focus on enhancing human effectiveness and human systems integration in military systems, particularly Air Force systems. The applicability of these technologies, and the relevance of the following analysis of the impacts of these technologies, to other military services and to nonmilitary problems should also be readily apparent.

## 4.1 Visually Coupled Targeting and Acquisition System

The Visually Coupled Targeting and Acquisition System (VCATS) provides aid to military aircraft pilots. VCATS includes a helmet-mounted tracker and display (HMT/D), associated signal-processing sensor/transducer hardware, interchangeable panoramic night vision goggle with head-up display (PNVG-HUD), and extensive upgrades to the aircraft's operational flight program software (Rastikis, 1998). VCATS enables the pilot to cue and be cued by on-board and off-board systems, sensors, and weapons as well as be spatially and temporally coupled with the control processes implemented with the HMT/D and PNVG-HUD. The system is particularly effective in helping pilots to cue weapons and sensors to targets, maintain "ownship" formation situation awareness, and avoid threats via provision of a real-time, three-dimensional portrayal of the pilots' tactical and global battlefield status. In general, VCATS enables pilots to acquire targets and threats faster. This results in improvements in terms of (1) how far, (2) how quickly, and (3) how long—for both initial contacts and countermeasures.

To a great extent, the case for advanced development has already been made for VCATS and current support is substantial. However, the transition from advanced development to production involves assuring that the options created by VCATS and validated by combat pilots are exercised. The case has also been argued for ongoing investments in basic research and exploratory development to assure that VCATS has future technology options, particularly for migration to multirole fighter aircraft. The maturity of the program should help in making this case in terms of benefits already demonstrated. However, in the current budget climate, there is also substantial risk that VCATS research may be viewed as essentially "done." This raises the potential for negative decisions regarding further investments.

## 4.2 Distributed Mission Training

Distributed mission training (DMT) involves aircraft, virtual simulators, and constructive models that, collectively, provide opportunities for military pilots to gain experiences deemed important to their performance proficiency relative to anticipated mission requirements (Andrews, 2000). The desired training experiences are determined from competencies identified as needed to fulfill mission requirements. These competency requirements are translated to training requirements stated in terms of types and durations of experiences deemed sufficient to gain competency.

The case to be made for DMT involves investments to address research issues and technology upgrades of near-term capabilities. The primary options-oriented argument is that investments in R&D in DMT will create contingent possibilities for cost savings in training due to reduced use of actual aircraft. More specifically, DMT options, if exercised, will provide cash flows of savings that justify the investments needed to field this family of technologies.

A much more subtle options-oriented argument concerns the training experiences provided by DMT that

could not otherwise be obtained. Clearly, the opportunity to have relevant training experiences must be better than not having these experiences. The option, therefore, relates to proficiency vs. possible lack of proficiency.

As straightforward as this may seem, it quickly encounters the difficulty of projecting mission impacts—and the value of these impacts—of not having proficient personnel. One possible approach to quantifying these benefits is to project the costs of using real aircraft to gain the desired proficiencies. While these costs are likely to be prohibitive, and thus never would be seriously considered, they nevertheless characterize the benefits of DMT.

## 4.3 Predictive Toxicology

Predictive toxicology (PTOX) is concerned with projecting the impacts on humans from exposure to operational chemicals (individual and mixtures). The impact can be characterized in terms of the possibility of performance decrement and consequent loss of force effectiveness, possible military and civilian casualties, and potential long-term health impacts. Also of concern are the impacts of countermeasures relative to sustaining immediate performance and minimizing long-term health impacts [Office of Science and Technology Policy (OSTP), 1998].

The case to be made involves investment in basic research and exploratory development programs, with longer term investment in an advanced development program to create deployable predictive toxicology capabilities. The requisite R&D involves developing and evaluating models for predicting performance and health impacts of operational chemicals. Advanced development will focus on field sensing and prediction, termed deployment toxicology. The nature of the necessary models is strongly affected by the real-time requirements imposed by deployment.

## 4.4 Applying the Methodology

The remainder of this section primarily addresses steps 1–4 of the cost/benefit methodology in the context of these three examples related to human effectiveness aspects of human systems integration. These steps constitute the "framing" steps of the methodology, rather than the "calculation" steps. Appropriate framing of cost/benefit analyses is critical to subsequent calculations being meaningful and useful.

### 4.4.1 Step 1: Identify Stakeholders

This step involves identifying people, usually types of people, and organizations that have a stake in costs and benefits. All three of the examples involve three classes of stakeholders: warfighters, developers, and the public. A key issue concerns the relative importance of these three types of stakeholders. Some would argue that warfighter preferences dominate decisions. Others recognize the strong role that developers, and their constituencies, play in procurement decisions. Yet another argument is that the dominating factor is value to the public, with the other stakeholders being secondary in importance.

Warfighters as stakeholders include military personnel in general, especially for PTOX. Warfighters of particular importance include aircraft pilots, personnel who support flight operations, and military commanders. Developers as stakeholders include companies and their constituencies, for example, stockholders, employees, and communities. Several agents, including Congress, the executive functions within the military services, and the military procurement establishment, represent the public's interests. Pilots and other military personnel are users of the technologies of interest, developers are the providers, and the public's agents are the customers for these technologies. There are obvious trade-offs across the interests of users, providers, and customers.

### 4.4.2 Step 2: Define Benefit and Cost Attributes

Benefits and costs tend to fall in general classes. Example benefits for military organizations and contractors include:

- Enhanced impact → increased lethality, survivability, and availability
- Enhanced operability → decreased response time and increased throughput
- Enhanced design → new techniques and larger pool of experienced people
- Increased opportunities → new tactics and countermeasures

Example cost attributes applicable to military procurement include:

- Investment costs → capital investments and R&D costs
- Recurring costs → operating and G&A costs
- Time costs → time from development to fielding to competent use
- Opportunity costs → other costs/benefits foregone

These general classes of benefits and costs can be translated into specific benefit and cost attributes for the three classes of stakeholders in VCATS, DMT, and PTOX. Benefits for warfighters (users) include enhanced performance (e.g., response time), confidence in performance, and health and safety in varying combinations for the three examples. Costs for these stakeholders include learning time and changing their ways of doing things to assure compatibility between new and legacy technologies.

Benefits for companies and their constituencies (providers) include R&D funds received, subsequent intellectual property created, and competitive advantages that result. Also important are jobs and economic impacts in the community. Direct costs include bid and proposal costs as well as opportunity costs. Less direct costs include, for instance, economic development resources and incentives provided to the companies by their communities.

The primary benefit sought by the public's agents (customer) is mission performance/dollar. It can easily be argued for all three examples that mission performance is increased. Unfortunately, it is difficult to attach a value to this increase. For example, what is the value of being able to generate 5% more sorties per time period? The answer depends on whether more sorties are needed.

Few would argue with the importance of successfully meeting mission requirements. However, if the types of innovations represented by these examples enable exceeding mission requirements, what are such increases worth? This is a politically sensitive question. If better performance is of substantive value, why wasn't this level of performance specified in the original requirements?

A good way to avoid this difficulty is to take mission requirements as a given and determine how much money could be saved in meeting these requirements by adopting the technologies in question. For example, could requirements be met with fewer aircraft, pilots, and support personnel? As shown in Table 2, the cost savings due to these decreases can be viewed as benefits of the technologies. It also might be possible for VCATS, DMT, or PTOX to enable meeting mission requirements with less-capable systems, rather than just fewer systems. This possibility provides substantial opportunities for increased benefits due to these technologies.

### Table 2  Public Benefits/Costs for Three Examples

|  | VCATS | DMT | PTOX |
|---|---|---|---|
| Benefits | Fewer aircraft and associated personnel to meet mission requirements due to better performance and fewer aircraft losses | Fewer aircraft and associated personnel to meet mission requirements due to better performance, fewer aircraft losses, and fewer aircraft for training | Fewer personnel to meet mission requirements and decreased medical costs due to fewer people affected by toxic materials, fewer people lost to toxic effects, fewer people to care for people affected, and decreased downstream medical costs |
| Costs | Initial investment (option price) for proposed R&D costs and later contingent investment (exercise price) for subsequent fielding of technology | Initial investment (option price) for proposed R&D costs and later contingent investment (exercise price) for subsequent fielding of technology | Initial investment (option price) for proposed R&D costs and later contingent investment (exercise price) for subsequent fielding of technology |

Note that this philosophy amounts to trying to provide a given level of defense for the least investment. Another approach might be to attempt to provide the most defense per investment dollar. However, this immediately begs the question of how much defense is enough. Unlike the business world where value is defined by the marketplace and, hence, can provide a basis for optimization [see Nevins and Winner (1999) for a good example], there is no widely agreed-upon approach to measuring military value and optimizing accordingly.

The rationale for the benefits indicated in Table 2 for each of the three examples include:

- VCATS enables pilots to compete with threats, increase the number of wins versus losses, and counter threats (e.g., missiles) in ways that they could not do otherwise. Consequently, it must be possible to meet *fixed* mission requirements with fewer aircraft and associated infrastructure. These benefits can be translated into financial returns in terms of cost avoidance.

- DMT provides opportunities to practice behaviors that would not otherwise be practiced, for the most part due to the costs of practice. This decreases the probability of not performing acceptably given inadequate training. DMT also provides training experiences that would not otherwise be possible. For example, in the DMT environment, pilot "kills" actually disappear. In contrast, field exercises often "reuse" kills because of the costs of getting adversaries into the exercise in the first place.

- PTOX enables larger proportions of deployed forces to be fully functional, be less dependent on medical surveillance or medication, and have earlier intervention, before the onset of problems. In principle, this should enable reducing the size of the deployed force, which is critical for increasingly likely expeditionary military missions (Fuchs et al., 1997).

- PTOX also provides cost avoidance due to downstream health impacts. The ability to predict the "body burden" of toxicity during deployment should enable removing personnel from risk once the burden is approaching predetermined limits. These capabilities are likely to also be very important for nonmilitary operations such as disaster clean-up.

It is *not* essential that the savings indicated in Table 2 actually occur. For example, it may be that the number of aircraft is not decreased, perhaps due to factors far beyond the scope of these analyses. However, one can nevertheless attribute to these technologies the benefits of having provided opportunities to meet mission requirements in less costly manners. Technologies that provide such opportunities are valuable; the extent of this value is the extent of the opportunities for savings.

This argument puts all three examples on common ground. The benefits of all alternative technologies can be expressed as reduced costs to meet requirements. From an options-pricing perspective, these savings can be viewed as free cash flow returned on investments in these technologies. The "option price" is the R&D costs. The "exercise price" is the subsequent costs of fielding the technologies. Thus, assuming costs savings can be projected (albeit with substantial volatility), the option values of investing in these technologies can be calculated.

### 4.4.3 Step 3: Determine Stakeholders' Utility Functions

Different stakeholders' preferences over the benefit and cost attributes will vary substantially with specific situations. However, there is a small family of functional relationships that captures most, if not all, expressed preferences (Keeney and Raiffa, 1976). Thus, while context-specific tailoring is needed, it can be performed within a prescribed (and preprogrammed) set of functions, both within and across stakeholders. Similarly, alternative parameter choices can be prescribed in terms of choices of weightings.

An important aspect of cost/benefit analyses, as advocated in this chapter, is the likely nonlinear nature of utility functions. In particular, diminishing returns and aspiration levels tend to be central to stakeholders' "preference spaces." In other words, while linear functions imply that incremental increases (or decreases) of attributes always yield the same incremental changes in utility, nonlinear functions lead to shifting preferences as attributes increase (or decrease). Figure 1 portrays a range of example utility functions.

To illustrate how these types of relationships can be employed to represent the preferences of users, providers, and customers, the general forms of each type of stakeholder's utility function are shown in equations (9)–(11):

$$U_{\text{user}} = U[u(\text{performance}), u(\text{confidence}),$$
$$u(\text{cost of change})] \tag{9}$$

$$U_{\text{provider}} = U[u(\text{resources}), u(\text{advantage}),$$
$$u(\text{cost of pursuit})] \tag{10}$$

$$U_{\text{customer}} = u(\text{option value}) \tag{11}$$

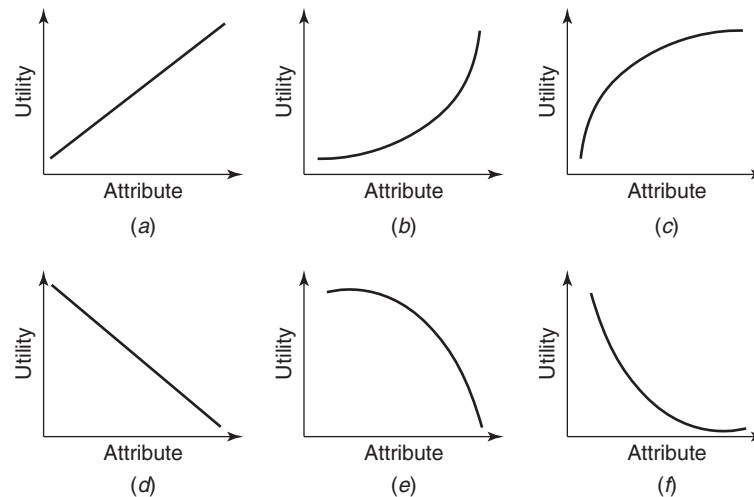
where, as noted earlier, users are primarily concerned about impacts of investments on their performance, their confidence in their performance, and the costs of changing their ways of performing; providers are concerned with the investment resources supplied to develop the technologies in question, the competitive advantages created by the intellectual property created, and the costs of pursuing the investment opportunities; and, finally, customers are focused on the financial attractiveness of the investments as reflected in the option values of the alternatives which are based on projected cash flows (i.e., costs savings), volatility of cash flows, magnitudes of investments required, and time periods until returns are realized.


**Figure 1**  Example utility functions: (*a*, *d*) inear relationships; (*b*, *e*) accelerating relationships; (*c*, *f*) diminishing relationships.

Considering the elements of equations (9)–(11), the appropriate functional forms from Figure 1 are likely to be as follows:

- *u*(performance) is an accelerating returns function (Figure 1*b*):
  - VCATS is least concave since relatively modest performance improvements are of substantial utility
  - DMT is moderately concave since training on otherwise untrained tasks must produce substantial improvements to yield high utility
  - PTOX is most concave since major decreases in performance risk are needed to assure high utility increases of personnel availability
- *u*(confidence) is a linear function (Figure 1*a*) since greater confidence is always better, but there are unlikely to be significant thresholds
- *u*(cost of change) is an accelerating decline function (Figure 1*f*) since low to moderate costs are easily sustained while larger costs present difficulties
- *u*(resources) is an accelerating returns function (Figure 1*b*) since moderate to large resources are needed to make opportunities attractive
- *u*(advantage) is a linear function (Figure 1*a*) since greater advantage is always better, but there are unlikely to be significant thresholds
- *u*(cost of pursuit) is an accelerating decline (Figure 1*f*) since low to moderate costs are easily sustained while larger costs present difficulties
- *u*(option value) is a linear function (Figure 1*a*) since customers will inherently gain the expected value across a large number of investments

It is important to note the importance of this last assumption. If customers', that is, the public's, utility function were not linear, it would be necessary to

entertain assessing the specific form of their function. Unlike users and providers, the public is not so easily identified and interviewed.

With the identification of the stakeholders (step 1) and framing of the cost/benefit attributes (step 2), the process of determining the form of stakeholders' utility functions (step 3) can draw upon considerable standard "machinery" of decision analysis. The specific versions of the functional forms discussed above are likely to vary with VCATS, DMT, and PTOX. However, the overall formulation chosen is quite general.

### 4.4.4  Step 4: Determine Utility Functions Across Stakeholders

Another important aspect of the utility functions is their typical lack of alignment across stakeholders. Specifically, either different stakeholders care about different things or possibly they care about the same things in different ways. For example, customers may be very price sensitive while users, who seldom pay prices themselves, are usually much more concerned with impacts on their job performance.

For the types of investment problems considered in this chapter, preferences typically differ across time horizons and across people with vested interests in different investment opportunities. Thus far in the formulation of the three examples, the stakeholders do not have attributes in common. However, they are nevertheless likely to have competing preferences since, for example, the alternative providing the greatest performance impact may not have the largest option value.

Differing preferences across stakeholders are often driving forces in pursuing cost/benefit analyses. These differing preferences can be aggregated, and traded off, by formulating a composite utility function such as

$$U = U\left[U_{\text{user}}, U_{\text{provider}}, U_{\text{customer}}\right] \qquad (12)$$

Often equation (12) will be linear in form with weights assigned to component utility functions to reflect the relative importance of stakeholders. Slightly more complicated are multi-linear forms which include products of component functions, for example, $U_{user} \times U_{customer}$. Multilinear formulations tend to assure that all stakeholders gain nonzero utility because, otherwise, zero in either term in a product yields zero overall.

Considering trade-offs across stakeholders, it is important to note that the formulation of the analysis can often be usefully expanded to include a broader set of stakeholders. These additional stakeholders may include other entities that will benefit by advances of the technologies in question, although they may have little or no stake in the immediate application for the technology. It is also quite possible that stakeholders such as "the public" have multiple interests, for example, military effectiveness and public safety from toxic risks.

Broadening the analysis in this way is likely to have differing impacts on the assessment for the three examples due to the natures of the technologies and issues being pursued. The three examples differ in this regard in the following ways:

- VCATS addresses a rather esoteric set of issues from the public's perspective.
- DMT addresses an issue with broad general support from the public, but narrower specific constituencies.
- PTOX addresses strong cross-cutting health and safety issues of substantial concern to the public.

These differences suggest that PTOX would gain a larger $\Delta U$ than DMT, and DMT would in turn gain a larger $\Delta U$ than VCATS, by broadening the number of stakeholders and issues. Quite simply, the "spin-off" benefits of PTOX are likely to be perceived as much greater by a larger number of stakeholders.

However, if the formulation is further broadened to consider the likelihood that the desired technologies will emerge elsewhere if investments are not made in these efforts, the $\Delta U$ impacts are likely be the opposite. PTOX research and development are being pursued by several agencies. DMT has broad applicability for both military and nonmilitary applications and consequently is being pursued by other parties. VCATS, in contrast, is highly specialized and is unlikely to emerge from other sources.

These two possibilities for broadening the formulation, in terms of stakeholders and issues, clearly illustrate the substantial impact of the way in which cost/benefit assessments are framed. If the framing is too focused, important spin-off benefits may not be included. On the other hand, framing the analysis too broadly may raise issues that are difficult to quantify, even roughly, and include stakeholders whose preferences are difficult to assess. Of course, many modeling efforts face such difficulties (Sage and Rouse, 1999).

### 4.4.5  Steps 5–7: Calculation of Overall Cost/Benefit

The remaining steps of the cost/benefit methodology involve assessing parameters of utility functions, forecasting levels of attributes, and calculating expected utilities. Performing these steps obviously depends on having data on stakeholders' preferences and projected/targeted attribute levels. Discussion of such data is well beyond the scope of this chapter—and, in light of the nature of the examples, it would be difficult to publish the requisite data.

The needed data can, in many instances, be quite difficult to compile. It can be particularly difficult to relate returns on human effectiveness investments to organizational impacts. Relationships between human and organizational performance are needed. These relationships should answer the following types of questions:

- How do improvements in human performance (e.g., via aiding) translate to increased organizational impacts? Specifically, how does a 2-second improvement in pilot response time due to VCATS affect mission performance?
- How do improvements in human potential to perform (e.g., via training) translate to actual performance and consequent increased organizational impacts? Specifically, how does increased practice via DMT impact subsequent performance and, in turn, translate to improved mission performance?
- How do improvements in human availability to perform (e.g., via health and safety) translate to actual performance and consequent increased organizational impacts? Specifically, how does prevention of toxic exposure, due to PTOX, affect immediate unit performance and thereby affect mission performance?

These can be difficult questions. However, they are not inherently cost/benefit questions. Instead, they are fundamental system design questions (Sage and Rouse, 1999). If answers are possible, then cost/benefit analyses are more straightforward.

For the VCATS, DMT, and PTOX examples, it may be possible to translate human performance improvements to organizational impacts via mission models. Such models are typically used to determine, for example, the "logistics footprint" needed to support a targeted sortie generation rate or, as another illustration, the combat wins and losses likely with competing defensive measures and countermeasures. Such models can be applied, perhaps with extensions, to project the impacts of faster responses due to VCATS, improved task performance due to DMT, and increased personnel availability due to PTOX.

It is important to note, however, that even if such projections are not available, the multiattribute methodology presented here can still be employed. However, the validity of cost/benefit assessments and predictions will then depend upon subjective perceptions of attribute levels and the relative importance of attributes. Any limitations of this more subjective approach reflect underlying limitations of knowledge rather than inherent limitations of the methodology.

Once $U[U_{\text{user}}, U_{\text{provider}}, U_{\text{customer}}]$ is fully specified, both functionally and in terms of parameters of these functions, one is in a position to project attribute levels (e.g., option values), calculate the expected utility of the alternative investments (e.g., VCATS, DMT, and PTOX), and perform sensitivity analyses. This provides the basis for making investment decisions. There are several ways that these cost/benefit assessments can be used to inform decision making.

The most common way of using expected utility cost/benefit assessments is to rank order alternative investments in terms of decreasing $U[U_{\text{user}}, U_{\text{provider}}, U_{\text{customer}}]$ and then allocate investment resources from highest ranked to lowest ranked until resources are exhausted. This approach allows the possibility of alternatives with mediocre $U_{\text{customer}}$ making the cut by having substantial $U_{\text{user}}$ and $U_{\text{provider}}$. To avoid this possibility, one can rank order by $U[U_{\text{user}}, U_{\text{provider}}, U_{\text{customer}}]$ all alternatives with $U_{\text{customer}} > U_{\text{co}}$, which implies a minimum acceptable option value.

If resources are relatively unconstrained, one can, invest in all alternatives for which $U_{\text{user}} > U_{\text{uo}}$, $U_{\text{provider}} > U_{\text{po}}$, and $U_{\text{customer}} > U_{\text{co}}$. This reflects situations where all stakeholders prefer investment to no investment. Of course, one can also rank order these alternatives by $U[U_{\text{user}}, U_{\text{provider}}, U_{\text{customer}}]$ to determine priorities for investment. However, if resources are truly unconstrained, this rank ordering will not change the resulting investment decisions.

### 4.5 Summary

The three examples discussed in this section have portrayed a cross section of human effectiveness investments to enhance human systems integration, ranging from aiding to training to health and safety investments. The discussion has shown how this range of investment alternatives can be fully addressed with an overarching multiattribute utility, multistakeholder cost/benefit formulation. The stakeholder classes of user, provider, and customer are broadly applicable. The classes of attributes discussed also have broad applicability.

These examples have also served to illustrate the merits of a hybrid approach. In particular, option value theory has been used to define the issue of primary interest to customers, assuring that investments make financial sense, and this issue has then been incorporated into the overall multiattribute formulation. This enabled including in the formulation a substantial degree of objective rigor as well as important subjective attributes and perceptions. As a result, rigor is not sacrificed but instead is balanced with broader, less quantifiable considerations.

It is useful to note that the knowledge capital construct was not employed in the formulation for these three examples, despite the intuitive appeal of the notion that investments in human effectiveness increase knowledge capital (Davenport, 1999). While the formulation reported here could have included increases of knowledge capital as possible benefits, there is no basis for predicting such impacts. Subjective estimates could, of course, be employed. However, this construct is not defined with sufficient crispness to expect reliable estimates from subject matter experts.

The discussion of these examples of human effectiveness investments has served to illustrate the value of an overall cost/benefit formulation. The generality of this formulation allows it to be applied to analyses of a wide variety of human system integration investment decisions. The types of information needed to support such analyses are defined by this formulation. While the availability of information remains a potential difficulty, this formulation nevertheless substantially ameliorates the typical problems of comparing ad hoc analyses of competing investments. Also of great importance, this formulation enables cross-stakeholder comparisons and trade-offs that, for the lack of a suitable methodology, are usually ignored or resolved in ad hoc manners.

## 5  CONCLUSIONS

It is difficult to make the case for long-term investments that will provide highly uncertain and intangible returns. This chapter has reviewed alternative ways to characterize such investments and presented an overall methodology that incorporates many of the advantages of these alternatives. This methodology has been illustrated in the context of R&D investments in human effectiveness aspects of human systems integration.

Central to the cost/benefit analysis methodology presented is a multiattribute, multistakeholder formulation. This formulation includes nonlinear preference spaces that are not necessarily aligned across stakeholders. The nonlinearities and lack of alignment provide ample opportunities for interesting trade-offs.

It is important to stress the applicability of this methodology to nearer term human effectiveness investments, which may or may not involve R&D. While the time frame will certainly affect choices of attributes—for instance, option values may not be meaningful for near-term investments—the overall cost/benefit methodology remains unchanged. This chapter focused on long-term R&D investments because such analyses are the most difficult to frame and perform.

It is also useful to indicate that cost/benefit analysis, as broadly conceptualized in this chapter, can be a central element in assessment activities related to life-cycle costing (e.g., affordability) and program/contract management [e.g., earned value management (EVM, 2000)]. For the former, attributes reflecting life-cycle costs can easily be incorporated. For the latter, costs and benefits can be tracked and compared to original projections. This does, of course, require that benefits be attributable to ongoing processes and not just outcomes.

This cost/benefit methodology, when coupled with appropriate methods and tools for predicting attribute levels (Sage and Rouse, 1999), can enable cost/benefit predictions and, thereby, support investment decision making. Using attributes such as option values and potentially knowledge capital can make it possible to translate the intuitive appeal of R&D and human

effectiveness investments into more tangible measures of value.

Note also that the methodology includes many of the elements necessary to developing a business case for human effectiveness investments. Markets (stakeholders), revenues (benefits), and costs are central issues in business case development and in this methodology. However, this methodology also supports valuation of investments with broader constituencies (e.g., the public) and ranges of issues (e.g., jobs created) than typically considered in business cases.

Finally, we have also found that use of the methodology presented here provides indirect advantages in terms of causing decision-making groups to clarify and challenge underlying assumptions. This helps decision makers avoid being trapped by common delusions which could mislead them relative to likely cost/benefits (Rouse, 1998).

## 1 INTRODUCTION

An underlying goal of all human factors research is to produce research that is compelling and meaningful. Meister (2004) suggests that this is accomplished in part by selecting appropriate research objectives and through careful experimental design. In Chapter 11, designing an experiment to collect reliable, valid data relevant to examining the identified research objectives was discussed. In this chapter we focus on another aspect of sound experimental design: selecting appropriate measures and outcomes to collect during an experiment and selecting appropriate methods of analyzing the experimental outcomes and drawing conclusions from them.

As demonstrated in this chapter, selecting the appropriate data outcomes to collect and the appropriate methods of analyzing the outcomes go hand in hand.

Certain characteristics of the data collected, such as the measurement type, drive which evaluation methods may be used to analyze the data, which in turn influence the types of conclusions that can be drawn from the results of that analysis. Other characteristics of the data, such as level of objectivity and specificity, affect the conclusions that can be made from the analysis and how or where those conclusions can be applied.

To help human factors researchers select the appropriate data outcomes and analysis methods for their research, we define characteristics of various outcome data and describe analysis and evaluation methods frequently used to analyze those outcomes. We begin by characterizing outcomes along a number of dimensions and discussing the implications these characteristics have on selecting both appropriate outcome measures

and appropriate evaluation method(s). Next, a variety of methods of evaluating both structured and unstructured outcome data are described. For structured data, statistical analysis methods frequently used in human factors are presented. For each method, the purpose, assumptions, methods, and results are described as well as guidelines for interpreting the results and drawing conclusions. Next, several methods of analyzing unstructured data, such as content analysis, are presented. The chapter concludes with an example of applying methods of analyzing structured and unstructured data to the analysis of survey data. Applying this knowledge of outcome characteristics and evaluation methods should enable human factors researchers to produce research outcomes and conclusions that provide compelling and meaningful insight into the field of human factors.

## 2   TYPES OF OUTCOMES

The types of outcome data that are produced in human factors research are as varied as the humans they strive to measure and analyze. To choose the appropriate data to collect to support the research objectives, we must first understand the nature and characteristics of the data. Outcome data and measures can be classified along a variety of dimensions. The dimensions most relevant to selecting appropriate outcomes and analysis methods are (1) level of structure, (2) level of objectivity, (3) specificity, (4) measurement type, and (5) multiplicity.

### 2.1   Level of Structure

In the dictionary (Merriam-Webster, 2010), *structure* is defined as "something arranged in a definite pattern of organization." Depending on the research methods used, the resulting data may be structured, unstructured, or a combination of the two. The level of structure is one of the most significant factors driving the methods appropriate for analyzing your data.

Based on this definition of structure, *unstructured data* are not arranged in a definite pattern. Unstructured data include descriptions, observation notes, answers to open-ended questions, video and audio recordings, and pictures. Field studies typically generate large amounts of detailed data that reflect the richness of the work being observed (Wixon, 1995). In a literature review, Kujala (2003) found that the authors of research papers involving field studies felt that the data gathered were invaluable and helped them in understanding the customer/user's needs, and the participants responses were positive. Field studies usually obtain unstructured data in the form of notes on observed actions and recordings of observed activities. Whereas the unstructured, or qualitative, data resulting from these observations contain invaluable detail on the activity being observed, the raw, unstructured data generally use more subjective methods of analyzing outcomes. Additionally, because unstructured data are so rich in detail, it can be more difficult to present findings clearly with this type of data. Because of their disadvantages, researchers often use unstructured data to produce structured data, as in the case of coding or classifying types of activities observed, or create figures and tables to summarize and communicate

the details in a more structured manner. These methods of analyzing unstructured data are addressed in more detail in Section 5.

*Structured data*, conversely, have a definite pattern in the way they are collected and stored. For example, consider a survey that asks: What factor is most important to reducing errors? If the question were open ended, the answer would be unstructured, since the subject could write in anything that comes to mind. On the other hand, if the question were multiple choice, the answer would have structure since all participants would have to choose from a limited number of available choices. Structured data typically lend themselves to quantification and are often referred to as *quantitative data*. Other examples of structured data include category classifications, rating scales, counts of events, and times/durations. When the data are structured, a wider range of analysis methods are available for evaluating the outcomes. In the case of structured data, the data items are sometimes also referred to as *measures*.

### 2.2   Level of Objectivity

*Objectivity* is "expressing or dealing with facts or conditions as perceived without distortion by personal feelings, prejudices, or interpretations" (Merriam-Webster, 2010). When it comes to human factors outcomes, the level of objectivity is a continuum with objective and subjective at either extreme and considerable gray area in between. At one end of the spectrum we have *objective data*, which are recorded "without the aid or expression of the subject whose performance is being recorded" (Meister, 2004, p. 81). For purely objective data, task performance is recorded manually or automatically, with minimal human involvement in the measurement. For example, time to complete a task, missed targets, height, and other physical measures are objective. *Subjective data*, on the other hand, are based on the subject or experimenter's opinions, values, and interpretations. Subjective measures rely on human perception, cognition, judgment, and experience (Wickens et al., 2003). Examples of subjective measures include responses from interviews/questionnaires, verbal reports of activities or thought processes, self-ratings, and other personal judgments. To illustrate the continuum of objectivity, consider verbal reports collected during an experiment. The validity of verbally reported thought sequences depends on the time interval between the occurrence of a thought and the verbal report, where the highest validity is seen in concurrent, think-aloud verbalizations and the lowest is retrospective reports where participants create inferential biases in the reported information (Ericsson, 2006).

So which is better, objective or subjective? The answer, of course, depends on the research objectives. Although the level of objectivity has little effect on which methods may be used to analyze the data, it has a great effect on the validity and the generalizability of the research and the conclusions that can be drawn from the research. In human factors, the subjects' subjective opinion of their performance, confidence, or workload is sometimes of as much or more interest than their objective performance on the task. In many cases, it is

useful for human factors researchers to collect *both* subjective and objective measures. If the results of both the objective and subjective measures support a particular conclusion, there is greater confidence in the validity of that conclusion. Therefore, when selecting outcome measures, researchers should consider whether objective measures, subjective measures, or a combination are best suited to supporting their research objectives and the conclusions they hope to draw from their research.

### 2.2.1 Preference-Based Measures

Within the set of subjective measures is a subset of measures, referred to as preference-based measures, which indicate a subject's likes or dislikes based on his or her experience and values. Survey questions that ask what a subject likes, prefers, or values or that ask the subject to rate value or importance of items are examples of preference-based measures. Similarly, comparisons and choices among options presented to subjects also capture preferences.

These measures are worth distinguishing from other subjective measures because they are notoriously difficult to measure reliably. This is caused in part by the nature of values and preferences and the uncertainty present in applying values to different sets of options and choices. People tend not to know their preferences in an unfamiliar situation, especially those with lasting consequences, and even when they are known, those preferences tend to be labile (Fischhoff et al., 1988). Often, preferences are "constructed" as people learn about or experience options. When preferences are known, they are extremely difficult to measure. Research has shown that people tend to construct their preferences during the process of elicitation and the method used to elicit their preferences can affect their final expressed preferences (Slovic, 1995). For example, studies in health care have shown that the use of different methods of eliciting preferences (Chapman and Elstein, 2000), physician's explanations of treatment alternatives (Mazur and Hickam, 1994), and framing of information about alternatives (positive, negative, or neutral) (Llewellyn-Thomas et al., 1995) affected patients' stated treatment preferences. Additional research has furthermore demonstrated that almost half of health care patients have dominant preferences when faced with discrete choices and that both past experiences and the complexity of the decision task influenced their dominant preferences (Scott, 2002). Therefore, when preference-based subjective measures are of interest, special care should be taken during experimental design to ensure the validity of these measures. The researcher must take steps to ensure that the way the preference-based measures are collected does not bias the results.

### 2.3 Specificity

Specificity indicates whether a measure refers to a particular task, industry, or situation, as opposed to being applicable to a variety of areas. Again, this characteristic is a continuum ranging from specific to generic. *Specific measures* are tailored to measuring a phenomenon of interest but have little generalizability to other phenomena. At the other end of the scale, *generic measures* are generalizable to a variety of tasks or situations. However, it can be quite difficult to define generic measures that are sensitive enough to capture the phenomenon of interest in a variety of situations that may be quite different. For example, in human–computer interaction (HCI), target highlight time (THT) is a measure used to quantify the salience of feedback received from the interface as the user completes a drag-and-drop task. THT, a specific measure for drag-and-drop tasks, is much more sensitive than total task time to measuring reaction time to feedback because task time is strongly affected by a number of other factors. Task time is a generic measure, and although it is less sensitive in this case, it has the advantage of being generalizable to other computer tasks. So task time could be used to compare drag-and-drop performance to performance on a different computer task, such as point and click.

Another example relates to measuring health outcomes resulting from various treatments. A generic measure would capture a range of health status dimensions (e.g., physical function, mental health, social function). On the other hand, a disease-specific measure will zoom in on specific symptoms and implications related to a disease of interest (e.g., lower back pain).

The specificity of a measure affects the conclusions drawn from the data. If very specific measures are used, the results may not generalize to a broad enough range of situations, thereby limiting the scope and applicability of the conclusions. Conversely, if the measures are too broad, they may not be sensitive enough to detect the phenomenon of interest through the statistical analysis methods used. Therefore, it is crucial to reconcile the specificity of the measures with the research objectives as the study measures are chosen. In some cases, researchers choose to collect a combination of specific and generic measures. In selecting generic measures, it is recommended that researchers look at industry standard metrics and measures used in related research to enable comparability across studies.

### 2.4 Measurement Type

In structured data, the measurement type determines to a large degree the statistical methods that may be used to analyze the data. The measurement type indicates the amount of information the measure contains with respect to the value being measured (Sheskin, 2007). The four measurement types, in order from least to greatest information provided, are nominal/categorical, ordinal/rank order, interval, and ratio. These categories are defined as follows (Sheskin, 2007; Argyrous, 2000):

1. *Nominal/categorical*: indicates the category to which an item belongs. The category may be represented as a number or text, but even if the category is represented as a number, it cannot be manipulated mathematically in a meaningful way. In human factors, nominal data would include gender, race, and part number. For each of these measures, it is not possible to add or rank order them, since the name/number is used solely for identification purposes.

2. *Ordinal/rank order*: indicates rank orders using numbers but does not provide information on the magnitude of difference between two ranks. An example of ordinal data from human factors is participant rankings of the preferred tool or method. If the participant is asked to rank three proposed tools, from the one they prefer most to the one they prefer least, those rankings (1–3) do not indicate if the participant strongly prefers the first ranked system to the second or only slightly prefers the first to the second.

3. *Interval*: indicates both order and magnitude of difference between values by providing a number along a scale that has intervals of equal distance between equal values on the scale. This means that a difference of 10 between two values represents the same magnitude of change regardless of whether the initial value was small or large. However, interval scales arbitrarily assign a zero score rather than having a true zero. For example, consider a question that asks participants to rate on a scale from 1 to 10 how hard they had to work physically to complete a task. A one-point increase in "work" is the same one-point increase in work whether the initial rating is 3 or 7. However, there is no true measurement of zero work; 1 on the scale was selected arbitrarily to represent an extremely low workload.

4. *Ratio*: like interval measures, provides a number along a scale that indicates both order and magnitude of difference between values. Unlike interval measures, however, ratio measures have a true zero point. Because there is a true zero point, it is possible to compare scores by taking their ratios. For example, age has a true zero point, so one can meaningfully say that a person who is 40 is twice as old as someone who is 20. In contrast, it is not appropriate to compare ratios of work in the previous example. Since the true zero point for work is unknown, saying that a task with a work rating of 10 is twice as much work as a task with work rating of 5 is inaccurate.

The measurement type has an enormous influence on the methods that can be used to analyze the data. Table 1 indicates which type of analysis is appropriate for each measurement type. Several of these analysis methods are discussed in further detail in Section 4.

## 2.5 Dimensionality

Another important characteristic of structured outcome data is the degree of dimensionality. Some outcomes can be captured directly with one overall measure (e.g., the time required to perform a given task, or how one person feels about his or her own health at a point in time as measured by a global five-point Likert scale with five possible answers: excellent, very good, good, fair, or poor). However, many outcomes need to be captured through a number of dimensions. In the case of multiple dimensions, a complex measurement task often then consists of appropriately aggregating the various dimensions into one overall quantitative measure of the outcome of interest. For example, although performance on a job clearly contains many different aspects, one may wish to combine the performance on different aspects into an overall assessment of global performance. To represent overall performance adequately, one needs to understand the potential relationships between the various elements.

Many scales are constructed based on different items and thus appear to be inherently multidimensional. However, it is important to differentiate between a scale and an index. A *scale* typically is comprised of multiple items whose values are caused by an underlying construct (or latent variable) (Bollen, 1989). On the other hand, an *index* consists of several cause indicators or individual variables that together determine, or at least strongly relate to or influence, the level of the construct of interest (Devellis, 2003). Thus, in a scale, the items that comprise the scale typically correlate to each other, and multiplicity of items increases the overall reliability of the scale. On the other hand, for an index, constituent variables may be independent of each other (e.g., physical function versus social function, both important cause indicators of overall health). Creating an index may or may not be important in terms of analyzing and understanding outcomes. In terms of analyzing multiple outcomes, however, an index is desirable if one overall metric is desired to represent the outcomes. Furthermore, an index allows for unidimensional analytical approaches to be used, whereas multidimensional outcomes typically require multivariate analysis methods.

## 2.6 Summary: Selecting Appropriate Outcome Data

As demonstrated in the preceding sections, a variety of outcome characteristics influence the methods used to analyze outcomes and the conclusions that can be

**Table 1  Analyses Appropriate for Each Measurement Type**

| Measurement Type | Compare Counts/ Frequencies | Greater Than/ Less Than Comparisons | Ratio Comparisons | Mathematical Operations | Statistical Analysis |
|---|---|---|---|---|---|
| Nominal | × | | | | |
| Ordinal | × | × | | | |
| Interval | × | × | | × | × |
| Ratio | × | × | × | × | × |

drawn from those outcomes. Therefore, selecting the appropriate outcome data to collect begins with the definition of the research objectives. However, it is important to consider the research objectives in broad terms when developing a data collection and analysis plan for human factors research. Instead of just thinking in terms of the phenomenon to be studied or the intervention to be evaluated, also think about the goals for communicating the outcomes before determining which outcome data to collect. If these objectives and goals are not well established up front, it is unlikely that you will by chance collect data that supports an ill-defined research objective.

Once the research objectives are established and well understood, the next step is to select what data outcomes to collect. It is always useful to begin by looking at the domain literature to identify frequently used data and measures and any gaps in those outcomes. Using measures consistent with other research is useful in that it is a prerequisite for having results that are comparable with other studies. However, do not be afraid to bridge any gaps that exist in the literature by creating new measures. For example, there may be a need for a new, more sensitive measure of a phenomenon of interest or a more generalizable measure that enables comparisons across multiple related tasks.

Next consider the types of conclusions that should be drawn to support the research objectives. What level of objectivity is required? What specificity? What analysis method(s) will enable drawing those conclusions? Do the required analysis methods impose any restrictions on the structure or measurement type of the outcome data? All of these questions should be answered to develop a data collection and analysis plan for the research study. Addressing these topics up front helps ensure that the outcome data collected will be valid and credible and will support the research objectives identified. Of course, this does not guarantee that the outcomes will always produce the expected results—human factors data are always full of surprises!

## 3  MEASUREMENT OF OUTCOMES

Measurement is a fundamental activity of science. As Krantz et al. (1971, p. 1) explain: "When measuring some attribute of a class of objects or events, we associate numbers (or other familiar mathematical entities, such as vectors) with the objects in such a way that the properties of the attribute are faithfully represented as numerical properties." Although this process can be relatively straightforward for physical measures such as length or density, it can be very difficult for psychosociological constructs, such as stress or health status. Whether one measure is created or multiple measures are used, fundamental psychometric properties need to be tested properly before using the measurement system created. These fundamental properties are described briefly in the next section. In addition, we describe briefly methods that can be used when multidimensional outcomes need to be aggregated into an overall scale or an index.

### 3.1  Psychometric Properties

There are two overall fundamental properties in measurement: reliability and validity. Ghiselli et al. (1981) consider reliability a fundamental issue in psychosociological measurement and, in the context of developing scales, define it as the proportion of variance attributable to the true score of the latent variable. Although several terminologies exist, there are essentially three types of validity in scale development: content validity, criterion-related validity, and construct validity. *Content validity* refers to the extent to which a set of items selected in a scale covers the content domain. *Criterion-related validity* refers to the extent to which the scale created relates to an existing criterion or "gold standard." Finally, *construct validity* refers to the extent to which a scale "behaves" as it is expected to, according to theoretical relationships with existing constructs, where these relationships have been formulated prior to the development of the scale. A number of techniques exist to ascertain the reliability and validity of scales (see, e.g., Devellis, 2003).

### 3.2  Multidimensional Outcomes

As mentioned above, many (complex) evaluation problems are by nature multidimensional and require the construction of a scale or an index. Scales and indices differ in fundamental ways and require very different techniques for their development. Devellis (2003) provides a structured eight-step process as a guideline for scale development:

1. Determine clearly what to measure.
2. Generate an item pool.
3. Determine the format for measurement.
4. Have the initial pool reviewed by experts.
5. Consider the inclusion of validation items.
6. Administer the items to a development sample.
7. Evaluate the items.
8. Optimize the scale length.

As part of the final step, data reduction techniques for creating scales are commonly used and are described in greater detail in Section 4.3.

As opposed to creating a scale, multiattribute utility theory (MAUT) can be applied directly to create an index. Edwards and Newman (1982, p. 10) distinguish "four different classes of reasons for evaluations: curiosity, monitoring, fine tuning, and programmatic choice.... These reasons for evaluation share two common characteristics that make MAUT applicable to them all. The first is that, implicitly or explicitly, all require comparison of something with something else.... The second characteristic is that [entities to be evaluated] virtually always have multiple objectives." Thus, MAUT is applicable to many situations where multiple outcomes need to be aggregated into an overall index.

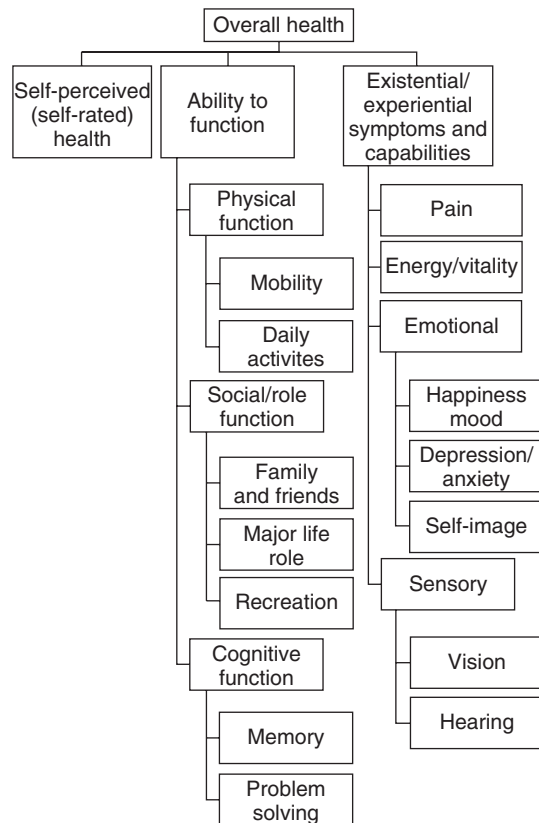
These multiple objectives lead to the identification of what Keeney and Raiffa (1976) call *evaluators* or *attributes* and purport to describe completely the


**Figure 1** Hierarchy of attributes to measure overall health. [Reprinted with permission from Fryback (1998) by the National Academy of Sciences. Courtesy of National Academies Press, Washington, DC.]

consequences of any of the possible actions or entities to be evaluated. According to Keeney and Raiffa, each attribute itself must be comprehensive and measurable, and the set of attributes describing the consequences must be complete, operational, decomposable, nonredundant, and minimal (p. 50). Often, these attributes can be structured meaningfully into a hierarchy. On top of the hierarchy is the all-inclusive objective, which indicates the reason for being interested in the problem in the first place. Figure 1 illustrates such a hierarchy in the context of creating an index comprising multiple outcomes to measure overall health.

MAUT provides a way of aggregating the information describing each entity on the multiple attributes into a summary measure or index. As described by Edwards and Newman (1982, p. 79), "the goal of MAUT is to come up with one number for each [entity] of evaluation, expressing in highly concentrated form how well that [entity] does on all evaluative dimensions. But whether that much compression is appropriate depends very much on the purpose of the evaluation." MAUT is widely used to combine multiple outcomes for at least three reasons. First, it is very appealing and convenient

to have a summary index. It is especially useful to have a summary index when the objective of the evaluation is to monitor changes, to compare alternatives, or to assign another quantity in proportion to the index score (e.g., assigning monetary rewards as a function of performance). Second, as pinpointed by von Winterfeldt and Edwards (1986), in practice, the additive and multiplicative models are the only workable ones; they are relatively simple and therefore easily accepted forms of aggregation. Third, MAUT is grounded in theory: The standard decomposition theorem for additive and multiplicative utility functions is seen as a determinant, to provide theoretical justification for the development of such evaluative models.

## 4  ANALYSIS OF STRUCTURED OUTCOME DATA

Both unstructured and structured outcome data result from human factors research. However, our discussion of analysis methods will begin by focusing on analyzing structured outcome data, or measures, since the results from these analytical methods are frequently the primary focus of research results presented in the human factors literature. There are a variety of statistical and graphical methods for exploring and analyzing structured data. In this section we review methods that are frequently used by human factors researchers. The methods are grouped according to the objective of the analysis. For each method we discuss when it is appropriate to use the method, the type of results produced by the method, and how to draw conclusions from the results. Delving into the statistical details of these methods is beyond the scope of this chapter, so suggested statistics reference(s) are also provided for each method. The decision model presented in Figure 2 is provided to help researchers decide which statistical tests are appropriate based on their analysis objectives and characteristics of the data.

### 4.1  Exploring Your Data

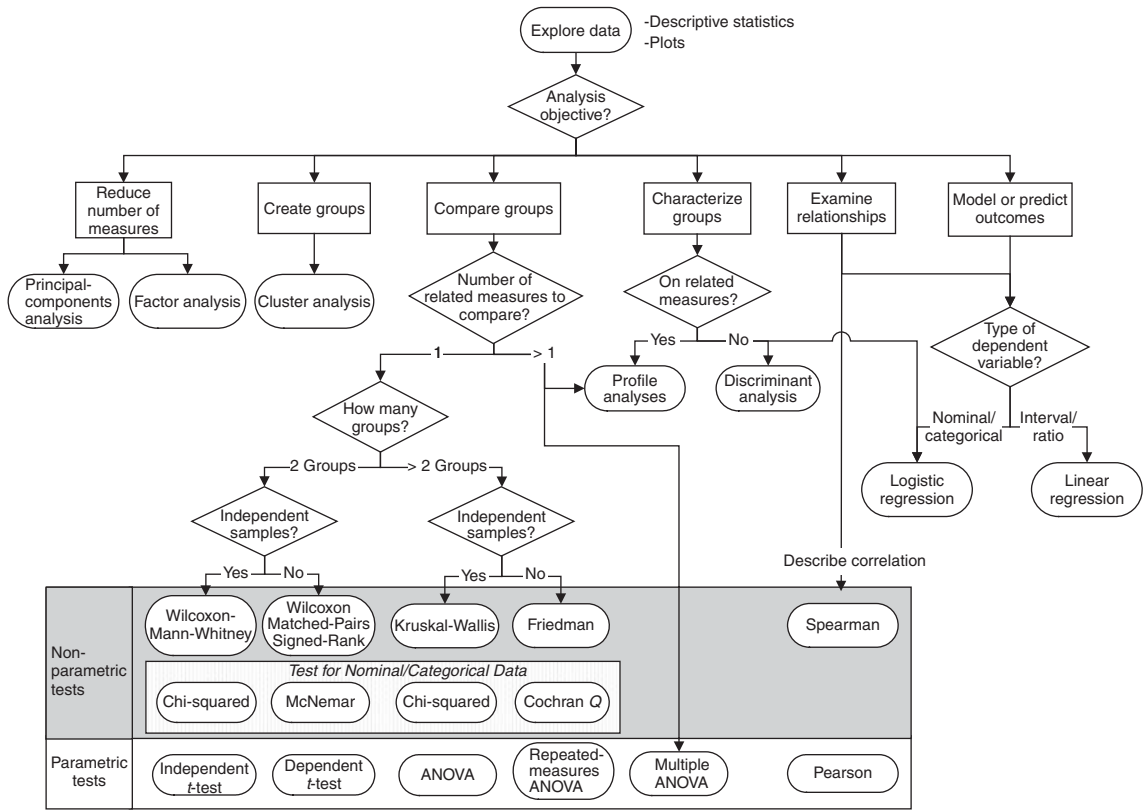
As Box et al. (1978) point out, when doing statistical analysis on outcome data, it is important not to forget what you know about the subject matter in your field. One way to build subject matter knowledge is to explore your data prior to completing any statistical tests. Human factors data can be quite different from data found in other domains. One of the distinguishing characteristics of human factors data is that it tends to be very noisy. This is especially true when the population being studied is very heterogeneous. Because the people being studied vary in physical and mental capabilities, expertise, and other factors, their performance on the same task will naturally vary. To compound this, even the same person acting under varying environmental factors may perform differently. The noise inherent in human factors data can reduce the power of statistical methods to detect effects. This is why it is very important to get to know your data before you start running statistical tests. By exploring and getting to know your data, you develop an initial understanding of potential occurrences and trends that can be used to validate and spot potential problems in the statistical analysis.


**Figure 2** Decision model for analyzing structured measures.

### 4.1.1 Exploring the Data Distribution

There are several graphical techniques useful for getting to know your data. For example, box plots (Figure 3) and histograms (Figure 4) may be used to get an overall feel for the distribution of the data. Both of these types of plots illustrate the minimum value, maximum value, and overall distribution and variability of the data. Additionally, a box plot indicates quartiles and the median value and highlights data points that are outliers or extreme values.

Identifying extreme values and outliers is important, as these data points are far outside the expected range of values, which is determined based on the variability of the data, measured by the standard deviation. These data points should be examined since they may be caused by a data collection or related error. For example, the value may be the result of a data entry error. In some cases, an unexpected event may have occurred during the trial, causing the data to be invalid. For example, in a task that is being timed, if the subject starts the task, then pauses to ask the experimenter a question, the task time for that trial may be artificially inflated and may need to be excluded from the data analysis. In another example, if all of the extreme values and outliers are from the same participant, there may be some characteristic of that participant that is causing the person to perform very

differently from the others. For example, one participant may have more experience with the experimental task, causing the person to perform much better than the other participants. The researcher needs to be aware of the cause of this difference and make an educated decision about whether or not it is appropriate to include the participant in the data analysis. If participant(s) or trials are excluded from analysis, the reason for excluding them should be presented when reporting the study findings, to ensure that correct conclusions are drawn from the study.

### 4.1.2 Descriptive Statistics

Descriptive statistics are used to convey information about the central tendency and dispersion of the data set. One frequently reported measure of central tendency is the *mean*, or average, value. However, one must be careful when reporting means because extreme values, which should be identified in your data exploration, can distort the mean. For example, if a researcher wanted to examine the net worth of a group of 10 people selected at random and Warren Buffet happened to be one of those people, Warren Buffet's net worth (in the billions) would distort the mean, making it in the hundreds of millions even if the net worth of all the others in the group was less than $100,000. Because the mean is vulnerable to
**Figure 3**   Box plot.

**Figure 4**   Histogram.

this distortion, it is often useful to look at the median and mode as well. The *median* is the value that splits the data set in half, with 50% of the values greater than that value and 50% less than that value. To find the median, the values are arranged in order from least to greatest; the middle value is the median. If there is an even number of values, the median is the average of the two middle values. The *mode*, on the other hand, is the value that occurs most frequently.

   In addition to examining measures of central tendency, examine the dispersion of the data as well. Dispersion is important for two primary reasons. First, dispersion, or variability, affects the power of statistical tests to detect significant effects, which is discussed in more detail later in the chapter. Second, in human factors, researchers are sometimes interested in reducing variability to gain more consistent performance over time. As a measure of dispersion, researchers frequently report the *variance* ($\sigma^2$) or *standard deviation* ($\sigma$). These two values are directly related, as the standard deviation is the square root of the variance. The variance is calculated based on the square of the difference between each value and the mean and therefore increases as more values are a greater distance from the mean. Statistical packages and spreadsheet programs calculate this value, so the mathematical equation is not provided here. However, any statistics book provides the mathematical definitions of these measures.

When discussing dispersion, it is also often worthwhile to examine the *range* of the values, defined by the *minimum* and *maximum values*, and *percentiles*. The *X* percentile is defined as the value at which *X*% of the values fall at or below that value. The range and quartiles (the 25th, 50th, and 75th percentiles) are depicted in a box plot, as discussed in Section 4.1.1.

*References for further details*: Sheskin (2007), Field (2005).

## 4.2  Statistical Analysis Methods

A variety of statistical analysis methods can be used to make inferences about structured outcome measures. The purpose of these statistical methods is to help you understand and draw conclusions from the outcome measures. The appropriate statistical test to use depends on the analysis objective and on characteristics of the data. The reader is again referred to the decision model in Figure 2 for assistance in choosing the appropriate method(s). The methods discussed in this section may be used to accomplish the following objectives:

- *Comparing groups'* *t*-test, Wilcoxon–Mann–Whitney, Wilcoxon matched-pairs signed-rank, chi-squared, analysis of variance (ANOVA), repeated-measures ANOVA, Kruskal–Wallis, Friedman
- *Characterizing groups*: profile analyses, discriminant analysis
- *Creating groups*: cluster analysis
- *Describing and modeling relationships*: correlation, linear regression, logistic regression

Since this is a book on human factors and ergonomics, not statistics, formulas and detailed mathematical explanations are not provided for these statistical methods. Since most statistical packages provide functions that automate these calculations, the focus is on understanding conceptually how each method works, when it is appropriate to use it, and how to understand and interpret the results in order to draw conclusions. Before delving into the methods, several general statistical concepts need to be reviewed.

### 4.2.1  General Statistical Concepts

In inferential statistical methods, the researcher seeks to determine whether or not phenomena observed in the data are caused by random variation in the data. If it is not caused by random variation, we can make inferences about the nature and cause of those phenomena. In making these inferences, several general statistical concepts play a role both in designing experiments and in interpreting and communicating results. In this section we review these concepts in the context of an example experiment in which a researcher wants to compare the time to complete a task using the current method to the time using a proposed new method. The researcher collects the data and computes the mean time to complete the task under each method. The new method has a lower mean time, but how can they be sure that the lower time is actually caused by using the new method instead of just by chance?

***Type I and II Errors***   Inferential statistical methods typically frame the research question as a hypothesis, which is then tested to determine whether or not it is true. In our example, the researcher's hypothesis would be that there is a difference between the mean times of the two methods. When testing a hypothesis, researchers are vulnerable to making two types of errors. First, if the researcher concludes that the hypothesis is true when the result is actually caused by chance, he or she has made a *type I error*. In our example, the researcher would make a type I error if he or she concluded that the new method reduced the time to complete the task when in reality the lower mean time was only caused by chance variation in the data. To avoid these errors, researchers typically limit the type I error rate ($\alpha$). In human factors research, $\alpha$ is usually set at 5%, which means that type I errors will occur at most in 5 of every 100 tests.

In the second type of error, *type II error*, the researcher concludes that the result was caused by chance when, in reality, the hypothesis is true. If our researcher concluded that there was no difference in the times for the two methods when the proposed method is actually faster, they would commit a type II error. The likelihood of making a type II error ($\beta$) is an indicator of the *power* ($1 - \beta$) of the test, its ability to detect a difference when one actually exists. The type I error rate ($\alpha$), the sample size ($n$), the mean, and the variance of the data determine the power of the test (Kutner et al., 2004). For researchers designing experiments, understanding this relationship between $\alpha$ and the power of the test is crucial. Since the industry practice is to control $\alpha$ at no more than 0.05, the only way to increase the power of a test is to collect more data, increasing $n$, or control the experiment to reduce variability in the data, which can be difficult with human factors data, as mentioned in the discussion on experimental design in Chapter 11. Some statistical packages, such as MiniTab, provide calculators that estimate the sample size needed to achieve the desired power given an estimate of the variance and mean. When designing an experiment, it is highly recommended that you estimate the power to ensure that enough data are collected to achieve the desired power for statistical testing.

***Experimentwise Error***   In situations where more than two groups are being examined or several, possibly related, dependent measures are being examined, researchers need to be careful to manage the *experimentwise error* rate to ensure the validity of their results. Experimentwise error is the combined type I error rate for all the statistical tests being performed. Take a simple example. A researcher is comparing the task time of three experimental groups. If the researcher uses the *t*-test to compare each test to the other tests, three *t*-tests are completed, comparing group 1 to 2, 1 to 3, and 2 to 3. If the researcher sets the type I error rate ($\alpha$) to 0.05, each test has a 0.95 chance that there will be no type I errors. Since there are three tests, each of which is assumed to be independent, the experimentwise probability that there is no type I error is $0.95 \times 0.95 \times 0.95 = 0.857$. This means that the experimentwise error rate ($1 - 0.857$) is 0.143. In other words, 14.3% of the time there will be a type I error!

However, statisticians are aware of this phenomenon, so tests are available that account for it and control the experimentwise error to the desired $\alpha$ level. For example, this is why ANOVA is used to compare more than two groups instead of multiple $t$-tests, as demonstrated in the example. ANOVA examines all of the groups together to determine whether any of them differ significantly at the $\alpha$ level of experimentwise error. Once it is established that there is a significant difference at the experiment level, post hoc comparisons are completed to determine which pairs are different. These post hoc comparisons adjust to account for the number of comparisons being performed.

***p-Values***   Researchers generally provide $p$-values when reporting the results of statistical analyses. The $p$-value indicates the likelihood of making a type I error. In other words, the $p$-value is the probability that the researcher will conclude that the hypothesis is true when the result is actually caused by chance. To continue the task time comparison example, if the statistical test resulted in $p = 0.25$, it would indicate that there is a 25% chance that the difference in the mean task time is simply caused by random variation in the data. This is clearly higher than the 5% $\alpha$ threshold that is generally accepted, so in this case, the researcher would conclude that there is not evidence to support the conclusion that there is a difference in the task times. This means that either there truly is no difference in the task times or the test did not have enough power to detect the difference, in which case the researcher could collect additional data to increase the power of the test. On the other hand, if the $p$-value were 0.03, it would indicate only a 3% chance that the difference in times is due to chance, and the researcher could conclude that the new process affects the task time.

***Confidence Intervals***   When comparing groups, the $p$-value indicates whether or not there is a difference between the groups but gives no indication of the magnitude of this difference. Confidence intervals (CIs) provide this information, making the results of the study easier for practitioners to interpret and apply. CIs indicate the magnitude for a value such as the mean or the mean difference between two groups. Because the mean is calculated from a sample of data, it merely provides an estimate for the actual population mean. Consequently, with a different sample of data, the estimate of the mean, although close to the first mean, is unlikely to be exactly the same. A CI provides a range in which the actual mean falls. The confidence interval is for a certain $\alpha$ level, typically $\alpha = 0.05$, and is referred to as the $(1 - \alpha)$-level CI. The interval is calculated using the mean and the variance (Wu and Hamada, 2009). In a 95% confidence interval, there is a 95% chance that the actual mean falls within the upper and lower bounds of the interval. How does knowing this help us?

In our example, the researcher might want to understand the magnitude of the difference in task time between the current method and the method proposed. If the 95% CI for the difference in task time (time$_{current}$)$-$(time$_{proposed}$) was found to be 33–45 s, it would indicate that the proposed process saves 33–45 s on the task.

***Statistical versus Practical Significance***   Just because an analysis indicates that a result is statistically significant does not mean that it has practical significance as well. For example, in the CI presented previously, we reported that the time savings achieved by using the proposed method is 33–45 s. If the task normally takes 60 min to complete, this time savings amounts to a mere 1% saving, so it may not be cost-effective to change to the new method. On the other hand, if the task normally takes 5 min, the time savings amounts to an 11–15% savings, a much more practically significant result. This illustrates why it is important for researchers to understand and report practical significance as well as statistical significance. Reporting practical significance makes it easier for people less familiar with statistics and human factors methods to understand and apply the results, increasing the use and impact of the results.

***Parametric and Nonparametric Tests***   In inferential statistics, many tests are classified as parametric or nonparametric. This distinction is made because *parametric tests* are based on certain assumptions about characteristics of the distribution of the data, whereas *nonparametric tests* make no such assumptions about the distribution of the data (Sheskin, 2007; Sprent and Smeeton, 2007). For example, when comparing two independent samples, the $t$-test, a parametric test, or the Mann–Whitney $U$-test (a nonparametric test) may be used to analyze the data. Which should the researcher choose?

In general, parametric tests are appropriate for interval and ratio data, whereas nonparametric tests are used for categorical/nominal and/or ordinal/rank-order data. With interval and ratio data, it is always preferable to use parametric tests because they have more statistical power. However, when using parametric tests, it is important to verify that the underlying assumptions of the test are met. Although many of these tests are robust enough to handle some departures from the assumptions (Sheskin, 2007; Newton and Rudestam, 1999), large departures from the assumptions may make the test inappropriate for use with the given data set. For example, the $t$-test assumes that the data being analyzed are characterized by a normal distribution (normality assumption) and that the variance of the underlying population is homogeneous (homogeneity of variance assumption). In the discussion of each test, the assumptions are listed and, if appropriate, ways to validate those assumptions. However, since many parametric tests assume that the data or the error between the data and a model of the data are normally distributed, it is worth recalling the normal distribution. Figures 3 and 4 are a box plot and histogram, respectively, of data that resemble a normal distribution. The reference line in the histogram displays how data with a normal distribution would be shaped—with a large number of values in the middle near the mean and progressively fewer occurrences as you move farther away from the mean. In the box plot, the line representing the median is located in the center of the box and the box and lines are fairly balanced. All of these things indicate that the
**Figure 5** Normal probability plot (normally distributed data).

data resemble a normal distribution. To confirm this, examine the normal probability ($Q$–$Q$) plot for these data (Figure 5). Since most of the data points fall along a straight line, this also indicates that the data resemble a normal distribution. In this case, we could conclude that the assumption of normality is met.

When significant violations of the parametric test assumptions are observed, the researcher has two alternatives. One alternative is to transform the measure ($y$) using one of the power transformations such as $\log(y)$ or $1/y$, so that the transformed measure meets the test assumptions. However, when using a transformation, researchers should take care to ensure that the results of the analysis are interpretable. This means that the results of the analysis on the transformed measure must still be meaningful (e.g., if $y$ = death rate, then $1/y$ = survival rate and the $1/y$ transformation has an interpretable meaning). Also, the researcher must take care to present the results in a manner that is clear, even to those with limited statistical knowledge. Many statistics books (e.g., Kutner et al., 2004; Newton and Rudestam, 1999; Wu and Hamada, 2009) provide details on how to select the appropriate data transformation. Refer to one of these books for more information on this topic.

The second alternative when a parametric test is not appropriate is to use an equivalent nonparametric test. In our $t$-test example, if the data set significantly violated the normality and homogeneity of variance assumptions, the researcher could instead use the Mann–Whitney test to compare the two groups. This test is based strictly on the rank order of the data points, so it makes no underlying assumptions about the distribution of the data or its variance. However, because it is based on the ranks, it sacrifices the additional information provided in the interval/ratio data, making it less powerful. This tradeoff between the power provided by parametric tests and the absence of data distribution assumptions in nonparametric tests is crucial for researchers when selecting the appropriate test for their data.

Note that there is some debate in the applied statistics community over whether a parametric or a nonparametric test should be used when there are departures from the parametric test assumptions. However, as Sheskin (2007) demonstrates with examples in his book, frequently, when both a parametric test and its nonparametric counterpart are applied to the same data set, they result in the same or similar conclusions. Therefore, the prudent researcher should use the decision process illustrated in Figure 6 when trying to decide whether a parametric or a nonparametric test is appropriate.

### 4.2.2 Comparing and Creating Groups

Now that the review of general statistical concepts is complete, we can focus on the methods used to accomplish the researcher's analysis goals. In human factors research, researchers are frequently interested in examining groups of participants, items, or events. For pre-existing groups, the researcher may want to compare groups on some dependent measure of interest or characterize those groups based on a number of different measures. In other cases, the researcher may be interested in creating new groups of related participants, items, or events to develop a better understanding of relationships and patterns in the data.

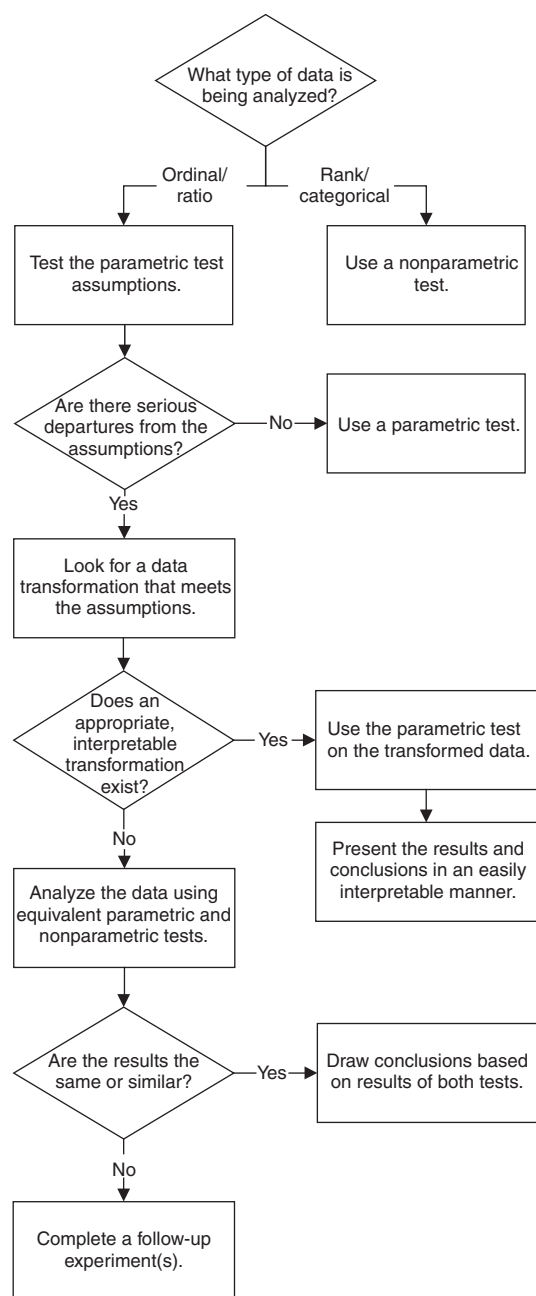
Of these three general analysis goals related to groups, comparing two or more experimental groups on a dependent measure of interest is the one most frequently seen in human factors research. For example, a researcher may be interested in examining worker efficiency, measured by task time, when using each of several available tools. After designing the experiment and collecting the data, as described in Chapter 11, the researcher must use the appropriate statistical test to analyze the data and draw conclusions about the influence of each tool on task time. In the first part of this section we review statistical tests used to compare two groups (e.g., $t$-test, Mann–Whitney $U$-test) and to compare two or more groups (e.g., ANOVA, Friedman test).


**Figure 6** Decision model for choosing between a parametric and a nonparametric test.

After the review of methods for comparing groups, two methods are presented for characterizing groups. The first is profile analyses, which characterize each group on a set of related measures. Profile analyses may also be used to compare the profiles of each group to determine whether or not they differ. The second method is discriminant analysis, which examines independent measures for items in each group to determine which measures can be used to separate the groups. These identified discriminant measures are then used to define rules for classifying or predicting which group a new item will belong to given its discriminant measures. The section concludes with cluster analysis, an exploratory method used to create groups. Cluster analysis examines characteristics of individual items and creates groups such that items in each group are highly similar to each other and highly different from items in other groups.

***Comparing Two Groups***   The tests presented here are used to determine if the variable of interest differs between two groups. The appropriate test to use depends on three factors. First, are the two groups dependent or independent? Referring to the experimental design concepts in Chapter 11, within-subjects (repeated-measures) designs are dependent because each subject receives each experimental condition. This means that the values for each condition are related since they come from the same participant. In contrast, in between-subjects designs different sets of randomly selected participants receive each experimental condition and are assumed to be independent of each other. The second factor in selecting the appropriate test is whether or not the data adequately meet the assumptions of the test, as described in the "Assumptions" section for each test. The third factor is measurement type of the dependent measure. Table 2 identifies these factors and the appropriate test for each. Note that since the McNemar test is not used frequently compared to the other tests, it is not discussed in detail in this chapter. However, more information about this test may be found in Sheskin (2007) or Sprent and Smeeton (2007).

***t*-Test**   The *t*-test is a parametric test used to compare means of a dependent measure for two groups. There are two forms of the test: (1) the *dependent* or *paired t-test*, used when the same subjects received both experimental conditions, and (2) the *independent t-test*, used when different subjects are assigned to each experimental condition. Both tests are used to examine the question: Do the means of the dependent measure differ in the two populations represented by the groups? If the difference between the groups is small, it may only be caused by chance variation in the data, but if the difference is large, we may conclude that there is, indeed, a significant difference between the two groups. The primary difference in the two tests is how they examine the values.

**Table 2  Tests for Comparing Two Groups**

|  | Parametric | | |
|---|---|---|---|
|  | Interval/ Ratio | Ordinal/ Rank | Categorical |
| Dependent groups | Dependent (paired) *t*-test | Wilcoxon signed-rank test | McNemar test |
| Independent groups | Independent *t*-test | Mann–Whitney *U*-test | Chi-squared test |

*Assumptions* The assumptions of both forms of the *t*-test are that (1) the dependent variable of each underlying population is normally distributed and (2) the two populations have equal population variances (i.e., homogeneity of variance). The independent *t*-test also assumes that the each group is selected randomly from the population it represents (i.e., the two groups are independent of each other). Note that the assumption of homogeneity of variance can be tested using Hartley's $F_{max}$-test for homogeneity of variance.

*Methods and Results* Both forms of the *t*-test calculate a test (*t*) statistic that is used to determine the *p*-value. Conceptually, the *t*-statistic is the ratio of the difference in the means to the standard error of the difference. The difference in the two tests is that the independent *t*-test examines the means of each group [$\text{mean}(Y_1) - \text{mean}(Y_2)$], while the dependent *t*-test examines the mean difference of the pairs of results for each participant [$\text{mean}(Y_{i1} - Y_{i2})$, where $i$ = participant number]. When completing a *t*-test using a statistical package, the results typically provide the *t*-statistic and the associated *p*-value. The *p*-value indicates the likelihood that the difference in the means occurred by chance. Therefore, the smaller the *p*-value is, the greater evidence the test provides that the two groups are indeed different.

*Drawing Conclusions* In human factors literature, *p*-values less than or equal to 0.05 are usually considered significant. Therefore, if the *p*-value is 0.05 or less, the researcher can conclude that evidence indicates that there is a significant difference in the dependent variable between the two groups (experimental conditions). However the *p*-value does not indicate the size of the difference between the groups; therefore, it is recommended that the researcher also consider and report the size of the difference when drawing conclusions. This can be done by calculating a 95% CI on the difference between the population means. Again, most statistical packages calculate the CI, so it is quite easy to include this additional information in the results. This helps ensure that the results have practical as well as statistical significance.
*References for further details*: Sheskin (2007), Lomax (2007).

### Wilcoxon–Mann–Whitney Test
The Wilcoxon–Mann–Whitney test is a nonparametric test used to examine differences between groups on ordinal/rank data where the two groups are independent. This test is approximately the same as the Mann–Whitney *U*-test, which yields comparable results using slightly different computations. This test examines the question: Do the two groups have different median values (i.e., do the mean ranks for the two groups differ)? If the underlying population for the two groups is the same, we would expect both groups to have a similar distribution of ranks from low to middle to high. Conversely, if the underlying populations are different, we would expect one group to be concentrated in the low ranks and the other in the high ranks.

*Assumptions* This test assumes that each group is selected randomly from the population it represents (i.e., the two groups are independent of each other). It also assumes that the two groups come from populations with similarly shaped distributions, although no assumptions are made about what that shape is.

*Methods and Results* In this test, the results from the two groups are combined, the data are sorted from least to greatest, and the data are ranked overall. Then the sum of the ranks for each group is calculated. Most statistical packages calculate automatically the *p*-value by comparing the sum of the ranks for the group with the smallest sum of ranks to the relevant critical value. If the *p*-value is not provided, it can be determined by comparing the smaller sum of ranks to critical values, typically provided in the appendix of statistics books.

*Drawing Conclusions* As with the *t*-test, the *p*-value indicates the likelihood that the observed differences in rank sums are from chance as opposed to being due to differences between the underlying populations for each group. A significant *p*-value (e.g., $p \leq 0.05$) provides evidence that the median of one group is lower than the median of the other group. In other words, the group with the lower rank sum has lower values of the dependent variable than those of the other group.
*References for further details:* Sheskin (2007), Argyrous (2000), Sprent and Smeeton (2007).

### Wilcoxon Matched-Pairs Signed-Rank Test
The Wilcoxon matched-pairs signed-rank test is a nonparametric test used to examine differences between groups when the two groups are *dependent*. This is in contrast to the Wilcoxon–Mann–Whitney test, which is used to examine two *independent* groups. The Wilcoxon matched-pairs signed-rank test is the nonparametric equivalent of the dependent (paired) *t*-test. The test is based on the ranks of the differences between scores for each participant. The test examines the question: Is the median value for the difference between the two scores equal to zero (i.e., does the experimental condition cause a difference in the scores)?

*Assumptions* This test assumes that participants are selected randomly from the population represented and that each subject receives both experimental conditions. It also assumes that original scores for each participant are ordinal/ratio data and that the distribution of scores for each experimental condition comes from populations with similarly shaped distributions, although no assumptions are made about what that shape is.

*Methods and Results* In this test, the ranks are generated based on the difference between the ordinal/ratio score obtained in each experimental condition for each participant. Therefore, the original ordinal/ratio score is needed. First the difference for each participant is calculated ($Y_{1i} - Y_{2i}$). Then the absolute value of the difference scores are ranked in order from least to greatest. These difference ranks are split into two groups: the positive ranks, which are those ranks where the difference score was positive ($Y_{1i} - Y_{2i} > 0$), and the

negative ranks, where the difference score was negative ($Y1_i - Y2_i < 0$). Next the sum of the positive ranks is calculated and compared to the sum of the negative ranks. The smaller of the two rank sums is used as the Wilcoxon's $T$-statistic, which is compared to the expected value of the rank sum if there was no difference between the groups. When using a statistical package to complete this test, the researcher is shielded from these calculations. The package usually calculates and reports the positive and negative rank sums, Wilcoxon's $T$-statistic, and the $p$-value.

*Drawing Conclusion* As with the Wilcoxon–Mann–Whitney test, the $p$-value indicates the likelihood that the difference observed between the smallest rank sum observed (Wilcoxon's $T$) and the rank sum expected are by chance, as opposed to being due to differences between the scores in each group. A significant $p$-value (e.g., $p \leq 0.05$) provides evidence that the median difference in scores is not zero. To determine whether experimental condition 1 or 2 resulted in higher differences, we must examine the positive and negative rank sums. If the difference scores were calculated as $Y_{1i} - Y_{2i}$, a larger positive rank sum indicates that condition 1 resulted in higher scores than condition 2. This is logical since a larger positive rank sum indicates that more participants had a positive difference in scores ($Y_{1i} - Y_{2i}$) and/or that the absolute value of the positive differences was larger than those observed for participants with negative differences.

*References for further details:* Sheskin (2007), Argyrous (2000), Sprent and Smeeton (2007).

## Chi-Squared Test

The chi-squared test is a nonparametric test used to examine differences between groups using nominal/categorical data. For example, it could be used to determine if there were significant differences in the number of males and females in two experimental groups. This test can be used to examine two or more groups.

## Comparing More Than Two Groups

The tests presented here are used to determine if the dependent measure differs between more than two groups of interest. Similar to the case in which two groups are being examined, the appropriate test to use depends on the answers to four questions: (1) Are the groups dependent or independent? (2) Do the data adequately meet the assumptions of the parametric test? (3) What is the measurement type of the dependent measure? (4) Are multiple, correlated measures being compared across groups? Table 3 identifies these factors and the appropriate test for each. Note that since the Cochran $Q$-test is not used frequently compared to the other tests, it is not discussed in detail in this chapter. However, more information about this test may be found in Sheskin (2007) or Sprent and Smeeton (2007).

## ANOVA Test

The ANOVA test is used to determine if two or more independent groups differ on an interval/ratio-dependent measure. This test answers the question: Is there a difference in the mean for at least two of the groups? ANOVA is closely related to the

**Table 3  Tests for Comparing More Than Two Groups**

| | Parametric: Interval/Ratio | Nonparametric Ordinal/Rank | Nonparametric Categorical |
|---|---|---|---|
| Dependent groups | Repeated-measures ANOVA test | Kruskal–Wallis test | Cochran $Q$-test |
| Independent groups | ANOVA test | Friedman test | Chi-squared test |
| Multiple, correlated measures | Multiple ANOVA test | | |

$t$-test and is preferred for examining more than two groups because it controls the experimentwise error rate. A variety of ANOVA procedures exist to support analyzing a variety of experimental designs, such as those with two grouping factors or using a mixed design. For simplicity, we address only one-factor ANOVA here since the concepts used in this procedure extend to more advanced ANOVA procedures.

*Assumptions* ANOVA assumes that the data being analyzed comprise a randomly selected sample. In the model on which the ANOVA is based, the error terms are normally distributed with mean zero. The variances of the data in each group are approximately equal (homogeneity of variance). Note that ANOVA is based on the general linear model, so these assumptions are the same as many of the assumptions for linear regression. See "Linear Regression" in Section 4.2.3 for more details on testing these assumptions.

*Methods and Results* ANOVA determines if the mean is equal for all the groups. To compare the groups, an ANOVA table is constructed which breaks down the sources of the variation in the dependent measure. For the one-factor ANOVA, there are two possible sources of variation: the independent measure used for grouping or random variation. The ratio of the variation accounted for by the independent measure [mean square treatment (MSTr)] to the random variation [mean square error (MSE)] is the $F$-statistic. The $F$-statistic is compared to a threshold value to determine the likelihood ($p$-value) that the differences in the means of the groups are due to random variation or actual differences in the mean of the underlying population. Most statistical packages report the full ANOVA table, including the breakdown of the variation (in terms of sum of squares, degrees of freedom, and the mean square for each source of variation), the $F$-statistic, and the $p$-value.

Results from the ANOVA $F$-test indicate only whether or not there is a difference between at least two of the groups. To determine which groups are actually different, post hoc tests, or paired comparisons, must also be performed. However, completing these multiple comparisons increases the experimentwise error rate ($\alpha$). Several post hoc comparison methods exist that are designed to control the experimentwise error rate. Two

commonly used methods are the Bonferroni and the Tukey. In both of these methods, the $t$-test is used to compare the means for each pair of groups. To control the error rate, the critical value to which the $t$-statistic is compared is adjusted to be more stringent and to account for the number of comparisons being made. Most statistical packages allow you to choose which post hoc method to use. The Bonferroni method is more conservative—it is more robust than other methods but as a result has less power to detect differences. The Tukey method is more sensitive but is not as robust when departures from test assumptions occur. When using statistical packages to complete paired comparisons, of interest in the output results are the mean difference between the groups, the $p$-value, and *the 95% CI on the mean difference.*

Because ANOVA analysis is based on the general linear model, it is important to complete a residual analysis as part of this procedure to ensure that the data meet all of the assumptions of the model. See "Linear Regression" in Section 4.2.3 for more details on how to validate these assumptions.

*Drawing Conclusions* To draw conclusions, first look at the $p$-value for the ANOVA $F$-test. If the $p$-value is sufficiently low, we may conclude that there is a difference among the groups and examine the results of the post hoc tests to determine which groups differ and the direction of that difference. When examining post hoc test results, first look at the $p$-values for each pair to identify which groups have means that differ significantly. Once these have been identified, examine the 95% CI on the mean difference to determine the direction of the difference based on the sign of the mean [e.g., positive (A – B) indicates group A > group B] and the magnitude of the difference.

**Repeated-Measures ANOVA Test** The repeated-measures, or within-subjects, ANOVA test is used to determine if two or more dependent groups differ on an interval/ratio-dependent variable of interest. This test is used to analyze data from repeated-measures and blocked experimental designs where each participant receives each experimental condition. This test answers the question: Is there a difference in the mean for at least two of the experimental conditions? The repeated-measures ANOVA is related conceptually to the dependent $t$-test and is closely related to the ANOVA used to examine multiple, independent groups.

*Assumptions* This test assumes that the data are a randomly selected sample. In the ANOVA model on which the test is based, the error terms are normally distributed with mean zero. In contrast to the ANOVA test, the repeated-measures ANOVA assumes sphericity instead of homogeneity of variance. Sphericity is a more complex concept related to the underlying variance and covariance of the populations being examined. For more information on this assumption, see Sheskin (2007).

*Methods and Results* Like ANOVA, this test examines whether the means for all groups are equal. The primary difference in the repeated-measures ANOVA is that it acknowledges and accounts for the variation between participants, in effect comparing each participant's performance across groups. To do this, this method decomposes the variation in the dependent variable into three possible sources of variation: (1) the independent measure used for grouping, (2) the participant completing the trial, or (3) random variation. In this case, two $F$-statistics may be calculated, one for the grouping measure (as in ANOVA) and one for the blocking variable, the participant. As with ANOVA, most statistical packages report the full ANOVA table, including the breakdown of the variation (in terms of sum of squares, degrees of freedom, and the mean square for each source of variation), the $F$-statistics, and the $p$-value. Upon completing the repeated-measures ANOVA, a post hoc test should be completed using the methods described in the section on ANOVA to examine the differences between groups in more detail.

*Drawing Conclusions* Drawing conclusions for repeated-measures ANOVA is essentially the same as that for ANOVA, so refer to that section for more detail. The primary difference is that, in addition to drawing conclusions about differences in the dependent measure related to the grouping measure, you can also draw conclusions about whether or not the participants varied significantly on the dependent measure. If there are differences among participants, further investigation may be warranted to try to determine if another characteristic of the participant is at the root of these differences.

**Effects of Measurement Errors on ANOVA** Liu and Salvendy (2009) recently demonstrated the effects of measurement errors on psychometric measurements in ergonomics studies. For ANOVA, they highlight the possibility of overestimating the error sum of squares. This can occur in the commonly used fixed-effect, single-factor balanced design, single-factor for repeated-measures, and factorial ANOVA. Liu and Salvendy (2009) suggest that these measurement errors reduce the statistical power of hypothesis testing; in other words they reduce the probability of getting a statistically significant result for a real effect in a population.

*References for further details*: Liu and Salvendy (2009).

**Multivariate ANOVA (MANOVA) Test** MANOVA is conceptually similar to ANOVA, except that MANOVA examines differences among groups on a set of correlated dependent measures. MANOVA takes steps to manage the experimentwise error by accounting not only for the number of groups being compared, as in ANOVA, but also for the number of dependent measures being examined. If the MANOVA test is significant, it indicates that there is a significant difference among the groups on at least one of the measures. Once this conclusion is made, use ANOVAs and the appropriate post hoc tests to analyze each of the dependent measures

individually to determine which dependent measures vary and between which groups those measures vary. Due to the complexity of this test, the reader is referred to the references for further details for additional information regarding specific assumptions, methods, and results of MANOVA.

*References for further details:* Johnson and Wichern (2007), Johnson (1998), Field (2005).

**Kruskal–Wallis Test**    The Kruskal–Wallis test is the nonparametric equivalent of ANOVA. It is appropriate for ordinal data and examines differences in ranks between independent groups. It is an extension of the Wilcoxon–Mann–Whitney test and is used to analyze more than two groups. As in the Wilcoxon–Mann–Whitney test, this test examines the question: Do the mean ranks for the groups differ? If there are true differences between the groups, we would expect one or more groups to be concentrated in the low ranks and the others to be concentrated in the high ranks.

*Assumptions*    Kruskal–Wallis assumes that the groups represent a random sample and are independent of each other. It also assumes that the groups come from populations with similarly shaped distributions, although no assumptions are made about what that shape is.

*Methods and Results*    As in the Wilcoxon–Mann–Whitney test, the data from all groups are combined and sorted from least to greatest, and the data are ranked overall. Then the sum of the ranks for each group is calculated. The test statistics, $H$, is calculated based on these sums. Statistical packages calculate the $H$-statistic and associated $p$-value by comparing $H$ to the relevant critical value. As with the ANOVA test, a significant $p$-value for this test only indicates that two or more groups vary in their median rank. To determine which groups differ, pairwise comparisons must be completed. Kruskal–Wallis uses the Wilcoxon–Mann–Whitney test to compare each pair of groups. To control experimentwise error $(\alpha)$, the Bonferroni method is typically used to adjust $\alpha$. For this method, divide the target $\alpha$ by the number of comparisons $(j)$. In other words, if your target is $\alpha = 0.05$ and you are completing four paired comparisons, the target $\alpha'$ for each comparison is $0.05/4 = 0.0125$. This means that $p$-values greater than 0.0125 would be rejected in the paired comparisons.

*Drawing Conclusions*    If the $p$-value for the Kruskal–Wallis test is sufficiently low, we conclude that there is a difference among the groups and examine the results of the post hoc tests to determine which groups differ. In the post hoc tests, if any pairs differ significantly (i.e., they have a $p$-value below the Bonferroni revised threshold,$\alpha'$), we may conclude that those pairs of groups differ. To determine the directionality of the difference, compare the sum of the ranks for each group. The group with the higher rank sum can be inferred to have higher values of the dependent measure than those of the other group.

*References for further details:* Sheskin (2007), Lomax (2007), Sprent and Smeeton (2007).

**Friedman Test**    The Friedman test is the nonparametric equivalent of the repeated-measures ANOVA. Like the Kruskal–Wallis test, the Friedman test uses ordinal data to examine whether the mean ranks differ for the groups. However, the Friedman test is used for dependent groups, such as those found in repeated-measures designs.

*Assumptions*    This test assumes that the data being analyzed comprise a randomly selected sample.

*Methods and Results*    To analyze differences among the groups, the Friedman test examines the rank of each group within a participant's results. This is in contrast to the Kruskal–Wallis test, which assigns an overall rank to pooled scores for all groups. Therefore, the Friedman test results in a set of rankings for each participant. After the ranks are assigned, the ranks for each group are summed. These rank sums are then used to calculate the Friedman test statistic $(\chi_r^2)$. When this test is run using statistical packages, the test statistic and the associated $p$-value are typically reported. As in the previous tests examining multiple groups, if the Friedman test is significant, post hoc comparison tests are required to determine which pairs of groups differ. One method of accomplishing this is to use the Wilcoxon matched-pairs signed-rank test to compare each pair of groups. To control the experimentwise error $(\alpha)$, the Bonferroni method is typically used to adjust $\alpha(\alpha' = \alpha/\text{number of tests})$, as described in the Kruskal–Wallis test.

*Drawing Conclusions*    The first step in drawing conclusions is to examine the $p$-value of the Friedman test. If $p$ is small (e.g., $p < 0.05$), we may conclude that there is a difference among the groups. If there is a difference in the groups, examine the post hoc test results to determine which groups differ. In the paired comparisons, identify any pairs that differ significantly (i.e., they have a $p$-value less than the Bonferroni revised threshold, $\alpha'$). For the pairs that differ, compare the sum of the ranks for each group in the pair to determine which group has higher values. The group with the higher rank sum can be inferred to have higher values of the dependent measure than those of the other group.

*References for further details:* Sheskin (2007), Lomax (2007), Sprent and Smeeton (2007).

**Chi-Squared Test**    The chi-squared $(\chi^2)$ test is a nonparametric test used to examine differences between groups on a nominal/categorical measure. The test is typically employed in association with a contingency or crosstab table. A contingency table is an $r \times c$ table where there is a row for each of the $r$ groups and a column for each of the $c$ possible values of the nominal measure being examined. Each cell represents the frequency with which the given row–column pair occurred. The chi-squared test examines whether or not there is a relationship between the group and the nominal measure. For example, is the number of females the same for all groups, or do a disproportionate proportion of women fall into a particular group?

*Assumptions* This test assumes that categorical data are used and that the $r \times c$ categories are mutually exclusive. That is, a participant/object will occur in only one cell in the contingency table. It also assumes that the data are from a random sample. An additional assumption is that the expected frequency of each cell is at least 1 and that no more than 20% of the cells have an expected value of 5 or less.

*Methods and Results* The chi-squared test compares the expected frequency of a category to the frequency of that category observed for each of the $r \times c$ categories in the table. The expected frequency is calculated based on the assumption that there is no relationship between the grouping measure and the nominal measure, so it is based on the proportion of overall participants who fall into that particular group. So in our example of examining gender differences among the groups, if you have 80 participants who are evenly divided among four experimental groups, we would expect each group to be 50% female, which translates to an expected frequency of 10 females [20 participants per group $\times$ 0.5 (expected percentage of females)]. The $\chi^2$-statistic is calculated based on the difference between the frequency observed and the frequency expected. When using a statistical package to complete this test, results typically include the contingency table with observed and expected frequencies (or proportions), the $\chi^2$-statistic, degrees of freedom, and the $p$-value. *Note:* The degrees of freedom are calculated as $(r-1)(c-1)$.

*Drawing Conclusions* Again, we begin drawing conclusions by examining the $p$-value. If $p$ is sufficiently small, evidence indicates that there is a significant difference between the expected and observed frequencies in the cells. This in turn indicates that there is a relationship between the grouping measure and the nominal measure. However, $p$ does not provide an indication of how they are related. Which cells differ from the expected frequencies? To determine this, most sources recommend completing paired comparisons in the form of $2 \times 2$ contingency tables for the subsets of the larger $r \times c$ table. As mentioned previously, these multiple comparisons can inflate the experimentwise error rate, $\alpha$. To control the error rate in the chi-squared test, we again use the Bonferroni method, which divides the target $\alpha$ by the number of comparisons ($j$).

Now we know which cells differ but still cannot draw any conclusions regarding the magnitude of the differences, which indicate the strength of the relationship. There are a number of measures of association or correlation that indicate the size of the effect that can be examined. These include the phi coefficient, for $2 \times 2$ tables only, and Cramer's phi, for tables larger than $2 \times 2$. Phi coefficients range from $-1$ to 1, with the absolute value indicating the strength of the effect. Cramer's phi ranges from 0 to 1 with a similar interpretation. Cohen (1988) suggests the following recommendations for interpreting the size of an effect:

- *Small effect:* between 0.10 and 0.30
- *Medium effect:* between 0.30 and 0.50
- *Large effect:* greater than or equal to 0.50

***Characterizing and Creating Groups*** In some cases we are interested in understanding the characteristics of known groups or in using the characteristics of items to create new groups. Several approaches are available for accomplishing either of these goals. To characterize a group based on a number of correlated measures, profile analyses are appropriate. On the other hand, discriminant analysis can be used to examine groups on a number of independent measures to determine which measures most distinguish groups from each other. These discriminating characteristics can then be used to classify or predict which group new items might fall into. When there are only two groups, logistic regression is sometimes used to predict classification of items into the two groups. Sometimes, however, we are simply interested in creating groups of items that are similar to each other on a number of characteristics. In this case, cluster analysis proves useful. In the following section we describe profile analyses, discriminant analysis, and cluster analysis. Logistic regression is described in Section 4.2.3.

**Profile Analyses** Profile analyses are used to examine the means of several measures for two or more groups. The measures are typically correlated. For example, they may be the results of several tests given to a participant. The profile for each group is a plot of the mean of each measure (see Figure 7). Profile analyses attempt to answer the following questions: Are the profiles for two groups parallel (e.g., is the difference in the means the same for all measures)? If they are parallel, are they coincident (e.g., is the mean for both groups the same)? Do the profiles show any trends?

*Assumptions* Profile analyses assume that each group's measures are independent of those of the other groups and normally distributed. It also assumes that the measures being used to create the profile use the same scale/units.

*Methods and Results* Profile analyses use a number of statistical tests, based on those discussed previously, to compare the difference in the mean values of the two groups for each measure. The primary difference between the two is that the statistical methods used in profile analysis take into account the number of measures being examined and their covariance, similar to MANOVA. To determine whether or not two profiles are parallel, the $T^2$-statistic is used to test if the difference between two groups in the means for each measure is the same.

*Drawing Conclusions* Looking at the profiles in Figure 7, we would intuitively suspect that the profiles for groups 1 and 2 could be parallel. If the $T^2$-statistics for these groups produced a sufficiently small $p$-value, we could conclude that this is indeed the case.

*Reference for further details:* Johnson and Wichern (2007).
**Figure 7**  Profile plot for four groups.

**Discriminant Analysis**  Discriminant analysis is used to explore features of items (e.g., participants, events) in existing groups to determine which features differentiate items in one group from the other group(s). In many cases, these discriminant features, represented by measures, can be used to develop rules for classifying new items into one of the existing groups. For example, a researcher who was examining an assembly task might group participants in a study into two groups: those who completed the task successfully and those who did not. This researcher could use discriminant analysis to determine which participant and environmental characteristics differentiate those who completed the task successfully from those who did not. These discriminant features could, in turn, be used to develop rules for predicting whether or not the task will be completed successfully in certain situations. Discriminant analysis develops rules used to predict which group a given item will belong to given a set of measures describing that item. In general, the goals of discriminant analysis are (1) to identify and describe the features most distinctly and separate items in known groups and (2) to derive rules used to optimally sort or classify new items into one of the given groups. In this section we examine the simple case of discriminating between two groups, although the method can be used for more than two groups.

*Assumptions*  Discriminant analysis assumes that the populations of the groups being examined have a multivariate normal distribution with equal covariance.

*Methods and Results*  The first step in discriminant analysis is to define a set of discriminant rules based on the means and variance–covariance of the measures for the two groups being examined. Although in many cases they result in the same rules, four different methods may be used to develop these rules: the likelihood rule, the linear discriminant function rule (Fisher's method), the Mahalanobis distance rule, and the posterior probability rule. The linear discriminant function rule (Fisher's method) is the best known. This method

finds a linear transformation ($Y$) of the measures ($X$'s) such that the $Y$'s of the two groups are separated as much as possible. The discriminant rule compares the $Y$ of the new item to the midpoint between the two groups. If the value is greater than the midpoint, it is assigned to the group with larger values of $Y$, and vice versa.

Once the discriminant rules are established, it is important to assess the adequacy of these rules by estimating the probability of classifying an item correctly. As researchers, we want to choose the rule that classifies items correctly a sufficiently high portion of the time. After all, a rule that only works 50% of the time is not very useful; we might as well flip a coin to assign an item to a group. Of the three methods that may be used, the simplest is to use resubstitution estimates. For this method, create predicted classifications for the original data based on the discriminant rules and compare how frequently the prediction is correct. The method is problematic because it tends to overestimate the probability of correct classification. For large data sets a second method of assessing adequacy of the rules is to use holdout data. In this method, a subset of the data available is withheld when the discriminant rule is created. The discriminant rule is used to predict classifications for the holdout group; then the percentage of correct classifications is examined. For smaller data sets, this method should not be used since all of the data are required to create the best possible discriminant rule. The most accurate method is known as cross-validation, jackknifing, or Lachenbruch's holdout method. This method is more complex than the other two, so refer to one of the references for further details on how to complete this method of estimating the likelihood of a correct classification.

*Drawing Conclusions*  The first step in drawing conclusions is to examine the probability of classifying an item correctly. If this percentage is sufficiently high considering the type of data and the purpose for which the discriminant analysis is intended, we may conclude that the discriminant rule is an adequate predictor for classification. Next, examine the coefficient/weight of

each measure in the discriminant rule. The measures with higher coefficients factor more heavily in attempting to separate the two groups; therefore, those measures are better for discriminating between groups.

*References for further details*: Johnson and Wichern (2007), Johnson (1998).

**Cluster Analysis** Clustering is an exploratory method used to examine a set of ungrouped items (e.g., participants, events) and to identify any naturally occurring clusters, or groups, of items. This is in contrast to discriminant analysis, in which there were preexisting groups and the goal was to define rules for classifying new items into those preexisting groups. In cluster analysis we start with a set of items (e.g., participants) and a number of descriptive measures related to those items (e.g., a variety of behavioral measures related to task performance). The primary goal is to identify groups of items (participants) that are highly similar to each other on the descriptive measures (behavior) but highly different from the items in the other groups. In other words, we want to minimize the distance between items within a group and to maximize the distance between groups.

Once these groups are defined, the methods identified previously for comparing groups can be used to examine differences between the groups on the descriptive measures used to create the groupings. Although this can provide interesting insights, it is often more interesting to examine the groups for differences on measures that were not used to create the groupings. For example, if behavioral measures were used to group participants, it might be interesting to examine the resulting groups for differences in demographic variables such as age, education, and experience level. Note that cluster analysis is exploratory in nature and is more of an art than a science. There are a number of arbitrary judgments that the researcher must make, such as the appropriate clustering method and number of clusters. Therefore, validating that the resulting groups are meaningful and useful is crucial to successful cluster analysis.

*Methods and Results* Cluster analysis uses one of several available algorithms to identify groups of items based on a number of similarity and/or dissimilarity measures. Before using an algorithm, always explore the data using scatterplots and other graphical representations to see if there are any apparent natural groupings. If obvious groupings are observed, they can be used to validate the number of clusters and assignment of items to those clusters after the clustering algorithm is run. They may also be helpful for selecting the appropriate clustering algorithm. There are two primary classes of algorithms for identifying clusters in a data set: nonhierarchical and hierarchical. Nonhierarchical methods begin with a given number of clusters and an initial set of seed points around which the clusters will be built. The disadvantage of these methods is that the researcher must make an initial guess at the number of groups and location of the initial seed points. If the data are already thoroughly understood, it may be possible to set these effectively, but frequently this is not the case. Therefore, hierarchical clustering algorithms are more widely recommended.

Frequently used hierarchical clustering algorithms begin with each item in a single group and merge the closest groups successively. These algorithms, known as *agglomerative hierarchical methods*, attempt to merge the most similar items into a group while keeping the groups dissimilar. When using these methods, several different linkage methods can be used to build the clusters, and these methods vary in how they measure dissimilarity, the distance between two clusters. Two frequently used methods are nearest neighbor and furthest neighbor. In nearest neighbor, at each step the two closest items/clusters are merged and the dissimilarity between two clusters is measured as the distance between the two closest members. Both methods result in a series of merged clusters, and it is up to the researcher to decide which number of clusters is appropriate. This can be done by examining a dendrogram, or hierarchical tree diagram (Figure 8). The dendrogram depicts each successive merging step through the lines used to join items (cases). The horizontal distance of the line indicates the distance between the two merged clusters. Therefore, we want to choose the number of clusters that results in the smallest horizontal lines connecting the members, indicating that the members are quite close, and the largest horizontal lines connecting the identified clusters, indicating the clusters are far apart. In Figure 8 it appears that selecting three clusters will accomplish this goal.

If a dendrogram does not present an obvious choice of groups, it is sometimes useful to try a different linkage method to see if it will produce more distinct groups. As this process demonstrates, choosing the appropriate linkage method and number of groups is a subjective judgment made by the researcher. This is the reason that cluster analysis is considered exploratory in nature. However, there are statistical tests that can also be used to validate the selected number of clusters. See the references identified at the end of this section for details on these procedures. Once the appropriate number of clusters is identified, each item is assigned to a cluster and further analysis can be performed on each cluster (group).

*Drawing Conclusions* Before drawing conclusions as to the results of a cluster analysis, we first determine if the clusters are meaningful and useful. Examining the dendrogram gives a good indication of whether or not the groups created are distinct. If they are not distinct, it is unlikely that the groups will be useful. Another way is to examine two- and three-dimensional scatterplots of the measures used to create the groups using a different symbol or color to represent items in each group. If the items form distinct visual clusters, it is an indication that the grouping is good. After confirming visually that the groups are distinct, it is also useful to use the statistical methods described previously to compare the groups on the measures used to create the groups. This provides statistical evidence that the groups indeed differ from each other on these measures. Once we are confident that the groups are meaningful, it is often interesting to compare the groups on measures that were not used to create the groups. This can sometimes give insight into complex relationships between

Rescaled distance cluster combine

**Figure 8**   Dendrogram from cluster analysis.

measures used in cluster analysis and other measures that might lead to interesting directions for further research and analysis.

### 4.2.3   Examining and Modeling Relationships

In previous sections we have focused on examining and in some cases creating groups. However, frequently, researchers are interested in examining relationships between certain measures, independent of specific groups. For example, a researcher might want to examine the relationship that several independent measures have with a dependent measure. Alternatively, we might want to examine relationships among independent variables to determine if some redundant variables can be excluded from future experimental designs and/or analysis. Although a number of advanced techniques for modeling performance are presented in Part 6, the simple modeling methods presented here focus on understanding and characterizing relationships among a number of measures. In fact, the insights gained through these simple modeling methods can inform the development of more complex models.

***Correlation Using Pearson and Spearman Coefficients***   Correlation is used to examine the relationship between two ordinal and/or interval/ratio measures. Correlation measures are used to examine the question: What is the degree of relationship or association between two measures? Correlation analysis is used to determine the strength of the relationship between the two variables—it does not imply causality in the relationship. Two commonly used measures of correlation are the Pearson product–moment coefficient, a parametric measure used for interval/ratio data, and the Spearman rank-order coefficient, a nonparametric measure used for ordinal data.

*Assumptions*   Both the Pearson and Spearman tests assume that the data used comprise a random sample. The Pearson coefficient additionally assumes that both variables use an interval/ratio scale and that the two variables have a bivariate normal distribution. In a bivariate normal distribution, both variables and the linear combination of the variables are normally distributed. The latter half of the assumption means that the Pearson coefficient assumes that the relationship between the two variables is linear.

*Methods and Results*   The Pearson coefficient examines the degree to which a linear relationship exists between the two measures of interest. The coefficient ($r$) ranges from −1 to 1 and the absolute value of $r$ ($|r|$) is an

indicator of the strength of the relationship. The closer $|r|$ is to 1, the stronger the relationship between the two variables. The sign of $r$ indicates the direction of the linear relationship, with positive values indicating a direct relationship and negative values indicating an inverse relationship. Here, $r^2$ represents the proportion of the variance in one measure accounted for by the other measure. When using the Pearson coefficient, create a scatterplot of the two variables to make sure that the assumption of a linear relationship holds. If a curvilinear relationship exists, $r$ will be 0 even if a relationship between the two variables does actually exist. Additionally, large sample sizes are best for this analysis. When small sample sizes are used, several factors, such as the presence of outliers and restrictions on the range of one of the variables, can distort the value of $r$. For this reason, in experiments with a small number of observations, even if $r$ is large, the $p$-value may indicate that the correlation is not significant. Conversely, in an experiment with a large sample, the $p$-value may indicate a significant correlation even though $r$ is relatively small.

In contrast to the Pearson method, Spearman's rank-order coefficient determines the degree to which a monotonic relationship exists between the two variables rather than a linear relationship. The Spearman coefficient accomplishes this by examining the relationship between two ordinal variables by analyzing the ranks of the two variables. Each participant is ranked on each variable, and the coefficient ($r_S$) is calculated based on the difference in the ranks for each participant. Once $r_S$ is calculated, the interpretation of the correlation coefficient and $p$-value are the same as the interpretation using the Pearson coefficient ($r$).

*Drawing Conclusions*   To draw conclusions, first look at the $p$-value and correlation coefficient ($r$). If $p$ is large, it does not necessarily indicate that no relationship exists since, as mentioned previously, $p$ is sensitive to the number of observations. For example, when using the Pearson coefficient, if $p$ is large, $r$ is large, and the number of observations is small, it might be advisable to collect more data. The additional data would make $r$ less vulnerable to distortions and reduce the threshold used to calculate $p$. In the case where $p$ is small enough to be declared significant, you must still examine $r$ to determine the strength of the relationship. As mentioned previously, Cohen (1988) provides suggestions for interpreting the size of a correlation effect based on $r$: small effect ($0.10 \leq r < 0.30$), medium effect ($0.30 \leq r < 0.50$), and large effect ($r \geq 0.50$). For an example of correlation analysis, see analysis 1 in the case study presented later in Figure 14.

*References for further details:* Kutner et al. (2004), Sheskin (2007), Lomax (2007).

**Linear Regression**   Linear regression is used to examine the effect that certain measures (predictors) have on a dependent measure when the dependent measure consists of interval/ratio data. Linear regression models predict the value of the dependent measure based on the values of predictors. A linear regression explores two primary questions: (1) What effect do the predictors

examined have on the dependent measure? (2) Given a set of values for the predictors, what is the value predicted for the dependent measure? For example, we might use linear regression to examine the factors that influence task completion time for a computer task. The measures used as predictors may be of any measurement type, but nominal data must be recoded to use a series of 0–1 indicators, where 1 indicates that a given category is present. For example, if job type is a predictor with three possible values (administrative, managerial, engineering), create three new variables, one for each job type, and assign a 1 to the variable representing the participant's job type and 0 to the remaining two variables. These three variables should be used in the analysis instead of the original nominal variable. There are two forms of linear regression: simple linear regression, which uses only one predictor in the model, and multiple linear regression, which includes multiple predictors.

*Assumptions*   Linear regression is based on a general linear model and therefore must meet the assumptions of that model. The first assumption is that the relationship between the predictors and the dependent measure is linear. This assumption can be validated by examining a scatterplot of the data and ensuring that the plot resembles a straight line. If the scatterplot between a predictor and the dependent measure is curvilinear and resembles an upright or inverted U, linear regression may still be used if both linear and quadratic components ($X$ and $X^2$) are included in the model. Additionally, multiple linear regression assumes that the predictors are *not* highly correlated. When two or more predictors are correlated, multicollinearity exists and this causes the regression model to be imprecise. There are several tests for multicollinearity; see Kutner et al. (2004) for more details. When multicollinearity exists, drop redundant predictors from the model or use the data reduction techniques discussed in Section 4.3 to develop a set of independent predictors based on the predictors correlated.

The next set of assumptions is related to the error terms, or residuals, of the model. The residuals are calculated by subtracting the observed value of the dependent measure from the value predicted. The linear model assumes that residuals are independent and randomly distributed. It also assumes that at each value of a predictor ($X$), the error terms are normally distributed with a mean of zero and, for all values of $X$, the variance of the error terms is the same (homogeneity of variance). To check several of these assumptions, examine scatterplots of the residuals. If there is a pattern to the residuals, it indicates that they are not random. This usually means that the model is a bad fit. This can be caused if predictors are missing from the model or if the underlying relationship between the dependent variable and one or more of the variables is not linear. If the distribution of points is not centered around zero, it indicates that the mean of the errors is not zero and that the model is consistently overestimating (mean $< 0$) or underestimating (mean $> 0$) the value predicted. If the scatterplot is funnel shaped, as illustrated in Figure 9, it indicates that the error variances change with the value of $X$, and
**Figure 9** Residual plot where the homogeneity of the variance assumption is violated.

**Figure 10** Good residual plot that meets the error distribution assumptions.

the homogeneity of the variance assumption is violated. In contrast, Figure 10 depicts a good residual plot that supports the assumptions that errors are randomly distributed with mean zero and with homogeneous variance. When the homogeneity of the variance assumption is violated, the violation can often be resolved by using a transformation of the dependent variable, as discussed in "Parametric and Nonparametric Tests" in Section 4.1.1.

To test the assumption that the error terms are normally distributed, create a normal probability plot of the residuals. If the points on this plot are in a straight line, the distribution of residuals is close to a normal distribution, as illustrated in Figure 11. When running the analysis, make sure that the option to create these plots is selected so that the statistical package will generate the residual graphs automatically as part of the linear regression analysis.

**Figure 11** Normal probability plot of residuals when error terms are normally distributed.

*Methods and Results*   Linear regression attempts to model the relationship between the dependent measure ($Y$) and a number of predictor measures or factors ($X_i$). Multiple regression generates a model in the following format: $Y = \beta_0 + \beta_1 X_1 + \cdots + \beta_i X_i$. In linear regression, the goal is to develop a parsimonious model with sufficient explanatory power. In other words, we want to gain the strongest match between the model and the data with the least number of predictors. A model with fewer predictors is preferred because it is simpler to interpret and use. In general, the Pareto principle applies to model building—a small number of factors account for a large portion of the variability. Therefore, we can often reduce the size of the model without sacrificing a significant portion of its explanatory power.

Several methods may be used to build a model from the predictors, including forward elimination, backward elimination, stepwise selection, and best subsets. Stepwise selection and best subsets are generally the preferred methods. In stepwise selection the predictor that contributes most to the explanatory model is added to the model. This continues, and as additional predictors are added, the predictors added previously are checked to make sure that they are still significant given the addition of the new predictor. The process ends when all of the predictors in the model are significant and all predictors excluded from the model are not significant. In the best subset method of model selection, all possible model combinations are examined and compared using Mallow's $C_p$-statistic, which indicates the explanatory power of the model adjusted to account for the number of variables. This adjustment factor ensures that more parsimonious models will be favored over larger models when the explanatory power of both models is similar. When comparing $C_p$ statistics, choose a model with a $C_p$-value that is low and close to 1 plus the number of predictors.

After the model has been selected, run the linear regression for the model. The results of the regression include the coefficient and $p$-value for each predictor and an $r^2$ and adjusted $r^2$ for the model. These two values are indicators of the proportion (0–100%) of the variation in the data that is explained by the model, so large values of $r^2$ are desirable. The adjusted $r^2$ adjusts the $r^2$-value to penalize models with a larger number of variables; therefore, it is the preferred measure of model fit.

*Drawing Conclusions*   After selecting a model and running the linear regression, first examine the $p$-values for each predictor included in the model to ensure that all predictors are statistically significant. Look at the $r^2$- and adjusted $r^2$-values to ensure that the model's explanatory power is sufficient for the intended use of the model. "Sufficient" will depend on the intended use. For example, in a situation where the goal is to tightly control the dependent measure within a certain range of tolerances, a higher explanatory power may be required. Next, examine the residual plots to ensure that none of the assumptions have been violated. Also, in cases where the explanatory power of the model is low, examining plots of the residuals versus the possible predictor variables may provide insight into how to improve the model. A pattern in one of these plots might indicate that the linear model is not adequately capturing an underlying relationship. For example, if the residuals make a U-shaped pattern, including a quadratic component ($X_2^1$) in the model might improve the fit.

After validating that the model meets the necessary assumptions and has sufficient explanatory power, the model can be interpreted and applied. The coefficient for each predictor indicates the size and direction of the effect that a predictor has on the dependent measure. Be careful when comparing the coefficients of several predictors to understand their relative contribution to the dependent measure. Differences in the scales used to measure those factors can skew the comparison. For example, if predictors A and B are in the model of dependent measure C and the range of values for these measures are 1–5, 100–1000, and 0–1000, respectively, A's coefficient may be larger than B's simply because of the difference in scale. To make comparisons of the size of the effect of several factors when different scales are used, it may be useful to run the regression using standardized values of the predictors. However, interpretation of the coefficient in terms of the effect of an incremental change in a given factor can be more complex and less generalizable (Lomax, 2007), since the standardized value is based on the variance of the specific sample.

Note that when drawing conclusions about the effects of predictors, it is best to limit them to the range of values examined for each predictor. It can be dangerous to extrapolate these trends to values far outside the range observed in the experiment since the underlying relationship between the predictor and the dependent measure may differ when the predictor is at levels extremely different from those examined.

*Effects of Measurement Errors on Linear Regression*   Measurement errors can also negatively impact ergonomics studies utilizing both simple linear regression and multiple linear regression. Remember from the previous section on linear regression assumptions that it assumes that at each value of a predictor ($X$) the error terms are normally distributed with a mean of zero and, for all values of $X$, there is homogeneity of variance. Liu and Salvendy (2009) point out that when $X$ is measured with errors, it causes the slope coefficient to be biased toward zero. For further information on measurement errors in linear regression see Liu and Salvendy (2009), Carroll and Stefanski (1995), and Fuller (1987).

**Logistic Regression**   A logistic regression is used to examine the effect that certain measures (predictors) have on a dependent measure when the dependent measure is nominal/categorical. Frequently, the dependent measure is binary (e.g., yes/no, true/false, 0/1). Conceptually, logistic regression is similar to linear regression except that, instead of modeling and predicting the value of the dependent measure, logistic regression models

the likelihood that the dependent measure will have a certain value (e.g., yes). Logistic regression explores two primary questions: (1) What effect do the predictors have on the probability that the event represented by the dependent variable will occur? (2) Given a set of values for the predictors, what is the probability that the event will occur? For example, a logistic regression could examine the likelihood that a worker will complete a task successfully given a certain set of tools and worker characteristics.

*Assumptions*   Logistic regression assumes that the dependent variable is categorical/nominal.

*Methods and Results*   The logistic regression analyzes the data to provide a model of how each predictor ($X_i$) affects the probability ($\pi$) that the event (e.g., Y = "yes") will occur. The model takes the format

$$\pi = \frac{e^{\beta_0 + \beta_1 X_1 + \cdots + \beta_i X_i}}{1 + e^{\beta_0 + \beta_1 X_1 + \cdots + \beta_i X_i}}$$

where $X_i$ is the value of the $i$th predictor and $\beta_i$ is the coefficient representing the effect that the $i$th predictor has on the likelihood ($\pi$) that the event will occur. Note that the equation representing the power to which $e$ is raised is the same as the equation used in a linear regression. As in linear regression, the goal in building a logistic regression is to create a parsimonious model with sufficient explanatory power. Therefore, the first step is to determine which of the available predictors to include in the model. Although several methods of variable selection are available, the backward stepwise method is used most frequently (Kutner et al., 2004; Field, 2005). This method begins by including all predictors in the model and at each step removes the predictor that has the smallest effect on model fit. This continues until all the predictors in the model meet an established threshold of significance, typically $p \leq 0.05$. Once the model is developed, examine the model's chi-squared statistic, derived from the likelihood ratio, to ensure that the model has an adequate fit to the data.

When using a statistical package to complete a logistic regression, the model output includes the estimated coefficient and odds ratio for each factor and a $p$-value indicating the level of significance of that factor as well as the model chi-squared statistics. It also reports a classification table that reports the number of cases in which the value predicted matched the value observed and the percentage of correct classifications. It is also useful to have the package save the predicted probability that the event will occur and the predicted value of the dependent measure, since these can both be used to examine how well the model fits the data. The predicted value is determined by comparing the predicted probability to an established threshold (usually, 0.50). If the probability is greater than the threshold, the predicted value is "yes," the event will occur; otherwise, it is "no."

*Drawing Conclusions*   The first step in drawing conclusions is to determine if the model has an adequate fit. If the model chi-squared statistics has a

**Figure 12**   ROC curve for a logistic regression.

sufficiently small $p$-value and the percentage of correct classifications is high, we can conclude that the model has an adequate fit. Unfortunately, in logistic regression there is no value equivalent to the $r^2$ used in linear regression to estimate the degree of fit between the model and the data. However, when the response being modeled is binary (yes/no or 0/1), a receiver operating characteristic (ROC) curve may be used to estimate the degree of fit. An ROC curve (Figure 12) indicates how well the model predicts the dependent measure by comparing the true positive rate (i.e., predicted = yes and actual = yes) to the false-positive rate (i.e., predicted = yes and actual = no). If chance were used to predict the dependent variable, the prediction would be correct on average 50% of the time. The diagonal line in the graph indicates this chance fit between the predicted and actual values. The area under the ROC curve represents the fit of the model. Therefore, if there is substantially more area under the ROC curve than under the diagonal line, the fit is good. A statistical test is used to test whether the area under the curve is significantly different from 50% and provide a 95% CI on the area. The closer the area is to 1 (100%), the better the model fit.

Once the model is deemed adequate, the results of the model may be interpreted. The model may be used for prediction by plugging in a set of values for the factors in the model to determine the likelihood that the event will occur given those values. Alternatively, the model coefficients for each predictor may be examined to determine that predictor's effect size. Unfortunately, this is not as straightforward as effect estimation in linear regression, since in logistic regression a unit increase in $X_i$ multiplies the odds of the event by $e^{\beta i}$. Therefore, to interpret the effect, we examine the odds ratio ($e^{\beta i}$), which is the ratio of the probability of the event with a unit increase in $X_i$ to the probability of the event without the unit increase in $X_i$. The odds ratio should be compared to a baseline of 1 (100%). So an odds ratio of 1.25 indicates a 25% increase in the event's likelihood, and an odds ratio of 5 would indicate

a fivefold increase in the odds. Conversely, an odds ratio of less than 1 would indicate that an increase in $X_i$ reduces the likelihood of the event. By examining the odds ratio for each factor in the model, we can identify those factors that have the greatest positive and negative impact on the dependent variable being examined.

## 4.3   Data Reduction Techniques

Several of the methods described in Section 4.2 assume that the measures being examined (e.g., predictors in linear regression, dependent measures in MANOVA) are independent of each other. However, frequently in human factors research a number of the collected measures are correlated but capture different aspects of a given phenomenon. This is often the case in complex concepts such as decision satisfaction, where it is difficult for one measure to capture every facet of the concept. When examining these correlated measures independently, it can be difficult to isolate the independent components of the phenomenon that are driving the underlying variation in those measures. When this is the case, data reduction techniques can be useful to isolate those independent components that explain the variation, thereby reducing the number of measures to be analyzed and aiding in interpretation of the data.

For example, data reduction techniques are often used to examine questionnaire data, as demonstrated in a study by Sainfort and Booske (2000) which examined postdecision satisfaction. See their case study in Figure 14. In this study, after completing a decision task, participants were asked to complete a questionnaire related to their satisfaction with their decision. The questionnaire presented 10 statements that addressed several aspects of decision satisfaction (e.g., "My decision is sound," "More information would help") and asked the participant to rate each statement on a scale from 1 (strongly disagree) to 5 (strongly agree). Obviously, the answers to a number of these statements are expected to be correlated. By examining the correlations among the measures and using factor analysis to isolate the underlying constructs affecting the variation in answers, Sainfort and Booske were able to identify four underlying dimensions of decision satisfaction: self-efficacy, satisfaction with choice, usability of information, and adequacy of information. Thus, in this example, factor analysis enabled the researchers to reduce a set of 10 highly correlated measures to four relatively independent measures and, as a result, gained insight into the underlying structure of the highly abstract concept of postdecision satisfaction.

In this section we examine two data reduction techniques: principal-component analysis and factor analysis. These two methods are conceptually very similar but differ in the mathematics used to accomplish the results. However, research has demonstrated that the two methods yield highly similar results, especially when sample sizes are large (Fava and Velicer, 1992). In general, sample sizes of at least 160 are recommended, but in some cases larger sample sizes (e.g., 300 or more) are necessary to ensure stability of the components

(Guadagnoli and Velicer, 1988). These two data reduction techniques are often not an end in and of themselves. Typically, the new component/factor variables created as a result of this analysis are used as input for other analysis techniques discussed in previous sections, such as regression or group comparisons.

### 4.3.1   Principal-Component Analysis

The primary objectives of principal-component analysis (PCA) are to reduce the dimensionality of a data set by discovering the true dimensionality of the data and identify new and meaningful underlying variables that represent the true dimensionality (Johnson, 1998). PCA is typically used as an exploratory technique to help researchers understand the data, especially the correlation structure of the data. PCA results in a set of new variables, principal components, which are uncorrelated and account for as much of the variability in the original data as possible.

*Methods and Results*   The focus of PCA is to explain the variability in the measures through the components identified. To accomplish this, PCA produces an orthogonal transformation of the measures into a number of principal components, which constitute a linear combination of the measures being examined and depend solely on the covariance of those measures. The method begins by identifying the component that accounts for the largest portion of the variation, as indicated by the eigenvalue. This continues, with each component accounting for less of the overall variation.

One of the first steps in PCA is determining the appropriate number of components. In other words, how many "true" dimensions are represented by the data? There are several methods for determining this number, although it is more of an art than a science. The first method is to establish a minimum threshold, usually 1, for a component's eigenvalue. Alternatively, we could examine a scree plot, which plots the eigenvalues of each component as illustrated in Figure 13. In the scree plot, look for the cutoff at which the eigenvalues level off or create an elbow. All components to the right of the elbow should be eliminated, since they add little additional explanatory power. Based on this method, for the results in Figure 13, we would keep components 1 and 2 and eliminate the others. The third method for selecting the appropriate number of components is to establish a threshold for the amount of variability in the original data that is accounted for by the principal components and then select the minimum number of components that meet this threshold. For example, if a researcher wanted to account for 80% of the variation in the original data, and the first four components accounted for 50, 25, 10, and 8% of the variation, respectively, the researcher would use the first three components, which account for $50 + 25 + 10 = 85\%$ of the variation.

Once the principal components are identified and derived, the factor loadings are reported for each component. The $i$th principal component ($C_i$) for a given item is calculated based on the factor loading ($\beta_i$) and value ($X_{ij}$, where $j$ represents the item) of each
**Figure 13** Scree plot in PCA.

measure that loads on that component: $C_{ij} = \beta_1 X1_j + \beta_2 X_{2j} + \cdots + \beta_i X_{ij}$. The absolute value of the factor loading indicates the weight of that measure in calculating the component. Absolute values close to 1 are very important to the component. The sign of the factor loading indicates the direction of the relationship between the component and original measure; a positive value indicates that an increase in the measure will increase the value of the component score. These factor loadings are used to calculate principal-component scores for each item based on the values of the original measures. After these values are calculated, they can be used for subsequent analysis. Frequently, principal components are used as inputs for cluster analysis, discriminant analysis, and multiple linear regression.

*Drawing Conclusions*     Although many researchers use the results of PCA as input to additional analyses, there are several interesting conclusions that can be made from the results of PCA themselves. These conclusions center around understanding the true dimensionality of the data. For example, if the percentage of variability accounted for by the components selected is sufficiently large, the number of components identified can be interpreted as the number of true dimensions in the construct being measured by the data. By examining the factor loadings for each measure that contributes to a component, we can determine if that component, which represents a dimension of the data, has any interpretable meaning. It is easiest to interpret the components when a measure has a high factor loading for one component but not on any of the others and when the combination of measures that have a high loading are conceptually or logically related in some way. For example, if we completed a PCA on a number of measures that contribute to productivity and one component had high factor

loadings for a worker's education level, number of training certifications, and number of years on the job, we might interpret this component as the worker's knowledge level. Note that in many cases the resulting principal components may not be interpretable. When this is the case, it is often worthwhile to complete a factor analysis on the data set as well, especially since functionality in the current generation of statistical packages makes running either analysis relatively quick and easy.

*References for further details:* Johnson and Wichern (2007), Johnson (1998).

### 4.3.2 Factor Analysis

Conceptually, factor analysis (FA) and PCA are quite similar. Both methods examine the true dimensionality for a large set of correlated measures. However, unlike PCA, which does not depend on an underlying model, FA depends on a reasonable statistical model. Also, FA is focused on explaining the covariance and correlation among the measures, which is in contrast to PCA, which focuses on explaining the variability of the measures. These are subtle distinctions from a conceptual standpoint, but they affect the mathematics used to develop the components, or factors, that result from each method. In PCA, the components identified are linear combinations of the measures. In contrast, in FA, the measures are linear combinations of the factors identified. In most cases, the results of the two methods are highly similar, but sometimes FA results are more interpretable as a result of factor rotation, as discussed next. As with PCA, the output of FA is a new set of uncorrelated measures or underlying factors.

*Methods and Results*     Similar to PCA, FA analyzes the variance or covariance of the measures being examined to identify factors (components) that account

for most of the variability in those measures. However, in FA, several different methods can be used to estimate the factors. Guidelines as to which method is best are relatively vague, but two frequently used methods are principal factor, which is similar to PCA, and maximum likelihood, which should only be used to analyze multivariate normal data. As in PCA, the researcher must determine the number of factors to include in the analysis. The criteria used in PCA, which are used to examine the eigenvalues, are typically used as a starting point, although additional guidelines can be used. For example, Johnson (1998) identifies minimizing Akaike's information criterion (AIC) or Schwarz's Bayesian criterion (SBC) as objective rules that can be used to determine the ideal number of factors.

In factor analysis, the set of factors and their factor loadings generated through the initial analysis are not unique. By multiplying the resulting factor loadings by an orthogonal matrix, the factor loadings can be rotated in space. What exactly does this mean? We won't dwell on the mathematics, but conceptually, rotating the factor loadings obtains a mathematically equivalent set of factor loadings that may be easier to interpret. In other words, we as researchers can look for the rotated set of factor loadings that can be interpreted most meaningfully. Note that some statisticians and researchers view this as a criticism of FA, since exactly which rotation is "meaningful" is open to interpretation; however, many people view this as an advantage since it enables the resulting factors to be more easily interpreted and applied (Johnson, 1998).

Several methods are available for rotating the initial factor loadings. Factor rotation methods have two goals. The primary goal is to rotate the factor loadings for each factor so that all measures either load heavily on that factor (i.e., have an absolute value near 1) or load very little on it (i.e., have an absolute value near zero). The secondary goal is for each measure to load heavily on only one factor. Meeting these goals typically simplifies interpretation since the measures that weigh heavily on a factor are isolated and each measure (ideally) contributes significantly to only one factor. There are two classes of rotation methods: orthogonal rotation methods, which maintain the independence between the identified factors, and oblique rotation methods, which are appropriate only when the factors are not assumed to be independent. In general, orthogonal methods are recommended over oblique rotation methods unless there are theoretical grounds for assuming that the factors are not independent. Of the orthogonal rotation methods available, varimax is used most frequently

*Drawing Conclusions* The conclusions drawn from FA are almost identical to those drawn in PCA: Researchers may use the resulting factors from FA as input to additional analyses and/or draw conclusions about the true dimensionality of the data. The number of components identified can be interpreted as the number of true dimensions in the construct being measured by the data, and by examining the factor loadings for each factor, we can determine if that factor has any interpretable meaning. Because FA uses factor rotation to

ensure that factors have high factor loadings for a subset of measures and low factor loadings for the remaining measures, meaningful interpretation of the factors is usually easier than in PCA. (For example, see the results highlighted in the case study in Figure 14.) However, because of the variety of methods that can be used to determine the number of factors, estimate the factors, and rotate the factors to find meaningful factor loadings, factor analysis is fairly subjective. As such, be prepared to support your conclusions with tests to ensure validity and reliability. When presenting your conclusions, provide sound theoretical support from related work in the literature. Furthermore, validity can be examined by comparing the resulting factors to related outcome measures not used in the FA. Reliability can be examined by completing the same analysis on a similar data set and comparing the number of factors and factor loadings that result from each data set. See the case study in Figure 14 for an example of how the researchers established the validity and reliability of their results.

*Effects of Measurement Errors on Factor Analysis* Measurement errors in correlations can result in the relationship between $X$ and $Y$ to be underestimated or attenuated (Liu and Salvendy, 2009). Because factor analysis is examining intercorrelations, it has similar results from errors in measurement. If measurement errors occur with variable $X_i$, then the correlations between $X_i$ and other variables will be deflated, causing the contribution of the first few important factors to decrease (Liu and Salvendy, 2009). For further information regarding measurement errors in factor analysis, see Liu and Salvendy (2009).

*References for further details:* Johnson and Wichern (2007), Johnson (1998).

# 5  ANALYSIS OF UNSTRUCTURED OUTCOME DATA

It is apparent that a wide variety of methods are available to analyze structured outcomes. But what can be done with all of the unstructured data that are generated? Unstructured outcomes are generated from a number of research methods. For example, unstructured outcomes are the results of open-ended interview or survey questions, observations from the field, observations during an experimental task, documents, and transcripts from video recording and think-aloud and other verbal protocols. These data are rich in detail, and unlocking the themes and trends from these data can provide invaluable insight into the topic being researched.

Unfortunately, unlocking these secrets can be quite challenging, especially when dealing with large amounts of data. Researchers usually begin by pulling out the data that are relevant, where relevance is determined by the nature of the data collected and the research questions to be answered (Wixon, 1995). Once the relevant data are identified, several techniques can be used to develop and communicate findings from unstructured data. In the following sections we discuss methods that can be used to accomplish these analysis objectives for unstructured data: (1) impose structure on unstructured data using coding and classification, (2) provide

*Research Objectives*: Given the proliferation of decision aids used to help individuals make complex, value-laden decisions, there is a need for reliable, objective methods for evaluating the effectiveness of these decision aids. In this study, Sainfort and Booske (2000) develop the decision-attitude scale, which is used to assess the decision maker's satisfaction after making a decision.

*Data Collection Method:* Participants examined information on health insurance plans using a computer-based decision aid. Participants selected a plan at two points in time: first after viewing a minimal amount of information about the plans, and again after having the opportunity to view extensive information about each plan. At each decision point, participants completed the decision attitude survey consisting of ten statements related to various aspects of decision satisfaction. Participants rated whether or not they agreed with each statement using a scale from 1 (strongly disagree) to 5 (strongly agree).

*Analysis 1: Examine relationships among decision satisfaction answers*
Test: Pearson's Correlation
Results: Correlation coef cients

| | | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | I had no problem using the information | 1.00 | | | | | | | | |
| 2 | I am comfortable with my decision | 0.50 | 1.00 | | | | | | | |
| 3 | The information was easy to understand | 0.64 | 0.39 | 1.00 | | | | | | |
| 4 | I wish someone else had made the decision for me | 0.10 | 0.07 | 0.09 | 1.00 | | | | | |
| 5 | It was diffcult to make a choice | 0.40 | 0.52 | 0.43 | 0.13 | 1.00 | | | | |
| 6 | I am satisfied with my decision | 0.54 | 0.70 | 0.46 | 0.07 | 0.50 | 1.00 | | | |
| 7 | My decision is sound | 0.41 | 0.57 | 0.40 | 0.14 | 0.49 | 0.61 | 1.00 | | |
| 8 | More information would help | 0.18 | 0.38 | 0.31 | 0.05 | 0.33 | 0.37 | 0.37 | 1.00 | |
| 9 | My decision is the right one for my situation | 0.29 | 0.46 | 0.35 | 0.12 | 0.40 | 0.49 | 0.57 | 0.40 | 1.00 |
| 10 | Consulting someone else would have been helpful | 0.20 | 0.30 | 0.37 | 0.04 | 0.31 | 0.33 | 0.22 | 0.49 | 0.32 |

Conclusions: Examining the correlation coef cients among the responses to each statement, most of the responses are correlated, with the exception of statement #4, which appears to be relatively independent of the other responses. Because of the correlations among the response, the researchers' next step was to use factor analysis in order to gain insight into the underlying factors driving the variation in these responses.

*Analysis 2: Exploring underlying factors of the correlated responses*
Test: Factor Analysis. Response #4 was excluded from analysis since the correlation indicated it is independent. To ensure the reliability of the scale, the factor analysis was performed on the responses obtained at the rst decision point. A second factor analysis was completed using the responses obtained at the second decision point to ensure that comparable factors and factor loadings resulted from both data sets.
Results: Three factors, accounting for 71% of the total variation, were identi ed. As an example, the factor loadings for factor 1 are provided below, sorted on the factor loadings. Factor 1 had an Eigenvalue of 4.37 and accounted for 48.6% of the variation.

| *Response* | *Loadings on Factor 1* |
|---|---|
| 7. My decision is sound | 0.828 |
| 2. I am comfortable with my decision | 0.741 |
| 9. My decision is the right one for my situation | 0.729 |
| 6. I am satisfed with my decision | 0.721 |
| 5. It was diffcult to make a choice | 0.574 |
| 8. More information would help | 0.364 |

| *Response* | *Loadings on Factor 1* |
|---|---|
| 1.  I had no problem using the information | 0.312 |
| 3.  The information was easy to understand | 0.197 |
| 10.  Consulting someone else would have been useful | 0.082 |

Conclusions: Based on the results, the first five responses (items 7, 2, 9, 6, & 5) factor most heavily on factor 1(loading > 0.55). These items also had much lower loadings on the other two factors. The remaining four factors, all had low loadings on this factor (loading < 0.4) and high loadings on one of the two other factors (loading > 0.75 for one of the remaining factors and loading < 0.3 on the remaining factor). Considering the items that loaded heavily on factor 1, the researchers concluded that factor 1 represents 'Satisfaction with Choice'. The remaining two factors had similar interpretability, representing 'Usability of Information' and 'Adequacy of Information'.

Note: In this study, a number of tests were completed to ensure the validity of the identified factors in the decision satisfaction scale. In the interest of brevity, only the results from one test are highlighted here.
Test: Paired t-test
Results: Paired t-tests examined difference on each of the factors between the time of the first decision point and the second:

| *Factor* | *t-statistic* | *p-value* |
|---|---|---|
| Satisfaction with Choice | − 3.461 | < 0.01 |
| Adequacy of Information | − 9.619 | < 0.01 |
| Usability of Information | − 1.608 | 0.11 |

Conclusions: Because additional information was made available to participants after the first decision point, intuitively, one would expect participants to be more satis ed with their choice and the adequacy of the information at the second decision point Results indicate that participants were indeed more satis ed with their choice (p< 0.01) and the adequacy of the information (p< 0.01) at the second decision point. This is indicates that the scale is sensitive enough to detect the differences in these two aspects of decision satisfaction. Usability of information had only a marginal difference (p=0.11), which, again, makes intuitive sense because though more information was presented between decision points one and two, a similar presentation format was used, so information usability would not necessarily improve. These results led the researchers to conclude that the scale had adequate discriminant ability to detect changes over time attributed to the presentation of additional information.

## 5.1   Content Analysis and Coding

Content analysis, or coding, is used by researchers to understand and summarize unstructured data. In content analysis, qualitative unstructured data are examined systematically to identify key themes and, subsequently, to classify events, observations, and answers into one or more of those themes or categories. Although there are subtle distinctions between coding and content analysis, we avoid those semantic discussions for now and focus on methods of completing these types of analysis, which are, for the most part, the same. Content analysis and coding are used in a variety of fields, especially in market research and the social sciences, where more descriptive research methods are frequently used. In human factors, coding has been used, for example, in incident and accident analysis and to provide structure to outcomes from verbal protocols such as think-aloud and other unstructured outcomes gathered during a research study.

When completing content analysis, the goal is to apply the coding scheme to the data objectively and systematically. The coding scheme is, in effect, the set of categories or themes to which an event/observation/ answer may belong and the rules used to classify a

given item into the appropriate category or theme. If the coding scheme is not applied consistently, the reliability of the coded data, and as a result the validity of the research results, is questionable. Therefore, close attention must be paid to the process used to code the data to ensure the reliability of the results.

### 5.1.1   Coding Process

The following steps comprise the coding process. For purposes of simplicity, an example of coding responses to an open-ended survey question is used. However, the same method could be applied to coding verbal protocols, observation notes, or other forms of unstructured data. Throughout this process, be on the lookout to avoid systematic biases that can result from inconsistent use of the coding scheme.

1.   Develop the coding scheme.
   a.   If there is an appropriate existing coding scheme that has been validated and used in the literature for the content being analyzed, use that coding scheme to improve the external validity and comparability of the results. For example, coding and classification schemes are available for analyzing certain types of communication. If

an appropriate existing scheme is available, skip to step 2.

b. To develop a specific reliable coding scheme, first examine the responses from a representative sample of the surveys. If there are only a small number of surveys, examine all of the responses.

c. Based on knowledge of the actual responses and research objectives, identify a set of categories for classifying responses. Design the categories such that minimal information is lost in the coding. Also, design the categories to be as distinct from each other as possible to reduce confusion in classification.

d. Establish definite rules and criteria for assigning a response to a category. Provide examples to clarify complex rules, especially when coding requires a judgment on the part of the coder. (For example, assigning a rating of "level of understanding" based on a participant's response requires more coder judgment than that needed for coding a fact-based response such as assigning a job category based on the participant's job title.) Defining clear rules for assigning responses to categories is *crucial* to ensuring intercoder reliability.

2. Establish a coding protocol.

a. Determine the number of coders. At least two coders should be used so that intercoder reliability can be assessed. For large data sets, more than two coders may be needed.

b. Recruit the coders. If possible, people with experience in content analysis and with relevant research content knowledge should be used.

c. Define the coding protocol, which should include how many responses each coder will code, how questions regarding coding of questionable responses will be resolved, how coding will be validated, and how differences in coding will be resolved.

3. Test and revise the coding scheme.

a. Using a small sample of responses, preferably not the same sample as that used to establish the initial coding scheme, test the coding scheme. If any categories appear too broad or narrow, adjust the coding scheme as needed. Also, if any of the classification rules are unclear, revise them as needed to ensure that they will be applied consistently.

4. Train the coders on the coding scheme and coding protocol. Allow them to practice with examples and to ensure that they have an adequate understanding of the coding scheme.

5. Code the responses.

a. Assign the appropriate number of responses to each coder. For small samples, have each coder code all responses. For larger samples, make sure that a representative sample of the responses is coded by multiple coders so that intercoder reliability can be assessed.

b. The primary researcher or a coding supervisor should resolve any questions that arise during the coding. Any clarifications should be communicated to *all* coders, so that coding will be consistent among all coders.

c. The primary researcher or a coding supervisor should spot-check a sample of the responses to ensure that they are coded properly. Any problems identified in the coding should be resolved as quickly as possible to prevent the need to recode responses.

6. Assess intercoder reliability using one of the methods described in Section 5.2.3.

## 5.1.2 Improving Intercoder Reliability

In their study of coder variability, Kalton and Stowell (1979) make several observations and recommendations intended to reduce the amount of variability in coding among coders. Considering and applying these findings when designing and executing coding schemes can improve intercoder reliability:

- When constructing coding frames, take into account the actual responses so that those responses can be more readily mapped to the codes.

- When constructing coding frames, limit the use of catch-all codes (e.g., "other"), since these codes tend to be applied unreliably. Instead, try to use more clear-cut codes whenever possible.

- Be aware that fact-based codings, which are more objective, tend to have higher reliability than judgmental codings, which require more interpretation on the coder's part.

- Use training and strict supervision to ensure that coding frames are applied uniformly.

- Especially when judgmental codings are required, the researcher should stay closely involved with the coding operations (training, spot-checking coded data, etc.) to ensure that the codes are being interpreted and used as intended to support the research objective.

## 5.1.3 Assessing Intercoder Reliability

Intercoder reliability is the degree of match between the assigned codes of two different coders who apply the coding scheme independently to the same set of responses. Even when researchers take great care to ensure that there is adequate intercoder reliability, they should always assess and report intercoder reliability to ensure the credibility of their results. Unfortunately, many researchers omit this step, probably because there is relatively little agreement on the best way to assess

intercoder reliability. Frequently, researchers report the percentage of agreement among coders. However, the one thing that most content analysis researchers agree on is that this is not the best approach. Instead, estimates of intercoder reliability should include adjustments that correct for chance agreement among coders (Hughes and Garrett, 1990; Grayson and Rust, 2001). Consider, for example, a case in which two coders are coding data that can fall into one of two categories. By random chance, those two coders will agree 50% of the time. Therefore, the assessment of reliability needs to indicate that agreement between coders is better than agreement that would be achieved by random chance.

A number of methods for assessing intercoder reliability have been presented in the content analysis literature. All of these measures range from 0 to 1, with values closer to 1 indicating high intercoder reliability. Cronbach's alpha is an intraclass correlation measure frequently used to measure agreement using the ratio of the true score variance to the sum of the true score variance and the error variance. Other methods used frequently include Scott's pi, Krippendorff's alpha, and Cohen's kappa. These three measures are conceptually similar: They are calculated by taking the difference between the agreement observed between coders and the agreement expected using random chance and adjusted based on the agreement expected using random chance (the chance correction). They differ in how they calculate the chance correction. Cohen's kappa is sometimes criticized because in certain cases the maximum possible value of kappa is less than 1. Due to the assumptions made in Scott's pi and Krippendorff's alpha, they are appropriate only in cases where intercoder bias is assumed to be negligible.

Once the appropriate method of calculating intercoder reliability is selected, there are several aspects of intercoder reliability that should be examined, even though the overall reliability is the only thing that is usually reported. First, if there are more than two coders, examine the reliability of each coder. If one coder's reliability is significantly less than the others, it indicates that they may have been using the coding scheme inconsistently with the other coders. Next, examine the reliability of each code. This will highlight any codes that are used less consistently than the others. This may indicate that the rules for assigning responses to this category need to be clarified or the category itself needs to be redefined. For an even deeper assurance of coder reliability, examine the percentages of coders assigning responses to each code. This helps pinpoint where the discrepancies are that reduce the reliability of specific coders or codes. For example, is coder A assigning a disproportionate amount of responses to the "other" category? Is coder B underutilizing category 2? By identifying these discrepancies, appropriate steps can be taken to revise the coding scheme or provide additional training to the coders to improve the overall reliability of the results.

### 5.1.4   Using the Results

Once the coding is completed, the results are structured data, usually in the form of frequencies of occurrence for each category. These results in and of themselves may provide the answers to the research questions of interest. Otherwise, these structured data derived from the unstructured data may be used as input for one or more of the structured analysis methods described previously. In either case, when reporting results based on the coded data, be sure to report an overview of the coding method used and the intercoder reliability achieved so that other researchers can be assured of the validity of the results and conclusions.

*References for further details:* Krippendorff (2003), Hughes and Garrett (1990), Oppenheim (1992).

### 5.2   Figures and Tables

Summarizing unstructured data in an informative figure or table can also be an invaluable tool for communicating findings gleaned from unstructured data. In some cases, figures and tables are more effective than text for communicating certain types of information. They are most effective when combined with written documentation that complements (but does not duplicate) the content in the figure or table. Take, for example, the decision model for selecting the appropriate structured analysis method presented in Figure 2. This figure does a much better job of conveying in a clear and concise manner the methods presented in the chapter, their relationships, and the factors that go into selecting the appropriate method than a written description of that information could. The text in the chapter supplements the figure by providing additional details on each of the decision points and methods identified in the figure. The figure, in effect, provides readers with a map of the content presented, helping them understand the big picture up front before delving into the details of a specific method. Using a figure instead of a text description to present the decision factors and relationships between goals and methods shortens the chapter. Also, presenting the big picture of the content up front makes it easier for readers to understand the detailed material as they read it. Both of these factors combined (hopefully!) make the chapter easier to read.

The appropriate type of figure or table to use will depend on the type of unstructured data being summarized and the purpose and audience of the document (or presentation) in which the figure or table will be included. A wide variety of figures and tables can be observed in the human factors and other literature. Examples of the several useful types are:

- *Maps.* Maps of physical space are obviously effective for conveying information relative to existing and proposed workspaces. They can also be effective for conveying paths that worker and/or materials must follow in the course of a given task.
- *Concept Maps.* Concept maps are a physical representation of relationships between ideas or concepts in a knowledge space. In a concept map, concepts that are closely related conceptually are placed close to each other on the content map, and vice versa. Concept maps, in effect, present

the relationship between abstract concepts in a physical manner.

- *Flowcharts*. Flowcharts have many obvious uses, including conveying processes or a series of tasks, communicating information/material flows, and others.
- *Decision Models*. Decision models can be used to map out the steps in a decision process. They include decision points, decision factors, and related activities (e.g., data gathering) that are part of the overall decision process. In situations where multiple people are involved in a decision, the decision model may also indicate who is responsible at each point in the process.
- *Organization Charts*. Organization charts graphically illustrate members of an organization (people or suborganizations) and how they are related. These can be quite useful for depicting divisions of responsibility, chains of command, and communication channels.
- *Hierarchies*. Hierarchies are useful for presenting the breakdown of high-level concepts or groupings into lower level concepts or grouping. For example, task hierarchies are used to break high-level tasks into the steps required to complete that task.
- *Time Lines*. Time lines are useful for presenting a series of events that took place during research. They can also be effective at presenting a historical perspective on a particular domain of research or results of related research over time.
- *Literature Tables*. Literature tables are useful to summarize concisely the relevant literature related to a particular research study or meta-analysis.
- *Matrices*. Matrices are useful for summarizing data along a small number of dimensions. For example, a matrix could present communication patterns and topics by presenting people along two axes and using a symbol in the row−column square to indicate frequency or topic of communication between the two people.

It is left to the reader to determine which type of figure or table will best convey the information they have to present. However, when developing these tables and figures, think like a human factors researcher and design them to be easy to perceive and use. Use the following guidelines (adapted from Gillan et al., 1998) to present quantitative data in papers to improve the readability and usability of figures and tables:

- Design your figure or table to support your readers' cognitive tasks.
- Make sure that all labels and text are readable. Use a sufficiently large font size and high contrast between the background and text (e.g., white background, black text).
- Use clear, concise wording. Long words and phrases can clutter the display and make it difficult to read. Also, more concise wording enables the use of larger font sizes.

- Make all colors and symbols used to convey information clearly discernible from each other and convey their meaning clearly through a legend or key (if there are many symbols) or labeling (if there are only two or three symbols).
- Use symbols, colors, and other meaningful features consistently within a figure or table and, if possible, across all figures and tables.
- Consider how readers will perceive the figure or table.
  - Make the main point visible at first glance.
  - Attract the readers' attention to the most important features.
  - Use graphical techniques (line thickness, color, etc.) for emphasis.
- Eliminate clutter to improve visual searching of the figure or table.
- Place related items close to each other so that relationships between them are more readily apparent.

Whenever possible, use structures and presentation methods that are familiar to the user. For example, in flowcharts, adhere to the generally accepted meanings associated with different shapes.

## 5.3 Documentation

Research results are presented in document(s) that detail a study's findings. When large volumes of unstructured data are involved, documentation may be the only way to communicate and present those findings. However, especially in the case of unstructured data, it can be difficult to determine the appropriate scope, level of detail, and organization for documenting the findings. When writing, keep in mind that the goal is not to write the largest document possible, including every detail encountered in the unstructured research outcomes. Instead, as my fifth-grade English teacher instructed, the goal is to make it long enough to cover the subject but short enough to be interesting. The last thing you want to do is spend weeks writing a detailed work analysis only to have the 4-in.-thick monster end up as someone's doorstop. "Brevity is the soul of wit," and it saves you and your readers time and increases the readability of your document. So the primary question becomes how you can clearly and concisely present results based on unstructured outcomes.

There are a number of technical writing guides that help provide the answer to that question. Many of these guides (e.g., Gerson and Gerson, 2007; Reep, 2010) provide guidelines for specific types of documents, so we will not delve into those details here. However, it is useful to review more general principles and methods for good technical writing. These principles are helpful in determining which unstructured outcomes to focus on in the report and how to present those outcomes:

1. *Know the audience.* To communicate effectively with the audience through the document, you must first identify and understand the audience. A variety of audience characteristics

should affect how your present the material. For example, it is important to consider the audience's subject knowledge or level of expertise (Gerson and Gerson, 2007; Reep, 2010). Readers who are experts will probably need less detailed explanations of concepts and definitions than novice or lay readers. Also consider the reader's motivation or purpose for reading the document. This will have a strong influence on the appropriate scope, level of detail, and structure of the document.

2. *Define the objective(s) of the document.* Before writing the first word, define the objective(s) of your document. Beginning with these objectives in mind, it will be easier to organize and present the information needed to achieve those objectives. Without a well-defined audience and objectives, you may find yourself mired in a series of extensive reorganizations and revisions. In the case where there are multiple objectives, consider carefully if all of the objectives identified can be met in one document. If any of the objectives require presenting significantly different information or target drastically different audiences, it may be more effective to address those objectives in separate documents. Although writing two documents may take more time, it will be time well spent if it ensures that the documents will be read and your objectives achieved.

3. *Keep in mind general objectives in technical writing.* Gerson and Gerson (2007) recommend that writers strive for clarity, conciseness, accuracy, and organization in their writing. Writing for *clarity* helps ensure that the audience understands what they have read. To achieve clarity, provide answers to anticipated questions, provide specific details, and use terms that are easily understood by the audience. Writing *concisely* is beneficial, as it saves time for both the author and reader, but it can also improve comprehension of the material. Conciseness can be achieved by limiting sentence length, omitting redundancies, and avoiding wordy phrases. *Accuracy* entails ensuring that the document is grammatically, factually, and textually correct. Accuracy can usually be achieved by thorough proofreading. Be especially careful to check figures, equations, and references. The *organization* of the document is crucial to communicating effectively. Although the appropriate organization will depend on the purpose and content of the document, be sure that the information is organized and presented logically. One way to achieve this is to start by constructing an outline.

4. *Construct an outline.* An outline is a useful tool for improving the clarity, conciseness, and organization of the document. Whether informal or formal, outlines usually begin as a list of major topics and subtopics that will be addressed in the document. The list is transformed into an outline as the author(s) reorders the topics until they are presented in a logical order that facilitates understanding the material and achieving the stated document objectives. As Reep (2010) points out, developing an outline enables the author to see the document structure before he or she begins writing. It also enables the author to focus on presenting and explaining information as they write the rough draft, as opposed to organizing and writing at the same time, which often results in poor organization and redundant content presentation. When multiple authors are working on the same document, creating an outline has added benefits. By creating an outline, the authors discuss and agree on the overall content and structure before they begin writing. Then each author can draft his or her sections of the document in parallel, knowing how they fit into the overall content and structure. This greatly simplifies merging those sections later in the writing process.

5. *Use figures and tables.* When appropriate, use figures and tables, as discussed earlier, to convey information. In many cases, figures and tables can convey complex information or provide a big picture overview more clearly and concisely than can a written description. Gerson and Gerson (2007) provide useful criteria for using figures and tables in documents. Good figures and tables:

   - Are integrated with the text (i.e., text explains graphic, and vice versa)
   - Add to the material conveyed in the text but are not redundant with the text
   - Communicate important information that would be difficult to obtain easily in longer text
   - Do not include details that would detract from the information conveyed
   - Are located close to the text that refers to them (preferably on the same page)
   - Are appropriately sized
   - Are readable
   - Are labeled correctly with legends, headings, and titles
   - Use a style consistent with other figures and tables in the document
   - Are well conceived and executed

6. *Use appendixes to convey supplementary information.* Use appendixes to provide useful additional detail that only some readers will need or that is too detailed for inclusion in the main body of the document. For example, an appendix might include highly technical information or examples of surveys. Also, when extensive statistical analysis has been completed, it can be useful to highlight the significant results in the main document and include the full statistical results in an appendix in order to improve the clarity and conciseness of the main document.

## 6 ANALYZING SURVEYS

The results of surveys are a special case in analyzing both structured and unstructured outcome data for human factors research. As shown in Chapter 11, surveys may vary greatly in their purpose, content, and structure, and great care must be taken in their development to ensure that the survey gathers data that are reliable and valid. In this chapter we do not revisit those concepts. Instead, our focus is on applying the analysis techniques discussed previously to analyze survey results in a way which ensures that the results and conclusions are valid.

In terms of format, survey questions can be either structured or unstructured (i.e., open ended). In structured questions, answers may be nominal/categorical, ordinal, or interval/ratio. As demonstrated earlier, the measurement type of the answer has a strong influence on which analysis methods can be used to examine the data and find answers to the study's research questions. Therefore, we recommend considering the research objectives and the data analysis methods that support meeting those objectives when designing survey questions. This ensures that the format of the question results in answers that are of the appropriate measurement type to support the analysis methods that will result in achieving your research objectives.

### 6.1 Validating the Data

Before analyzing survey results, it is important to review the responses to ensure that there are no gaps in the data. One of the steps in validating the data is to check the overall response rate to ensure that it is sufficiently high. This is not as much of an issue for surveys administered by researchers in the course of lab-based research where response rates should be 100%. However, in mail or telephone surveys, response rates are very important. If a large number of potential participants do not respond or there is a pattern to the participants that do not respond, it can inadvertently bias the survey results. If this is the case, do not even bother analyzing the results. Unfortunately, this means that you should reexamine your survey and data collection procedures and modify them as needed to increase your response rate; then begin collecting data again.

If the overall response rate is adequate, review the individual questions to determine if there are missing answers. If a participant did not answer a large portion of the questions, it could indicate that he or she did not understand the survey or questions. If this is the case, it may make sense to remove that person's entire survey from the results. In general, if a participant is missing data for only one or two questions, it is all right to leave the data in for analysis that does not involve that question. Of course, if the missing data are crucial to the analysis, the participant's entire survey may need to be excluded. For example, if a survey is examining gender differences in communication and a participant omits his or her gender, those data are useless. If a large number of participants omit answers to the same question, it could indicate that the question was confusing or that participants were uncomfortable answering the question.

In this case, again, the research must judge whether on not it is valid to include this question in the analysis. Whatever the cause for the missing data, it is crucial for the researcher to be aware that the data are missing and of the implications the missing data have or can have on the results. It is up to the researcher to determine the appropriate course of action to ensure that the missing data do not compromise the results of the survey analysis.

### 6.2 Analysis of Unstructured Answers

Although unstructured questions are typically less time consuming to write, their answers are more time consuming to analyze. The appropriate analysis of unstructured answers, of course, depends on the purpose of the question and research. Some researchers, interested in general information gathering only, may be able to get away with simply reading and summarizing the answers. Unfortunately, a more rigorous method is often required to summarize the answers in a structured manner so that statistical methods can be used to summarize and analyze the results. For this more rigorous analysis of answers, coding is required.

Note that coding for survey answers can be more difficult than coding a researcher's field notes and other unstructured data captured by the researchers involved in a study. One reason for this increased difficulty is that answers from different participants are often not directly comparable (Alreck and Settle, 2003). When unstructured data are gathered from researchers, they (hopefully) share a common understanding of the research objectives and intent and a relatively similar vocabulary. However, survey participants frequently do (and should) vary widely. Participants may use different vocabularies, have different meanings for similar words, or have different understanding of the question's intent. Additionally, their answers may be vague and the researcher is often unable follow up with a participant to get clarification on an answer. (Also, given the amount of time that has elapsed between when the survey is administered and when a clarification is requested, the validity of the clarification may be called into question.) Therefore, when coding unstructured answers to survey questions, it is vital to take special care in developing a coding scheme and assessing intercoder reliability as recommended in Section 5.1.

For unstructured questions, the purpose of coding the answers is often to capture common themes. For example, if the question was "What did you like best about this interface?" the researcher might want to identify common concepts or themes regarding what participants liked best about the interface. Coding the data based on these concepts results in nominal/categorical measure(s). Using these nominal measures, the researcher could count the frequency with which each concept was mentioned and examine relationships between these frequencies and demographic or other measures collected through the research study. In other words, coding the unstructured answers imposes structure on those data so that the researcher can use analysis methods for structured data to gain further insights from the data.

**Table 4  Example Question Formats**

| Question Format | Example | Measurement Type |
|---|---|---|
| Multiple choice | What is your job category?<br>(a)  Sales<br>(b)  Administrative<br>(c)  Engineering<br>(d)  Management<br>(e)  Other | Nominal/categorical |
| Single response item | Have you completed XYZ certification? | Nominal/categorical |
| Order/rank items | Rank the three tools based on which is easiest to use (1 = easiest, 3 = hardest) | Ordinal |
| Likert scale | 1              2         3          4           5<br>Strongly agree    agree    Neutral   Disagree   Strongly disagree | Interval |
| Frequency scale | 1      2        3          4         5<br>Always  Often  Sometimes  Seldom   Never | Interval |

## 6.3  Analysis of Structured Answers

When analyzing structured answers from surveys, a number of the analysis methods described previously in this chapter may be used. However, there are some special considerations that must be taken into account in analyzing survey answers. In this section we address some of those considerations as well as map some of the general measurement and statistical concepts discussed previously as to their use for survey analysis.

### 6.3.1  Measurement Types

At the beginning of this chapter, several measurement types were defined. The answers to structured survey questions can be classified using these measurement types, which determine the appropriate analysis methods. Table 4 identifies the measurement type for several common survey question formats. Note that in multiple-choice questions, where the participant can select multiple items, for data analysis purposes it is sometimes easier to treat each possible answer as a separate single response (yes/no) item and/or to create a measure that indicates the number of responses. For example, if a question asks users to mark all the types of computer applications they use, code each application as a separate answer [e.g., word processing (Y/N), spreadsheet (Y/N)]. This enables comparing use among application types and comparing application use to other measures collected in the study (e.g., task performance, participant preferences). Additionally, comparing the number of application types used (i.e., a count of the application types used) to other participant responses and/or task performance can also provide interesting insights. In this example, the number of application types used can measure the breadth of computer experience, which can be a crucial covariate in human–computer interaction research.

### 6.3.2  Exploring and Describing the Data

As in any analysis of structured outcomes, the first step is exploring and describing the data (answers). The methods described in this chapter apply here. Begin by graphing the answers individually through histograms and box plots to examine the distribution, range, and variability of answers. Next, describe the data using the mean, median, percentiles, minimum, and maximum. Note that the appropriate descriptors will depend on the research objectives (e.g., measuring central tendency vs. range and distribution of values) and the type of data. For example, with ranking data, it may make more sense to examine percentages of responses (e.g., 60% ranked this item 1, 10% ranked it 2, and 30% ranked it 3) instead of mean ranks (what does a mean rank of 1.7 mean?).

After examining each answer individually, the next step is to explore possible relationships between answers. Here, again, scatterplots are useful graphical means of examining possible relationships. Also use correlation to examine and describe relationships among ordinal and interval/ratio answers. Use contingency tables (crosstabs) and the chi-squared test to examine relationships among nominal/categorical answers. When correlations exist, they often provide interesting insight into the relationship between two answers, but keep in mind that correlations do not necessarily imply causality. These correlations are, however, crucial to determining the appropriate way to analyze and make inferences from the data.

### 6.3.3  Making Inferences from the Data

Once we have gotten familiar with the structured data, we can use the more advanced statistical methods presented in this chapter to make inferences about the results. However, because of the nature of survey data, special care must be taken when using these methods. Survey data require special considerations for two reasons: (1) since surveys generally include many questions, statistical tests may be used many times to examine the results for different questions/sets of questions; (2) the answers in many surveys, especially surveys dealing with user preferences and opinions, are frequently correlated.

Recall our earlier discussion on experimentwise error. Because we are performing statistical tests on a

number of potentially correlated answers, there is a danger that the experimentwise error in the survey analysis will be inflated. Although many researchers overlook experimentwise error, researchers are encouraged to consider this and, whenever possible, use statistical methods and analysis approaches that manage this error appropriately. For example, in cases where answers to questions are logically and statically correlated, MANOVA tests should be used to examine group differences instead of only doing separate ANOVA analyses for each question. MANOVA tests are designed to control experimentwise error and provide additional insights into group difference on combinations of answers.

Aside from considerations on experimentwise error, the structured data analysis methods presented earlier can be used as described. Refer once more to Figure 2 for assistance in selecting the appropriate methods based on the analysis objectives and data characteristics of the answers. Although the appropriate analyses will depend on the content of the survey collected and the context of the research design, the following examples are presented to generate ideas on how these methods could be used:

- *Compare demographic groups on survey answers*. For example, use gender or age group to group participants; then compare each group's answers using the appropriate method [e.g., *t*-test for gender (two groups) or ANOVA for age group (more than two groups)].
- *Use demographic and other data to model a preference-related response*. For example, in an experiment examining two interfaces, demographic characteristics, previous experience measures, and performance measures could be used to create a logistic regression model to model the likelihood that a participant will prefer one interface to the other.
- *Use correlated preference or opinion responses to develop a new measurement for a complex concept*. For example, the research presented in the case study in Figure 14 used factor analysis to examine questions that addressed various aspects of decision satisfaction and to decompose those answers into factors that capture four underlying dimensions of decision satisfaction.

## 7 CONCLUSIONS

As demonstrated in this chapter, a number of factors influence which outcome data to gather in human factors research and how to analyze and draw conclusions from those outcomes. We first described the characteristics of outcome data and how those characteristics affect how the outcomes may be analyzed and the types of conclusions that can be drawn from the analysis and outcomes. Next, we examined a number of methods for analyzing both structured outcomes, often using statistical methods, and unstructured outcomes, which require less concrete analysis methods. The discussion of both the outcome characteristics and analysis methods has stressed how both of these relate to the research

objectives through the types of conclusions they support. By applying this information, human factors researchers can ensure that the outcome data they collect and the analysis methods they use produce reliable, valid results that support their research goals.

# PART 8
# HUMAN−COMPUTER INTERACTION

**Kevin B. Bennett, Allen L. Nagy, and John M. Flach**
**Wright State University**
**Dayton Ohio**

## 1 INTRODUCTION

Advances in computer science and artificial intelligence currently provide new forms of computational power with the potential to support human problem solving. One use of this computational power is to provide an expert system or an automatic assistant that provides advice to the human operator at the appropriate times. For example, there has been some progress in the use of production systems and neural networks as the drivers for decision support. An alternative, complementary use is to integrate information graphically (or more generally, "perceptibly"). Here computational power is used to create and manipulate representations of the target world rather than to create autonomous machine problem solvers (e.g., representation aiding: Zachary, 1986; Woods and Roth, 1988; Woods, 1991).

More generally, this alternative use of computational resources constitutes interface design or human computer interaction. Effective interfaces provide a very real potential to improve overall performance of human–machine systems. The technologies needed to produce interfaces are mature, and when designed properly, they will maintain the flexibility of the human in the loop and improve the capability of the overall system to respond to unforeseen circumstances. The challenge in providing effective interfaces centers around how best to use these technological capabilities to support human decision making and problem solving. Although this chapter focuses on concepts and principles of design to meet this challenge, we see interface design and machine problem solvers as complementary tools in the designer's tool chest and we expect that for very complex systems both approaches will be necessary.

The design of effective interfaces turns out to be a surprisingly difficult challenge, a fact that is attested to by the often-frustrating experiences we all encounter in today's digital world. Effective interface design requires a deep appreciation of human capabilities with regard to both perception (i.e., displays) and action (i.e., controls). It also requires a deep appreciation of the work domain itself: interface design strategies that are appropriate for one category of domains may very well not be appropriate for another. Elsewhere we have provided a comprehensive treatment of interface design (Bennett and Flach, 2011); here we focus on one facet of interface design (perceptual displays) for one category of domains (law-driven, tightly coupled work domains).

In contrast to most other treatments of display design, we did not provide a "cookbook" of detailed guidelines and recommendations (primarily because they tend to be conflicting and difficult to apply). Instead, we chose to describe a set of general heuristics for display design. Because these heuristics are necessarily abstract, we have made the discussion more concrete by illustrating

them within the context of a simple domain. We describe how the heuristics apply to that domain and annotate our written descriptions with concrete graphic examples. Our goal is to transfer functional knowledge of display design to practitioners.

We begin our discussion with a description of basic physiological, perceptual, and technological considerations in display design. These considerations are the foundation for display design and represent the baseline conditions that must be met for a display to be effective. We next consider four alternative approaches to display design. Each approach emphasizes a different conceptual aspect of the display design puzzle, and each approach has both strengths and weaknesses. A fifth approach is outlined; this approach draws from the strengths of the earlier approaches and incorporates new considerations that are particularly relevant to the design of displays for complex, dynamic domains. We discuss some analytical tools of the approach and illustrate their use in determining the various types of information that are required for a simple domain. We describe alternative displays and discuss how each display provides a specific mapping that emphasizes certain aspects of the domain but de-emphasizes or even eliminates other aspects. We end the chapter by considering the limitations of our discussion and examples and additional challenges for display design.

## 2 PHYSIOLOGICAL, PERCEPTUAL, AND TECHNOLOGICAL CONSIDERATIONS

In this section we consider fundamental aspects of the visual system and visual perception that are relevant for display design. Information on the surface of a display is most often represented by a difference in perceived brightness or a difference in perceived color between the information-carrying stimuli and the background of the display field. This section is concerned primarily with the detection and perceived appearance of these differences. Although this chapter is focused primarily on emissive displays, it is useful to begin by discussing some of the differences between reflective and emissive displays and the implications of these differences for visual perception. Emissive displays, such as the cathode ray tube (CRT), generate the light that is used to produce text, symbols, or pictures that carry information. Reflective displays such as road signs, pages in a textbook, and the speedometer in an automobile do not produce any light but reflect some portion of the light that falls on them. Although emissive displays are much more versatile and flexible in some respects, it is probably safe to say that the use of reflective displays to present information was, and still is, far more common. With regard to the visual system and visual perception, there are some fundamental differences between reflective and emissive displays. We begin by examining properties of achromatic, or colorless, displays that illustrate these differences and later in this section take up chromatic displays.

### 2.1 Reflective Displays

The surface of a reflective display reflects some portion of the light energy that falls on it in many different directions. The percentage of light reflected, known as the *reflectance* of the surface, and the dependence of this percentage on the wavelength of the light, known as the *spectral reflectance function* of the surface, are determined by the physical properties of the surface (Nassau, 1983). We begin by discussing surfaces with flat spectral reflectance functions that reflect approximately the same percentage of light for all wavelengths. Images are placed on the surface by changing the properties of the surface in local regions. For example, suppose that a printer for a personal computer deposits black ink on a gray page so as to form text. The gray page reflects a percentage, perhaps 50%, of the light energy at each wavelength falling on it. The ink deposited on the page appears very dark because it reflects only a small percentage, for example, 5%, of the light energy falling on it. Suppose that an observer views this page tacked to the wall painted uniformly white so that the surface of the wall has a reflectance of 90%.

The reflectance of surfaces varies with the angle of incidence of the illumination and the angle at which the reflectance is measured. Reflectances of surfaces can be described with two components, a specular component and a diffuse component (Shafer, 1985; Hunter and Herold, 1987). The specular component is mirrorlike, in that a large proportion of the light is reflected off at an angle equal to the angle of incidence. The diffuse component is characterized by light reflected off in all directions. Shiny surfaces such as mirrors have a large specular component and a small diffuse component, whereas matte surfaces such as a velvet cloth have a large diffuse component and a small specular component. For simplicity we ignore these complexities here. Figure 1*a* illustrates idealized spectral reflectance curves for the page, the ink, and the wall. Real spectral reflectance curves would only approximate flat curves. Surfaces with flat curves are neutral in the sense that they do not change the spectral quality of the light that falls on them.

To characterize the light reflected back from the surface, we need to know something about the light falling on the surface. A typical spectrum for sunlight is shown in Figure 1*b*, where the relative energy is plotted as a function of wavelength. This spectrum is referred to as typical because the spectrum for sunlight varies with time of day, time of year, latitude, and atmospheric conditions. Not all of the energy in sunlight is effective in generating a visual response. Some wavelengths of light are more likely than others to be absorbed by the receptors in the eye, the rods and cones. A function describing the relative effectiveness of different wavelengths for photopic or cone vision (Figure 2) was standardized by the International Commission on Illumination (CIE) in 1924 (Wyszecki and Stiles, 1982). This function, known as the *photopic luminosity function*, has served as a standard in science and industry ever since.

A similar function for scotopic or rod vision was standardized in 1951 (Wyszecki and Stiles, 1982). Since most displays are viewed under photopic conditions, we concentrate on cone vision here. To get a measure of the visual effectiveness of the light energy from the sun, we multiply the energies at each wavelength in Figure 1*b*

**Figure 2** CIE 1924 photopic luminosity curve.
**Figure 1** (*a*) Idealized spectral reflectance curves for the ink, the page, and the wall in the example described in the text; (*b*) relative energy at each wavelength in sunlight.

by the value of the photopic luminosity function at that wavelength. The sum or integral of these weighted energies, multiplied by a constant to convert the energy units to a convenient unit of visual effectiveness, is known as the *luminance* of the source. A commonly used unit for luminance today is the candela per square meter ($cd/m^2$).

For our purposes, the more important measure is the amount of light that actually falls on the wall, the page, and the ink. This quantity is known as *illuminance*, the amount of visually effective light that actually falls on a surface in space. We assume that the wall is evenly illuminated so that this measure is the same across the wall, the text, and the page. A common unit of illuminance is the lux. The measurement of luminance, and the related quantity illuminance, is itself a complex

topic, and many different types of units are used in measuring light. [For discussions of light measurement, see Grum and Bartleson (1980) and Wyszecki and Stiles (1982).] To find the amount of visually effective light reflected from the surface, we multiply the reflectance at each wavelength by the illuminance provided by the sunlight at each wavelength. Alternatively, we could measure directly the amount of visually effective light reflected in a particular direction using a device called a photometer. [For a discussion of devices for measuring light, see Post (1992).]

An important property of reflective displays, such as our page of printed text mounted on the wall, is that the physical contrast between the text and the page, or the page and the wall, does not vary with the amount of light falling on them as long as all of the surfaces are illuminated at the same level. The term *physical contrast* is used to refer to the difference in the light reflected from two regions of a scene. The physical contrast of a stimulus on a background is often defined as the *contrast ratio*, $\Delta L/L$, the difference between the light reflected from the stimulus and the background divided by the background level. In our example the physical contrast between the text and the page could be specified as the difference in the amounts of light reflected by the ink and by the page divided by the amount of light reflected by the page. Note that as the amount of light falling on the wall is changed, the physical contrast ratios calculated for the text and the page, the text and the wall, and the page and the wall will remain constant (Figure 3). The reader can demonstrate this by setting up the contrast ratios and demonstrating that the light level, which appears in both the numerator and the denominator of the contrast ratio, will cancel out, and the contrast ratios are determined by the reflectances alone.

The human visual system appears to have evolved to take advantage of the reflective properties of surfaces. One of the earliest relationships established in the study of visual perception is that the intensity difference between a stimulus and a background necessary for

Contrast ratios:

$$\text{Text / page} = \frac{0.5\,I - 0.05\,I}{0.5\,I} = \frac{0.45}{0.50} = 0.90$$

$$\text{Page / wall} = \frac{0.9\,I - 0.5\,I}{0.9\,I} = \frac{0.40}{0.90} = 0.44$$

$$\text{Text / wall} = \frac{0.9\,I - 0.05\,I}{0.9\,I} = \frac{0.85}{0.90} = 0.94$$
**Figure 3**   Calculation of contrast ratios for the page, the text, and the wall. The values of *R* indicate the reflectances of the three surfaces in the figure. The illumination level *I* is identical for all three surfaces in the figure and therefore cancels out of the equations.

detection of the stimulus is a constant proportion of the intensity of the background field. This rule, known as *Weber's law*, is often written in equation form as $\Delta I = kI$. Here $\Delta I$ refers to the difference between the intensity of the stimulus and the intensity of the background, $k$ is the proportionality constant or the Weber fraction, and $I$ is the intensity of the background field. Weber's law indicates that the visual system becomes less sensitive to differences between the stimulus and the background as the intensity of the background field increases. That is, in order to keep the stimulus detectable, the difference between the stimulus and the background is increased. Notice, however, that if we rearrange Weber's law by dividing both sides of the equation by $I$, we get $(\Delta I/I) = k$.

At threshold, the difference between the intensities of the stimulus and the background ($\Delta I$) divided by the background intensity ($I$) is constant. This is exactly the situation for the reflective displays described above. It means that if the text on a page is detectable at any light level, it will remain detectable as the light level is changed. A somewhat different form of Weber's law also applies to the discrimination of two stimuli presented on a background. In this case, at

threshold the difference in the contrasts between the two stimuli relative to the background must be a constant proportion of one of the contrasts (Whittle, 1986, 1992; Webster et al., 2005; Nagy and Kamholz, 1995). Thus, for reflective displays, if two stimuli at different contrast levels on a background are discriminable from each other, they will remain discriminable as the illumination level is changed. It is well known that Weber's law is only approximately true and that it breaks down under many conditions, perhaps most important, when the light levels involved are low and approach absolute threshold. However, the change in the sensitivity implied by Weber's law is an important property of the visual system. It is a component of another property of the visual system known as *lightness constancy*, which refers to the fact that the visual system operates in such a manner as to keep the perceived appearance of reflective objects approximately constant under changing illumination levels. That is, the wall, the page, and the text in our example appear white, gray, and black, respectively, whether they are viewed outdoors under intense sunlight or indoors under dim illumination. Lightness constancy depends on many other factors in addition to the change in sensitivity indicated by Weber's law and has been a topic of intense interest in the last couple of decades (Gilchrist et al., 1983; Adelson, 1993).

## 2.2   Emissive Displays

We will use a CRT as an example of an emissive display. CRTs generate light by shooting beams of electrons at substances called *phosphors* which are painted on the screen of the CRT. When the electrons hit a point on the screen, light energy is given off by the phosphor at that point. The intensity of the light given off can be changed by varying the strength of the beam of electrons directed at the point. Images are created on the screen by varying the intensity of the electron beam hitting different points on the screen. The physical contrast between different regions of the screen can be defined in the same manner as for reflective displays.

Suppose that we mount the CRT on the white wall and use it to generate a page of dark text on a gray page. Suppose also that we adjust the CRT so that the page gives off 50 units of light and the text gives off 5 units of light. The physical contrast ratio between the text and the page would be 0.90, as it was for the reflective display (see Figure 3). Suppose that the white wall is illuminated initially so that 90 units of light are reflected from it. Also suppose for the moment that the surface of the CRT reflects none of this light. In this case the contrast ratios between the three surfaces would be the same as in our first example with the reflective page of text, and we might expect that the CRT display would look very similar to the reflective display.

Note what happens as the illumination falling on the wall is increased, however. The intensity of the light reflected from it increases, but the intensities of the lights from the text and the page on the CRT do not change. The contrast ratio between the text and the page on the CRT remains constant, but the contrast ratios between the page and the wall and the text and the wall

increase. Thus, we might expect the appearances of the text and the page to change considerably as the light level falling on the wall is changed. If we regard the text and the page as individual incremental stimuli against the large background provided by the wall, Weber's law suggests that their discriminability will decrease as the light reflected from the wall increases. The decrease in discriminability occurs because the difference in contrast ratios decreases with increasing light level. In this case the decrease in the sensitivity of the visual system with increasing background light level reduces the ability to detect the difference between the text and the page, which remains constant.

Any light that is reflected from the glass face of the CRT will reduce the discriminability of the text on the page even further, because it will be reflected from both the region containing the dark text and the region containing the page. The reflected light actually reduces the physical contrast between the text and the page and makes them even less discriminable. Thus, emissive displays behave quite differently than reflective displays in natural environments. These differences do not present much of a problem when emissive displays are placed in a constant environment such as an office illuminated by a fixed light source. However, when emissive displays are placed in natural environments in which the illumination level may vary by a factor of a million or more, the problems caused by the varying contrast ratios are evident. For example, this problem occurs when emissive displays are used in aircraft. The detectability and the appearance of elements within the display may vary dramatically. To keep the appearance of the text and the page constant, the light levels given off by the CRT must be adjusted in accord with the change in the illumination of the wall.

## 2.3 Factors Affecting Perceived Contrast

Besides the physical contrast, there are many other factors, such as adaptive state, location in the visual field, eye movements, and the interpretation of the perceived illuminant, which affect the perceived contrast of a stimulus against a background. One of the most important of these factors is stimulus size. In the last few decades this problem has been investigated very successfully with an approach based on Fourier analysis. [For extensive reviews and applications, see Ginsburg (1986), Olzack and Thomas (1986), Graham (1989), DeValois and DeValois (1990), Pavel and Ahumada (1997), and Makous (2003).] Fourier analysis suggests that any pattern of light and dark on the retina can be described as a sum of sinusoidal components of different frequency and amplitude. The application of this idea to visual perception involves measuring an observer's sensitivity to a number of sinusoidal patterns of different spatial frequency (Figure 4). These repetitive spatial patterns of light and dark are known as *gratings*.

Spatial frequency is essentially a measure of the size of the bars in the pattern. The spatial frequency of the pattern is defined as the number of cycles that occur in 1° of visual angle. As spatial frequency increases, there are more cycles per degree of visual angle and the bars become smaller. Visual angle is used as the unit of

**Figure 4** Variation in luminance for sinusoidal patterns: (*a*) spatial frequency of 1 cycle/degree at a contrast of 100%; (*b*) spatial frequency of 2 cycles/degree at a contrast of 100%; (*c*) spatial frequency of 1 cycle/degree at a contrast of 50%.

size because it gives a measure of the size of the image on the retina (e.g., a book 12 in. long makes a larger image on the retina when it is held up close to the eye than when it is held far away). To get a measure of the size of an image on the retina, the distance between an object and the observer's eye must be considered. Thus, the visual angle subtended by an object is defined as
**Figure 5**   Calculation of the visual angle.

**Figure 6**   Typical plot of a contrast sensitivity function for a human observer. (Based on data from DeValois and DeValois, 1990.)

twice the arctangent of one-half the height divided by the distance (Figure 5).

Sensitivity is measured by finding the physical contrast level at which a given pattern of light and dark is just detectable. To give a measure of sensitivity, the reciprocal of the threshold is calculated by dividing 1 by the threshold contrast. The measure of physical contrast typically used in this approach is slightly different from the contrast ratio described above and is called the *Michelson contrast*. It is defined as $L_{max} - L_{min}$ divided by $L_{max} + L_{min}$, where $L_{max}$ is defined as the maximum luminance level in the pattern and $L_{min}$ is defined as the minimum luminance in the pattern. The curve described by plotting contrast sensitivity against the spatial frequency of the grating pattern is called the *contrast sensitivity function*.

A typical contrast sensitivity function for photopic or cone vision obtained from a human observer is shown in Figure 6. The curve shows that when spatial frequency is low (i.e., the bars are large), the sensitivity to contrast is low. As spatial frequency is increased, the sensitivity increases up to spatial frequencies of about 5–10 cycles per degree. With further increases in spatial frequency (i.e., smaller and smaller bars), sensitivity falls off rapidly until at a spatial frequency of approximately 50 cycles per degree a grating of 100% contrast (the highest physical contrast obtainable) is not visible. Spatial patterns of even greater frequency also are not visible. Thus, very fine patterns are visible only if the spatial frequency is below 50 cycles per degree and they are very high contrast.

Over the last few decades many physical factors, such as overall light level, number of cycles present in the pattern, and location of the pattern in the visual field, have been shown to affect the contrast sensitivity function. The shape of the curve as well as the overall
sensitivity can vary considerably. The shape and height of the curve are affected by several components within the visual system that play a role in determining the contrast sensitivity function. For example, the optics of the eye, the lens and cornea, which form an image of the pattern on the retina, influence the contrast sensitivity function, because they do not form a perfect image of the external pattern on the retina. A good introductory treatment of the optics of the eye is given by Millodot (1982). The distribution of rods and cones on the retina also plays a role in determining the contrast sensitivity function. The rods and cones absorb light and initiate neural signals in the visual system. Thus, their size and the distances between them have some effect on the contrast sensitivity function. A good introduction to the sampling properties of rods and cones is given by Wandell (1995). The way the rods and cones are connected to the neurons that carry signals out of the eye also plays a role in determining the contrast sensitivity function, because many receptors are connected to each neuron. Psychophysical evidence suggests that the visual system may be organized into approximately five to seven neural channels, each sensitive to a different band of spatial frequencies (Olzack and Thomas, 1986). Thus, the contrast sensitivity function is the result of many factors which have been studied intensely over the last few decades. Nevertheless, it is a very useful and fundamental description of the ability of a human observer to detect contrast in patterns of different size. For example, recent studies suggest that the recognition of text may be mediated by the same mechanisms that mediate the contrast sensitivity function (Alexander et al., 1994; Solomon and Pelli, 1994).

The perceived contrast of patterns that are well above threshold is not simply related to the contrast sensitivity function (Cannon and Fullenkamp, 1991). That is, if we measure the threshold contrast for sinusoidal patterns at a number of different spatial frequencies and then increase the physical contrast of all of these patterns so

that the contrast for each one is five times the threshold contrast, the patterns will not appear to have equal contrasts. This is similar to the situation in audition where equal-loudness curves for tones of different frequencies do not have the same shape as the audibility curve, a plot of threshold as a function of frequency, and change shape as the loudness level is raised. Thus, the contrast sensitivity function can be used to predict whether a pattern of a given spatial frequency is visible, but it cannot be used to predict accurately the perceived contrast of patterns that are well above threshold. For example, if a display designer wants to equate the perceived contrast of patterns of different size that are well above threshold, the contrast sensitivity function cannot be used to do this accurately.

The notions of visual angle, spatial frequency, and contrast sensitivity that were introduced briefly above are very useful in thinking about both reflective and emissive displays. Here we concentrate on emissive displays. Consider a standard CRT display that is 9.5 in. wide and 7 in. high. Assume that this CRT has 640 columns of pixels, each containing 480 rows (standard $640 \times 480$ resolution). If the observer views this display from a distance of 2 ft, the screen subtends about $22.4°$ horizontally and $16.6°$ vertically (see Figure 5), and each pixel subtends about $0.035°$. If we want to make patterns of light and dark bars on the screen, we might want to know the highest spatial frequency that can be represented. If we make alternate pixels black and white, we need two pixels to make one cycle, which will subtend $0.07°$. Thus, the highest spatial frequency that can be represented accurately will be 1/0.07, or slightly over 14 cycles per degree.

Looking back at our representative contrast sensitivity function, we see that this frequency is well below the upper limit of approximately 50 cycles per degree. Looking at the vertical axis, we find that the sensitivity at 14 cycles per degree is approximately 30. For an observer to detect this pattern on the screen, we can determine that the Michelson contrast will have to be approximately 1/30, or 3.3%. These calculations also tell us something else. Patterns with spatial frequencies higher than 14 cycles per degree just cannot be represented accurately on the monitor. Thus, if we want to view an image with a lot of fine details at high spatial frequencies, such as a digitized photograph that subtends $9.5 \times 7$ in., spatial frequencies greater than 14 cycles per degree that were visible when the original photograph was viewed from a distance of 2 ft will not be represented accurately on the monitor if they are composed of spatial frequencies above 14 cycles per degree.

One solution to this problem is to use a monitor with higher resolution or smaller pixels. For example, if we could pack $1280 \times 960$ pixels into the same $9.5 \times 7$-in. screen, patterns with spatial frequencies up to nearly 29 cycles per degree could be represented. To make a display that matches the upper limit on the resolution of the visual system, we would need to pack about $2240 \times 1660$ pixels into the display. A $9.5 \times 7$-in. CRT with this resolution would permit the presentation of patterns with spatial frequencies up to 50 cycles per degree at a viewing distance of 2 ft. This would be very difficult

to accomplish with the present technology, making the display and the computer hardware that drives it very expensive.

It is also possible to portray patterns with spatial frequencies greater than 14 cycles per degree on the original CRT by moving the observer farther away so that each pixel subtends a smaller visual angle. The drawback to this approach is that the entire display field now subtends a smaller portion of the field of view. For example, if we move the observer back to a distance of about 4 ft, patterns with spatial frequencies up to nearly 29 cycles per degree could be portrayed on the screen. This example helps to illustrate a fundamental trade-off in emissive displays, the trade-off between field of view and resolution. With a fixed number of pixels, this trade-off is always present in an emissive display. If the pixels are spread over a larger viewing area, the resolution will be poor. If they are packed into a smaller viewing area, the resolution will improve but the field of view will decrease.

The resolution of an emissive display may be limited either by the display itself or by the hardware that drives it: that is, the video card in a computer or the signals generated on a television cable. The detail in an image, or the spatial frequencies that can be portrayed, and the field of view that is visible will be limited by this resolution and the size of the screen.

## 2.4  Color

Although black-and-white pictures carry much of the information in the real world, they do not carry information about color. Color in images is certainly important for aesthetic reasons, but in addition to the aesthetic qualities it brings to an image, color serves two important basic functions (Boynton, 1990). First, chromatic contrast between two regions in an image can add to the luminance contrast between these regions to make the difference between the regions much more noticeable, especially when the luminance contrast is small. Second, since color is perceived to be a property of an object (although, in fact, it also depends on illumination, as we will see), it is useful in identifying objects, searching for them, or grouping them. Boynton (1990) regards the second function of color, which he describes as related to categorical perception, as the more important one. It is probably because of these categorical properties that color is often used as a coding device and as a means of segregating information in visual displays (see Widdel and Post, 1992).

Several excellent treatments of the basics of human color vision and the science of specifying colors for applications are available (e.g., Wyszecki and Stiles, 1982; Pokorny and Smith, 1986; Travis, 1991; Post, 1992, 1997; Kaiser and Boynton, 1997; Gegenfurtner and Sharpe, 1999; Nagy, 2003; Hansen and Gegenfurtner, 2006; Eskew, 2009), so a very brief review will be given here. Normal human color vision depends on the presence of three types of cone receptors in the retina. These cones differ in the type of light-absorbing pigment contained in them. One of these pigments absorbs best, meaning the greatest percentage of the light falling on it, in the short-wavelength region of the spectrum;

hence the cone containing it is referred to as the *S cone*. The second pigment absorbs best in the middle of the spectrum, and the cone containing it is referred to as the *M cone*. The third pigment absorbs best at slightly longer wavelengths than the M pigment and the cone containing it is referred to as the *L cone*.

The differences in the signals generated in these cones by a given light provide some information about the spectral content of the light. For example, a light source that gives off more energy in the long-wavelength portion of the spectrum than in the middle- or short-wavelength regions would tend to stimulate the L cones more than the other two cone types. On the other hand, a light source that gives off more energy in the short-wavelength region would tend to stimulate the S cones more than the other two types. The differences in the stimulation of the cone types serve as a means for discriminating between the lights and result in the perception of color.

Since there are only three types of cones, normal human color vision is said to be *three-dimensional* or *trichromatic*. Furthermore, since there are only three signals from different types of cones in the visual system, it follows that only three numbers are needed to specify the perceptual quality of a color. Much effort has gone into developing systems of specifying colors with three numbers such that they represent the perceptual qualities of the stimulus in useful ways. The fact that only three numbers are needed to specify the chromatic quality of a stimulus also means that there are many physically different stimuli that stimulate the three cones in the same way and thus appear to be the same color. Stimuli that are physically different but appear to be the same are called *metamers*.

Consider the reflective display example given above. Suppose that we print the text on our gray page using red ink rather than black ink. The ink appears red because it tends to absorb short- and middle-wavelength light that falls on it while reflecting long-wavelength light. A spectral reflectance curve showing the percentage of light reflected as a function of wavelength for red ink might look like the curve shown in Figure 7. To get the light reflected back from the ink, we multiply the reflectance at each wavelength by the energy at each wavelength. To calculate the luminance of this light, we would weight the reflected energy at each wavelength by the photopic luminosity function and integrate or sum over the entire curve as we did for achromatic stimuli above. However, the text appears to differ from the gray page and the white wall in color as well as in lightness. To characterize this difference, we would like some means of measuring the colors of the text, the page, and the wall. The most widely used system for doing this is based on the CIE 1931 chromaticity diagram. This diagram is based on color matches of normal human observers. A good introduction to the color-matching experiment and the development of chromaticity diagrams can be found in Kaiser and Boynton (1997). In the color-matching task, observers were asked to adjust the intensities of three primary lights that were mixed together in a single stimulus field so as to match the colors of a wide variety of other lights presented in another

**Figure 7**    Spectral reflectance curve for red ink.

stimulus field. The CIE chromaticity diagram uses three numbers (related to the intensities of the primaries needed to make a match in the color-matching experiment) to represent the color or, more specifically, the chromaticity of a stimulus. These numbers are called the *chromaticity coordinates* of the color and are referred to as $x$, $y$, and $z$. The color-matching data were normalized so that the values of these three chromaticity coordinates add up to 1 for any real color. As a result, only two of the chromaticity coordinates need to be given to specify a color, because the third can always be obtained by subtracting the sum of the other two from 1. Therefore, all colors can be represented in a two-dimensional diagram such as the CIE 1931 diagram shown in Figure 8, where only $x$ and $y$ are plotted. Many measuring instruments

**Figure 8**    CIE 1931 chromaticity diagram. (Based on data from Wyszecki and Stiles, 1982.)

have been developed and are commercially available for measuring the CIE coordinates of a color. [See Post (1992) for some discussion of these.]

The chromaticity coordinates specify the chromatic properties of a color but do not specify its appearance, because the appearance of the color can change with many viewing conditions that do not change its chromaticity coordinates. For example, the size of the stimulus, in terms of visual angle, can affect the color appearance even though the chromaticity coordinates of the ink used to make it do not change (Poirson and Wandell, 1993). This is a severe limitation on the meaning and usefulness of the CIE chromaticity diagram. One would like to have a system in which the appearance of the color is specified, but this is a very difficult problem that has not yet been solved. Nevertheless, the specification of colors in the chromaticity diagram is still very useful, because any two stimuli with the same chromaticity coordinates will appear to be identical in color when viewed under the same conditions. What the chromaticity coordinates specify is how to make a color that will appear the same as a given sample under the same viewing conditions.

The chromaticity coordinates of a reflective display change with the chromaticity of the light used to illuminate it. The change occurs because the amount of light reflected back from an object at each wavelength depends in part on the amount of light falling on it. Therefore, when the chromaticities of objects, or dyes, or paints are specified, they are usually given with reference to a standard light source. [For a discussion of standardized light sources, see Wyszecki and Stiles (1982).] One might expect that the change in the chromaticity coordinates accompanying a change in the light source would change the color appearance of a reflective display. Such changes in light source are actually quite common. As noted above, the spectral quality of daylight changes with time of day, atmospheric conditions, season, and location on Earth. A large variety of artificial light sources are commercially available, and these can differ considerably in the spectral quality of the light given off. However, these changes do not generally result in large changes in the appearances of objects, because mechanisms within the visual system act to maintain a constant color appearance despite these changes in illumination. Color constancy has generally been shown to be less than perfect (Arend and Reeves, 1986; Brainard and Wandell, 1992). However, it appears to work well enough to prevent confusing changes in the appearance of reflective objects. The visual mechanisms mediating color constancy have been of intense interest over the past few decades (D'Zmura and Lennie, 1986; Maloney and Wandell, 1986; Lennie and Movshon, 2005). Selective adaptation within the three cone mechanisms is thought to be one of the major mechanisms mediating color constancy (Worthy and Brill, 1986) much as the change in sensitivity described by Weber's law plays a role in lightness constancy.

Although mechanisms of color constancy work to maintain a constant appearance in reflective displays, they actually work against the maintenance of a constant appearance in emissive displays, much as mechanisms of lightness constancy worked against the constant appearance of black-and-white emissive displays. Color CRTs take advantage of the fact that human color vision is trichromatic by using only three different phosphors. Each phosphor emits light of a different color when it is stimulated. The light from the three phosphors is mixed together in different proportions to give all other colors, including white.

The chromaticity of a color produced on an emissive display does not change with changes in the illumination of the surroundings. Thus, the mechanisms of color constancy, activated by changes in the illumination of the surroundings, introduce changes in the appearance of these chromaticities, which may be quite noticeable to the observer. Under some conditions these changes in appearance may be large enough to cause some confusion in identifying objects on the basis of color.

### 2.4.1 Factors Affecting Perceived Color Contrast

Much as the perception of achromatic contrast is affected by many factors, color contrast is affected by many factors, such as light level, adaptive state, location in the visual field, and stimulus size. The spatial frequency approach has also been applied to the detection of color contrast. It is possible to produce grating patterns which vary sinusoidally in color, with little or no variation in luminance. The color contrast between the bars of the grating required for detection of the pattern can be measured as a function of the spatial frequency (Kelly, 1974; Noorlander and Koenderink, 1983; Mullen, 1985; Sekiguchi et al., 1993). Typical results for red/green and yellow/blue gratings are shown in Figure 9. Comparison of the results for chromatic patterns with those shown for luminance patterns reveals clear differences. Sensitivity to color contrast is high at low spatial frequencies but begins to fall off dramatically

**Figure 9** Typical plot of contrast sensitivity for isoluminant chromatic gratings. (Based on data from Mullen, 1985.)

at rather low spatial frequencies compared to luminance contrast. Above spatial frequencies of approximately 12 cycles per degree color contrast is not detectable even at the highest color contrasts producible. Thus, chromatic contrast information is limited to fairly low spatial frequencies, or large patterns, as compared to luminance contrast information. Within this range of spatial frequencies, the color appearance of the bars of a pattern that is well above threshold is also affected by spatial frequency (Poirson and Wandell, 1993). As the spatial frequency of the pattern is increased, the apparent color contrast between the bars is reduced. Thus, the detectability of color contrast and the color appearance of stimuli are affected dramatically by stimulus size.

## 3  FOUR ALTERNATIVE APPROACHES TO DISPLAY DESIGN

Earlier we discussed physiological, perceptual, and technological considerations in designing visual displays. This has been the traditional focus for human factors research: to design displays that are legible. For example, the knowledge that a user will be seated a particular distance from a particular type of display under a particular set of ambient lighting conditions can be used to determine the appropriate size and luminance contrast that will be necessary for the characters to be seen. Thus, the previous considerations provide us with an understanding of the baseline conditions of display design that must be met (are necessary) for a person to use a display.

Although these considerations are necessary for the design of effective displays, they are not sufficient. Compliance with these considerations will make the *data* required to complete domain tasks available but may not provide the *information* necessary to support an observer in decision making and action. Woods (1991) makes an important distinction between design for data availability and design for information extraction. Designs that consider only data availability often impose unnecessary burdens on the user: to collect relevant data, to maintain these data in memory, and to integrate these data mentally to arrive at a decision. These mental activities require extensive knowledge and tax-limited cognitive resources (attention, short-term memory) and therefore increase the probability of poor decision making and errors.

Our discussion of display design will begin with a consideration of four broadly defined approaches. Each approach is complementary in the sense that it approaches the display design problem from a different conceptual perspective (i.e., graphical arts, psychophysical, attention-based, and problem solving/decision making).

### 3.1  Aesthetic Approach

Tufte (1983, 1990) reviews the design of displays from an aesthetic, graphic arts perspective. Tufte (1983) describes principles of design for data graphics or statistical graphics which are designed expressly to present quantitative data. One principle is the *data–ink ratio*, a measurement of the relative salience of data versus nondata elements in a graph. It is computed by determining the amount of ink that is used to convey the data and dividing this number by the total amount of ink that is used in the graphic. A higher data–ink ratio (a maximum of 1.0) represents the more effective presentation of information. A second measure of graphical efficiency is *data density*. Data density is computed by determining the number of data points represented in the graphic and dividing this number by the total area of the graphic. The higher the data density, the more effective the graphic. Other principles include eliminating graphical elements that interact (e.g., moire vibration) and eliminating irrelevant graphical structures (e.g., containers and decorations) and aesthetics (e.g., effective labels, proportion, and scale).

The two versions of a statistical graphic that are shown in Figure 10 illustrate several of Tufte's principles. The version in Figure 10*a* is poorly designed; the version in Figure 10*b* is more effectively designed. In Figure 10*b* the irrelevant data container (the box) that surrounds the graph in Figure 10*a* has been eliminated. In addition, several other nondata graphical structures have been removed (grid lines). In fact, these grid lines are made conspicuous by their absence in Figure 10*b*. Together, these manipulations produce both a higher data–ink ratio and a higher data density for the version in Figure 10*b*. In Figure 10*a* the striped patterns on the bar graphs produce an unsettling moire vibration and have been replaced in Figure 10*b* with gray-scale patterns. In addition, the bar graphs in Figure 10*b* have been visually segregated by spatial separation. Finally, the three-dimensional perspective in Figure 10*a* complicates visual comparisons and has been removed in Figure 10*b*.

Tufte (1990) broadens the scope of these principles and techniques by considering nonquantitative displays as well. Topics that are discussed include micro/macro designs (the integration of global and local visual information), layering and separation (the visual stratification of different categories of information), small multiples (repetitive graphs that show the relationship between variables across time or across a series of variables), color (appropriate and inappropriate use of), and narratives of space and time (graphics that preserve or illustrate spatial relations or relationships over time). The following quotations (Tufte, 1990) summarize many of the key principles:

- "It is not how much information there is, but rather, how effectively it is arranged." (p. 50)
- "Clutter and confusion are failures of design, not attributes of information." (p. 51)
- "Detail cumulates into larger coherent structures ... Simplicity of reading derives from the context of detailed and complex information, properly arranged. A most unconventional design strategy is revealed: to clarify, add detail." (p. 37)
- "Micro/macro designs enforce both local and global comparisons and, at the same time, avoid the disruption of context switching. All told, exactly what is needed for reasoning about information." (p. 50)
**Figure 10** Six alternative mappings. Parts (*a*) and (*b*) represent alternative versions of a separable (bar graph) graphical format that provide a less effective (*a*) and a more effective (*b*) mapping. Parts (*c*) and (*d*) represent alternative versions of a configural display format that provide a less (*c*) and a more (*d*) effective mapping, due primarily to layering and separation. Parts (*e*) and (*f*) represent the least effective mappings.

- "Among the most powerful devices for reducing noise and enriching the content of displays is the technique of layering and separation, visually stratifying various aspects of the data.... What matters—inevitably, unrelentingly—is the proper relationship among information layers. These visual relationships must be in relevant proportion and in harmony to the substance of the ideas, evidence, and data displayed." (pp. 53–54)

This final principle, layering and separation, is graphically illustrated in Figures 10c and d. These two versions of the same display vary widely in terms of the visual stratification of the information that they contain. In Figure 10c all of the graphical elements are at the same level of visual prominence; in Figure 10d there are at least three levels of visual prominence. The lowest layer of visual prominence is associated with the nondata elements of the display. The various display grids have thinner, dashed lines, and their labels have also been reduced in size and made thinner. The medium layer of perceptual salience is associated with the individual variables. The graphical forms that represent each variable have been gray-scale coded, which contributes to separating these data from the nondata elements. Similarly, the lines representing the system goals ($G_1$ and $G_2$) have been made bolder and dashed. In addition, the labels and digital values that correspond to the individual variables are larger and bolder than their nondata counterparts. Finally, the highest level of visual prominence has been reserved for those graphical elements which represent higher level system properties (e.g., the bold lines that connect the bar graphs). The visual stratification could have been enhanced further through the use of color. The techniques of layering and separation will facilitate an observer's ability to locate and extract information.

To summarize, Tufte (1983, 1990) addresses the problem of presenting three-dimensional, multivariate data on flat, two-dimensional surfaces (focusing primarily on static, printed material) very admirably. He attacks the problem from a largely aesthetic perspective and provides numerous examples of both good and bad display designs that clearly illustrate the associated design principles. Although there are critical aspects of dynamic display design for complex domains that are not considered, the principles can be generalized.

## 3.2  Psychophysical Approach

Cleveland and his colleagues have also developed principles for the design of statistical graphics. However, in contrast to the aesthetic conceptual perspective of Tufte, Cleveland has used a psychophysical approach. As an introduction, consider the following quotation (Cleveland, 1985, p. 229):

When a graph is constructed, quantitative and categorical information is encoded by symbols, geometry, and color. Graphical perception is the visual decoding of this encoded information. Graphical perception is the vital link, the raison d'etre, of the graph. No matter how intelligent the choice of information, no matter how ingenious the encoding of the information, and no matter how technologically impressive the production, a graph is a failure if the visual decoding fails. To have a scientific basis for graphing data, graphical perception must be understood. Informed decisions about how to encode data must be based on knowledge of the visual decoding process.

In their efforts to understand graphical perception Cleveland and his colleagues have considered how psychophysical laws (e.g., Weber's law, Stevens's law) are relevant to the design of graphic displays. For example, psychophysical studies using magnitude estimation have found that judgments of length are less biased than judgments of area or volume. Therefore, visual decoding should be more effective if data have been encoded into a format that requires length discriminations as opposed to area or volume discriminations. Cleveland and his colleagues have tested this and similar intuitions empirically. Their experimental approach was to take the same quantitative information, to provide alternative encodings of this quantitative information (graphs that required different "elementary graphical–perception tasks"), and to test observers' ability to extract the information.

The results of these experiments provided a rank ordering of performance on basic graphical perception tasks: position along a common scale, position along identical, nonaligned scales, length, angle/slope, area, volume, and color hue/color saturation/density (ordered from best to worst performance) (Cleveland, 1985, p. 254). Guidelines for display design were developed based on these rankings. Specifically, graphical encodings should be chosen that require the highest ranking graphical perceptual task of the observer during the visual decoding process. For example, consider the three graphs illustrated in Figures 10b, e, and f. For decoding information contained in Figure 10b, an observer is required to judge position along a common scale (in this case, the vertical extent of the various bar graphs). For Figure 10e the observer is required to judge angles and/or area. Finally, to decode the information in Figure 10f, the observer is required to judge volume (note that because of the three-dimensional representation, angles and area are no longer valid cues). According to the rankings, Cleveland and his colleagues would therefore predict that performance would be best with the bar chart, intermediate with the pie chart, and worst with the three-dimensional pie chart.

## 3.3  Attention-Based Approach

A third perspective on display design is to consider the problem in terms of visual attention and form perception. From this perspective the basic issues in display design include the following. What are the fundamental units of perception? What are the basic types of visual information that are available; what are the relationships between these types of information? How do parts group into wholes? Is the perception of the "parts" of a form secondary to the perception of the

"whole," or vice-versa? What constitutes visual attention and how can it be distributed over parts and wholes? The answers to these questions are relevant to principles of display design since visual displays need to provide different types of information and to support a range of activities.

Specifically, there is a continuum of attention demands that operators might face in complex, dynamic domains. At one end of the continuum are "focused" attention tasks that require selective responses to specific elements in the display. Here a response is contingent on the value of an individual variable (e.g., adjusting vehicular speed in a driving task). At the opposite end of this continuum are "divided" attention tasks that require the distribution of attention across many features that must be considered together to choose an appropriate response. Here a response is contingent on the relationship between a number of variables (e.g., braking or changing lanes when the car in front of you slows down). Thus, tasks can be characterized in terms of the relative demands for selective attention to respond to specific features with specific actions and distributed or divided attention in which multiple display elements must be considered together to choose the appropriate actions.

Attention-based approaches to display design have examined how the design of visual representations can help to meet the cognitive load posed by this continuum of attention demands. Garner (Garner, 1970, 1974; Garner and Felfoldy, 1970) and Pomerantz (Pomerantz et al., 1977; Pomerantz, 1986; Pomerantz and Pristach, 1989) have used the speeded classification task to examine the dimensional structure of stimuli. Carswell and Wickens (1990) have generalized these results by investigating perceptual dimensions that are representative of those found in visual displays. Three qualitatively different relationships between stimulus dimensions have been proposed: separable, integral, and configural (Pomerantz, 1986).

**Separable Dimensions**   A separable relationship is defined by a lack of interaction among stimulus dimensions. Each dimension retains its unique perceptual identity within the context of the other dimension. Observers can attend selectively to an individual dimension and ignore variations in the irrelevant dimension. On the other hand, no new properties emerge as a result of the interaction among dimensions. Thus, performance suffers when both dimensions must be considered to make a discrimination. This pattern of results suggests that separable dimensions are processed independently. An example of separable dimensions are color and shape: The perception of color does not influence the perception of shape, and vice versa.

**Integral Dimensions**   An integral relationship is defined by a strong interaction among dimensions such that the unique perceptual identities of individual dimensions are lost. Integral stimulus dimensions are processed in a highly interdependent fashion: A change in one dimension necessarily produces changes in the second dimension. In their discussion of two integral stimulus dimensions, Garner and Felfoldy (1970, p. 237) state that "in order for one dimension to exist, a level on the other must be specified." As a result of this highly interdependent processing, a redundancy gain occurs. However, focusing attention on the individual stimulus dimensions becomes very difficult, and performance suffers when attention to one (selective attention) or both (divided attention) dimensions are required. An example of an integral stimulus is perceived color: It is a function of both hue and brightness.

**Configural Dimensions**   A configural relationship refers to an intermediate level of interaction between perceptual dimensions. Each dimension maintains its unique perceptual identity, but new properties are also created as a consequence of the interaction between them. These properties have been referred to as *emergent features*. Pomerantz and Pristach (1989, p. 636) describe emergent features in the following fashion: "Basically, emergent features are relations between more elementary line segments, relations that can be more salient to human perception than are the line segments themselves." Using parentheses as our graphic elements will allow us to demonstrate several examples of emergent features. Depending on the orientation, a pair of parentheses can have the emergent features of vertical symmetry, () and)(, or parallelism,)) and ((. The definition offered by Pomerantz and Pristach is overly restrictive, however, since graphical elements other than line segments can produce emergent features. A sampling of other emergent features that can be produced by configural dimensions include colinearity, equality, closure, area, angle, horizontal extent, vertical extent, and good form.

There are two significant aspects of performance with configural dimensions. First, relative to integral and separable stimulus dimensions, there is a smaller divided attention cost, suggesting that performance can be enhanced when both dimensions must be considered to make a discrimination. The second noteworthy aspect of this pattern of results is that there is an *apparent* failure of selective attention. Bennett and Flach (1992) discuss why this failure may be apparent and not inherent; Bennett and Walters (2001) investigate design strategies to overcome potential costs.

### 3.3.1   Attention-Based Principles of Display Design

The "proximity compatibility principle" (PCP) offered perhaps the first set of design guidelines derived from this perspective. The original version of PCP (Barnett and Wickens, 1988; Carswell and Wickens, 1987; Wickens and Andre, 1990) emphasized the role of integral and separable stimulus dimensions, along with the notion of perceptual "objects." PCP predicted an inherent trade-off between displays and tasks. PCP maintained that presenting multiple variables in a single perceptual object (i.e., an object display; see Figure 10*d*) would facilitate performance at divided tasks. This was based on the belief that object displays were composed of integral stimulus dimensions: The global perceptual properties produced by interactions between dimensions

improved divided attention performance. However, the associated loss of unique perceptual identities of the individual dimensions degraded focused performance. The opposite pattern of results was predicted for displays that incorporated separable stimulus dimensions (e.g., a bar graph display with separate and unique representations for each variable; see Figure 10*b*): Focused tasks benefit from the lack of interactions between dimensions; divided tasks suffer from the lack of higher order visual properties that arise from the interactions between dimensions.

In the early 1990s we performed a literature review of the empirical laboratory studies that had been conducted on these issues in display design (Bennett and Flach, 1992). The review indicated that the overall fit between the predictions of PCP and the obtained results was not particularly good. Slightly more than one of three empirical findings (19/54, 35%) were found to support the predictions for divided-attention tasks; less than one of four (7/30, 23%) were consistent with the predictions for focused-attention tasks.

Bennett and Flach (1992) proposed the design principle of "semantic mapping" based on configural stimulus dimensions [as opposed to integral dimensions and perceptual objects; see also Sanderson et al. (1989) and Buttigieg and Sanderson (1991)]. This principle maintains that most representational choices will involve configural stimulus dimensions that produce a hierarchically nested set of emergent features. Because of the unique properties of configural dimensions (see above), an inherent trade-off between display and task is not predicted.

If these emergent features are salient (i.e., they can be picked up easily by the human observer) and if they reflect critical aspects of the task (i.e., the constraints of the work domain), then performance at divided-attention tasks will be enhanced. On the other hand, if the emergent features are not salient or if they are not well mapped to domain constraints, then performance will be degraded. This is true whether the representational format is a geometric form, a collection of bar graphs, a point in space, or any other representational form that could be devised.

Designing displays to support focused-attention tasks involves isomorphic considerations. Specifically, performance depends upon the quality of very specific mappings between the task, the visual properties of the display, and the perceptual abilities of the agent. For example, Bennett et al. (2000) and Bennett and Walters (2001) investigated four design techniques (i.e., bar graphs/extenders, scale markers/scale grids, color coding/layering/separation, and digital values) aimed at improving performance at focused tasks. These techniques were applied alone and in combination to a configural display. The results indicate that three of these design techniques were successful because they provided display constraints (either additional analog visual structure or precise digital information) that matched the constraints of the task (i.e., provide a quantitative estimate of an individual variable).

In summary, the semantic mapping principle of display design does not predict inherent trade-offs between displays and tasks; a carefully designed configural display can support performance across the continuum of attention demands that operators might face in complex, dynamic domains. The issues in design and potential solutions that have been described here are necessarily brief. We encourage the interested reader to visit Bennett and Flach (2011) for much more detailed descriptions and analyses of the foundations of display design from the visual attention perspective, including critiques of a revised version of PCP (e.g., Wickens and Carswell, 1995).

### 3.4 Problem-Solving and Decision-Making Approach

The fourth perspective on display design to be discussed is problem solving and decision making. Recently, there has been an increased appreciation for the creativity and insight that experts bring to human–machine systems. Under normal operating conditions, a person is perhaps best characterized as a decision maker. Depending on the perceived outcomes associated with different courses of action, the amount of evidence that a decision maker requires to choose a particular option will vary. In models of decision making, this is called a *decision criterion*. Under abnormal or unanticipated operating conditions, a person is characterized most appropriately as a creative problem solver. The cause of the abnormality must be diagnosed, and steps must be taken to correct the abnormality (i.e., an appropriate course of action must be determined). This involves monitoring and controlling system resources, selecting between alternatives, revising diagnoses and goals, determining the validity of data, overriding automatic processes, and coordinating the activities of other people. Thus, the literature on reasoning, problem solving, and decision making has important insights for display design.

There is a vast literature on problem solving, ranging from the seminal work of the Gestaltists (e.g., Wertheimer, 1959) to the paradigmatic contributions of Newell and Simon (1972) to contemporary approaches. For the Gestalt psychologists, perception and cognition (more specifically, problem solving) were intimately intertwined. The key to successful problem solving was viewed as the formation of an appropriate gestalt, or representation, that revealed the "structural truths" of a problem. For example, Wertheimer (1959, p. 235) states that "thinking consists in envisaging, realizing structural features and structural requirements . . . ." The importance of a representation is still a key consideration today; it is probably not an overstatement to conclude that the primary lesson to be learned from the problem-solving literature is that the representation of a problem has a profound influence on the ease or difficulty of its solution.

Historically, decision research has focused on developing models that describe the generation of multiple alternatives (potentially, all alternatives), evaluation (ranking) of these alternatives, and selection of the most appropriate alternative. By and large, perception was ignored. In contrast, recent developments in decision research, stimulated by research on naturalistic decision making (e.g., Klein et al., 1993), have begun to

give more consideration to the generation of alternatives in the context of dynamic demands for action. Experts are viewed as generating and evaluating a few "good" alternatives. The emphasis is on recognition (e.g., how this problem is similar to or dissimilar from problems encountered before). As a result, perception plays a dominant role. This change in emphasis has increased awareness of perceptual processes and dynamic action constraints in decision making.

These trends have, either directly or indirectly, led researchers in interface design to focus on the representation problem. Perhaps the first explicit realization of the power of graphic displays to facilitate understanding was the STEAMER project (Hollan et al., 1984, 1987), an interactive inspectable training system. STEAMER provided alternative conceptual perspectives: "conceptual fidelity" of a propulsion engineering system through the use of analogical representations. In addition, the current approach to the design of human–computer interfaces (direct manipulation) (Hutchins et al., 1986; Shneiderman, 1986, 1993) can be viewed as an outgrowth of this general approach. More recently, scientific visualization (the role of diagrams and representation in discovery and invention) is being investigated vigorously (Bonneau et al., 2006; Brodie et al., 1992; Earnshaw and Wiseman, 1992). Thus, the challenge for display design from this perspective is to provide appropriate representations that support humans in their problem-solving endeavors.

## 4   MEANING-PROCESSING APPROACH TO DISPLAY DESIGN

It should be noted that in the aesthetic, psychophysical, and most attention-based approaches little consideration is given to a domain behind the display. It was not necessary for us to describe the "problem" behind the displays shown in Figure 10. However, the correspondence between the visual structure in a representation and the constraints in a problem is fundamental to the problem-solving and decision-making approaches. Recently, a number of research groups have recognized that effective interfaces depend on both the mapping from human to display (the coherence problem) and the mapping from display to a work domain or problem space (the correspondence problem). Terms used to articulate this recognition include direct perception (Moray et al., 1994), ecological interface design (Rasmussen and Vicente, 1989; Vicente, 1991, 1999; Burns and Hajdukiewicz, 2004), representational design (Woods, 1991), or semantic mapping (Bennett and Flach, 1992).

Thus, our approach (Bennett and Flach, 2011) is a problem-driven (as opposed to user- or technology-driven) approach to the design and evaluation of displays and interfaces. By this we mean that the primary purpose of an interface is to provide decision-making and problem-solving support for a user who is completing work in a domain. The goal is to design interfaces that are (1) tailored to specific work demands, (2) leverage the powerful perception–action skills of the human, and (3) use powerful interface

technologies wisely. This can be conceptualized as a "triadic" approach (domain/ecology, human/awareness, interface/representation) to human computer interaction that stands in sharp contrast to the traditional "dyadic" (human, interface, information processing) approaches.

Ultimately the success or failure of an interface is determined by the interactions that occur between all three components of the triad. Each component contributes a set of constraints that will influence the effectiveness (and/or the pleasurableness) of the interaction. A particular work domain will introduce a particular set of constraints (e.g., tasks, goals, limits) that will determine the nature of the work to be completed. Another set of constraints are introduced by the cognitive agent (human, machine) that completes the work. For a human agent this will include a specific set of cognition/perception/action capabilities and limitations. The functionality/design of the interface introduces a third set of constraints: Particular characteristics of the interface will introduce cognitive demands that will vary in terms of the nature and amount of cognitive resources that are required. These three sources of constraints are independent but mutually interactive and mutually constraining. The effectiveness of graphical decision support will ultimately depend upon the quality of *very specific sets of mappings* between these constraints. Thus, the focus of our approach is not on information-processing characteristics, graphical forms, events, trajectories, tasks, or procedures per se. Instead, the focus is on the quality of the mappings between the person, the interface, and the domain. Any approach that fails to consider all of these components and their interactions (i.e., dyadic approaches) will be inherently, and severely, limited.

### 4.1   Correspondence Problem: Semantics of Work

*Correspondence* refers to the issue of content: What information should be present in the interface in order to meet the cognitive demands of the work domain? Correspondence is defined neither by the domain itself nor by the interface itself: It is a property that arises from the interaction of the two. Thus, in Figure 11, correspondence is represented by the labeled arrows that connect the domain and the interface. One convenient way to conceptualize correspondence is as the quality of the mapping between the interface and the workspace, where these mappings can vary in terms of the degree of specificity (consistency, invariance, or correspondence). As we will demonstrate, within this mapping there can be a one-to-one correspondence, a many-to-one, a one-to-many, or a many-to-many mapping between the information that exists in the interface and the structure within the workspace.

### 4.1.1   Rasmussen's Abstraction Hierarchy

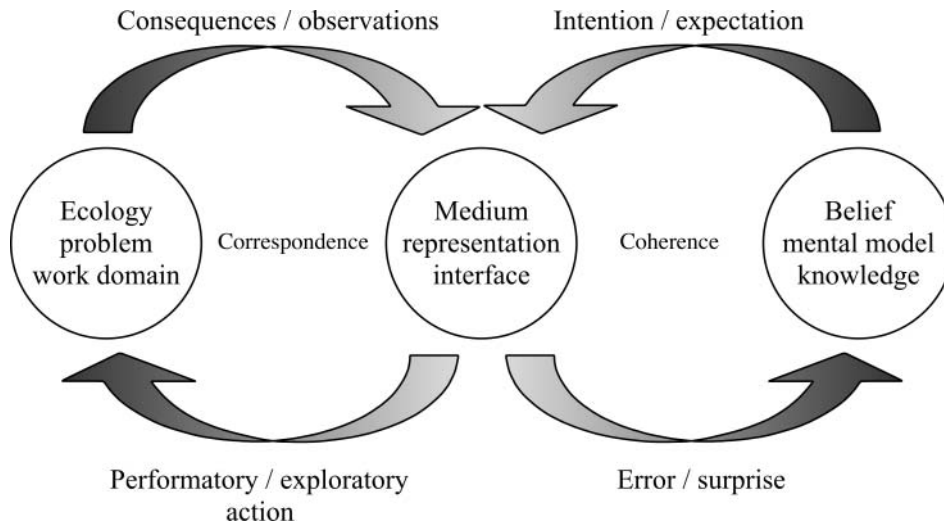
Addressing the issue of correspondence requires a deep understanding and explicit description of the "semantics" of a work domain. Rasmussen's (1986) abstraction hierarchy is a theoretical framework for describing domain semantics in terms of a nested hierarchy of functional constraints (including goals, physical laws,


**Figure 11** The dynamics of a meaning-processing approach to interface design. These dynamics involve interactions between a cognitive system and an ecology mediated by an interface (displays and controls). Perception and action are dynamically coupled in parallel so that every interaction has dual implications.(Adapted with permission from Bennett and Flach, 2011. Copyright CRC Press.)

regulations, organizational/structural constraints, equipment constraints, and temporal/spatial constraints). One way to think about the abstraction hierarchy is that it provides structured categories of information (i.e., the alternative conceptual perspectives) that a person must consider in the course of accomplishing system goals. Consider the following passage from Rasmussen (1986, p. 21):

> During emergency and major disturbances, an important control decision is to set up priorities by selecting the level of abstraction at which the task should be initially considered. In general, the highest priority will be related to the highest level of abstraction. First, judge overall consequences of the disturbances for the system function and safety in order to see whether the mode of operation should be switched to a safer state (e.g., standby or emergency shutdown). Next, consider whether the situation can be counteracted by reconfiguration to use alternative functions and resources. This is a judgment at a lower level of function and equipment. Finally, the root cause of the disturbance is sought to determine how it can be corrected. This involves a search at the level of physical functioning of parts and components. Generally, this search for the physical disturbance is of lowest priority (in aviation, keep flying—don't look for the lost light bulb!).

Thus, in complex domains, situation awareness requires the operator to understand the process at different levels of abstraction. Further, the operator must be able to understand constraints at one level of abstraction in terms of constraints at other levels. The correspondence question asks whether the hierarchy of

constraints that define a work domain are reflected in the interface.

### 4.2  Coherence Problem: Syntax of Form

*Coherence* refers to the mapping from the representation to the human perceiver. Here the focus is on the visual properties of the representation. What distinctions within the representation are discriminable to the human operator? How do the graphical elements fit together or coalesce within the representation? Is each element distinct or separable? Are the elements absorbed within an integral whole, thus losing their individual distinctness? Or do the elements combine to produce configural or global properties? Are some elements or properties of the representation more or less salient than other elements or properties?

In general, coherence addresses the question of how the various elements within a representation compete for attentional and cognitive resources. Just as work domains can be characterized in terms of a nested hierarchy of constraints, complex visual representations can be perceived as a hierarchy of nested structures, with local elements combining to produce more global patterns or symmetries. Ultimately coherence refers to the extent to which a human agent can obtain and make sense of information about a work domain that is present in the display.

### 4.3  Mapping Problem

In human–machine systems, a display is a representation of an underlying domain, and the user's tasks are defined by that domain rather than by the visual characteristics of the display itself. Thus, whether or not a display will be effective is determined by both correspondence and coherence. More specifically, the

effectiveness of the display is determined by the quality of the mapping among the agent, interface, and domain.

The constraints that characterize a particular work domain will have a substantial impact on the type of representations that will provide effective support. Rasmussen et al. (1994) have analyzed the various types of constraints that characterize different work domains and have developed a continuum for classification. At one end of the continuum are domains in which the unfolding events arise from the laws of nature (e.g., process control). An example of such a law is the conservation of mass: If more mass is flowing into a reservoir than out of a reservoir, the level of fluid that it contains will rise. In these "law-driven" domains, the user is required to control, monitor, and compensate for the demands that arise from the domain. At the opposite end of the spectrum are domains in which the unfolding events arise from the user's intentions, goals, and needs (e.g., information search and retrieval). In these "intent-driven" domains, the demands are created by the user rather than by the domain. The domain structure is more loosely coupled (e.g., attributes that differentiate among books of fiction) and the process of searching and identifying the appropriate information (e.g., a particular book of fiction to read) is ultimately user dependent. Note that an understanding of the domain structure is still critical to the development of effective decision support (Flach et al., 2011).

The design strategies and techniques that are required to develop effective interfaces for these two categories of domains are quite different. In law-driven domains, the constraints of the system (e.g., physical, functional, and goal-related structure) are the primary consideration. Display design involves the development of abstract geometric forms that reflect these inherent constraints. A simple example is using an axis in a graph to represent time. We will use the general term "analog" to refer to these representations, since a continuous incremental change in a domain variable or property is reflected by a corresponding continuous and incremental change in its graphical representation.

We will also use the more specific term "configural" to refer to these representations, since they use configural perceptual dimensions and produce the emergent features that were discussed in Section 3.3. In configural representations the geometric display constraints will generally take the form of symmetries: equality (e.g., length, angle, area), parallel lines, collinearity, or reflection. In addition, Gestalt properties of closure and good form are useful. Each particular representation that is chosen will produce a different set of display constraints, defined by the spatiotemporal structure (the visual appearance of the display over time).

The core problem in implementing effective configural displays for law-driven work domains is to provide visual representations that are perceived as accurate reflections of the abstract domain constraints: Are the critical domain constraints reflected appropriately in the geometric constraints in the display? Are breaks in the domain constraints (e.g., abnormal or emergency conditions) reflected by breaks in the geometric constraints (e.g., emergent features such as nonequality,

nonparallelism, nonclosure, bad form)? Only when this occurs will the cognitive agent be able to obtain meaning about the underlying domain in an effective fashion.

One source of ideas for configural displays is the graphical representations that engineers use to make design decisions. For example, Beltracchi (1987, 1989) (see also Moray et al., 1994; Rasmussen et al., 1994) has designed a configural display for controlling the process of steam generation in nuclear power plants based on the temperature–entropy graphic used to evaluate thermodynamic engines (Rankine cycle display). Effective interface design for law-driven domains allows trained operators to use high-capacity perceptual and motor skills to monitor and control the system as opposed to limited capacity resources (e.g., working memory).

A very different design strategy is required for intent-driven domains, where the needs and goals of the user are the driving force in the unfolding interaction. Relative to law-driven domains, agents working in intent-driven domains will interact with the system more sporadically, will have far less training and experience, and will possess more diverse sets of skills or knowledge. Under these circumstances the appropriate interface design strategy is to use metaphors and icons.

Metaphorical representations use spatial or symbolic relations from other, more familiar work domains to convey meaning. They are designed to relate the functioning of the system and the requirements for interaction to concepts and activities with which the majority of potential agents will already be familiar. Ultimately, the goal is to enhance the transfer of skills from one domain to another. Perhaps the most obvious example is the "desktop" metaphor that is used in personal computer systems. Another example is the BookHouse metaphor, developed by Pejtersen (1980; 1992) to facilitate library information retrieval. Rasmussen et al. (1994, pp. 289–291) describe the metaphor and its justification:

> The use of the BookHouse metaphor serves to give an invariant structure to the knowledge base.... Since no overall goals or priorities can be embedded in the system, but depend on the particular user, a global structure of the knowledge base reflects subsets relevant to the categories of users having different needs and represented by different rooms in the house.... This gives a structure for the navigation that is easily learned and remembered by the user.... The user "walks" through rooms with different arrangements of books and people.... It gives a familiar context for the identification of tools to use for the operational actions to be taken. It exploits the flexible display capabilities of computers to relate both information in and about the data base, as well as the various means for communicating with the data base to a location in a virtual space.... This approach supports the user's memory of where in the BookHouse the various options and information items are located. It facilitates the navigation of the user so that items can be remembered in given physical locations that one can then retraverse in order to retrieve a given item and/or freely browse in order to gain an overview.

In addition to metaphors and configural displays, there is a third type of representation: propositional. This refers to the use of digital values (i.e., numbers), the alphabet (i.e., words and language), and other forms of alphanumeric labels. Propositional representations are compact and precise. They capitalize on an extensive knowledge base and provide the opportunity for the most detailed and precise representation of an ecology. However, unlike metaphorical and analogical representations, the mapping between symbol and referent is an arbitrary one for propositional representations. This form of representation is therefore the most computationally expensive, in terms of placing demands on knowledge-based processes. Thus, propositional representations can be an important source of information, when configured within metaphorical and analogical forms of representations.

Whether analogical, metaphorical, or combined representations are used, the key to successful design is the quality of the mapping. The visual salience of the information in the display must reflect the relative importance of that information in terms of the work domain. For analogical, configural displays the geometric symmetries must correspond to higher-order constraints on the process. For metaphorical displays, the intuitions and skills elicited by the representational domain must map appropriately to the target domain.

## 5   EXAMPLE-BASED TUTORIAL OF MEANING-PROCESSING APPROACH

The concepts and principles of display design that have been introduced thus far include correspondence, coherence, process constraints, display constraints (e.g., emergent features), and the mappings between process and display constraints. These concepts and principles are necessarily abstract, and for them to be useful for display design they must be presented in a clear and unambiguous fashion. In this section we provide a tutorial that illustrates these concepts and principles through a series of concrete examples.

We begin with an analysis of a law-driven domain: a simple system from the domain of process control. The goal is to provide a description of the associated process constraints. We then consider various types of displays that could be devised for the system. The goal is to consider the alternative mappings between process constraints and geometric (display) constraints that are provided by each representation: in particular, the implications for correspondence and coherence. The representations are chosen to illustrate the continuum of visual forms from separable, through configural, to integral geometries. We then examine one representation in greater detail and discuss the implications of this mapping for normal and abnormal operating conditions. We end the section with a set of practical guidelines for display design.

### 5.1   Simple Domain from Process Control

The process is a generic one that might be found in process control, and it is represented graphically in the lower portion of Figure 12. There is a reservoir (or tank, represented by the large rectangle in the middle of the figure) that is filled with a fluid (e.g., coolant). The volume, or level, of the reservoir ($R$) is represented by the filled portion of the rectangle. Fluid can enter the reservoir through the two pipes and valves located above the reservoir; fluid can leave the reservoir through the pipe and valve located below the reservoir. We categorize the information in this simple process using a simple distinction in which the term *low-level data* refers to local constraints or elemental state variables that might be measured by a specific sensor. The term *higher level properties* will be used to refer to more global constraints that reflect relations or interactions among multiple variables.

***Low-Level Data (Process Variables)***   There are two goals associated with this simple process. First, there is a goal ($G_1$) associated with $R$, the level of the reservoir. The reservoir should be maintained at a relatively high level to ensure that sufficient resources are available to meet long-term increases in demanded output flow rate ($O$). The second goal ($G_2$) refers to the specific rate of output flow that must be maintained to meet an external demand. These goals are achieved and maintained by adjusting three valves ($V_1$, $V_2$, and $V_3$) that regulate flow through the system ($I_1$, $I_2$, and $O$). Thus, this simple process is associated with a number of process variables that can be measured directly: these low-level data are listed in the upper, left-hand portion of Figure 12 ($V_1$, $V_2$, $V_3$, $I_1$, $I_2$, $O$, $G_1$, $G_2$, and $R$).

***High-Level Properties (Process Constraints)***   In addition, there are relationships between these process variables that must be considered when controlling the process (see the upper, right-hand portion of Figure 12). The most important high-level properties are goal related: Does the actual reservoir volume level ($R$) match the goal of the system ($G_1$)$-K_5$? Does the actual system output flow rate ($O$) match the flow rate that is required ($G_2$)$-K_6$? Even for this simple process, some of the constraints or (high-level properties) are fairly complex. For example, an important property of the system is mass balance, which is determined by comparing the mass leaving the reservoir ($O$, the output flow rate) to mass entering the reservoir (the combined input flow rates of $I_1$ and $I_2$). This relationship determines the direction and the rate of change for the volume inside the reservoir ($\Delta R$). For example, if mass in and mass out are equal, the mass is balanced, $\Delta R$ will equal 0.00, and $R$ will remain constant.

Controlling even this simple process will depend on a consideration of both high-level properties and low-level data. As the earlier example indicates, decisions about process goals (e.g., maintaining a sufficient level of reservoir volume) generally require consideration of relationships between variables (is there a net inflow or a net outflow or is mass balanced?) as well as the values of the individual variables themselves (what is the current reservoir volume?).

#### 5.1.1   Abstraction Hierarchy Analysis

The constraints of the simple process in Figure 12 will be characterized in terms of the abstraction

Low-level data
(process variables)

High-level properties
(process constraints)

$T$ = time
$V_1$ = setting for valve 1
$V_2$ = setting for valve 2
$V_3$ = setting for valve 3
$I_1$ = flow rate through valve 1
$I_2$ = flow rate through valve 2
$O$ = flow rate through valve 3
$R$ = volume of reservoir

$K_1$ = $I_1 - V_1$  Relation between comman-
$K_2$ = $I_2 - V_2$  ded flow ($V$) and actual flow
$K_3$ = $O - V_3$  ($I$ or $O$)

$K_4$ = $\Delta R = (I_1 + I_2) - O$
Relation between reservoir
volume ($R$), mass in ($I_1 + I_2$),
and mass out ($O$)

$G_1$ = volume goal
$G_2$ = output goal (demand)

$K_5$ = $R - G_1$  Relation between actual states
$K_6$ = $O - G_2$  ($R, O$) and goal states ($G_1, G_2$)

**Figure 12** Simple domain from process control that has a reservoir for storing mass, two input streams that increase the volume of mass in the reservoir, and a single output stream that decreases the volume. The low-level data (the measured domain variables), the high-level properties (constraints that arise from the interaction of these variables and the physical design), and the domain goals (requirements that must be met for the system to be functioning properly) are listed.
